Abstract

Weighting methods are a common tool to de-bias estimates of causal effects. And though there are an increasing number of seemingly disparate methods, many of them can be folded into one unifying regime: causal optimal transport. This new method directly targets distributional balance by minimizing optimal transport distances between treatment and control groups or, more generally, between a source and target population. Our approach is model-free but can also incorporate moments or any other important functions of covariates that the researcher desires to balance. We find that the causal optimal transport outperforms competitor methods when both the propensity score and outcome models are misspecified, indicating it is a robust alternative to common weighting methods. Finally, we demonstrate the utility of our method in an external control study examining the effect of misoprostol versus oxytocin for treatment of post-partum hemorrhage.

1 Introduction

1.1 Weighting in causal inference

Weighting is a versatile methodology used in a variety of fields from survey sampling to causal inference. In survey sampling, weighting can adjust for unit-level non-response to give unbiased estimates of sample means; in causal inference, weighting can adjust for unit-level treatment decisions to give unbiased estimates of causal effects. Most weighting methods explicitly or implicitly model the treatment assignment mechanism and generate a propensity score, or the probability of having received treatment (Rosenbaum and Rubin, 1983). Inverse propensity score weighting (IPW) weights observations by the inverse of these

*edunipace@mail.harvard.edu
treatment probabilities to yield estimates of treatment effects (Rosenbaum, 1987; Robins et al., 1994; Rotnitzky et al., 1998). The mechanism by which IPW works is simple: it weights the distribution in a source sample to look like the distribution in some target sample of interest. For example, in an observational study this source sample could be the controls who we wished looked more like the treated individuals.

Though commonly used, typical models for IPW estimators are not without their problems. One potential issue is that the propensity score model must be correctly specified, or at least offer predictions close to the correct specification, to get good estimates of causal effects. Another potential issue with IPW methods is that estimators based on the propensity score are unstable when the estimated propensity scores are close to 0 or 1 (Kang and Schafer, 2007).

1.2 Weighting for covariate balance

Other weighting methods address these concerns by balancing observable functions of the covariates so that balance can be empirically assessed. Imai and Ratkovic (2014) do this by adding moment balancing conditions to propensity score estimation while other authors target moment balance directly with either an entropic (Hainmueller, 2012) or an $L_2$ penalty on the weights (Zubizarreta, 2015). These methods will perform well when the chosen covariate functions either lead to distributional balance or to basis function balance—that is balance of the covariate functions that determine the conditional mean outcome function (Fan et al., 2016; Ratkovic and Tingley, 2017; Wang and Zubizarreta, 2019a; Li and Li, 2021). Though these basis functions are rarely known in practice, applied researchers are still able to specify outcome models in many settings that in turn suggest hypothesized basis functions. In principle, these functions can be progressively expanded as the sample size grows—for small data, researchers may only adjust for only covariate means and then add quadratic terms and cubic terms when more data is available. In this way, these parametric basis functions estimators can be considered as being part of a non-parametric class. Other authors use more direct non-parametric approaches through reproducing Kernel Hilbert spaces or RKHS, which in principle capture the basis functions of the data but require the estimation of unknown tuning parameters (Kallus, 2016; Kallus et al., 2018; Wong and Chan, 2018; Kallus and Santacatterina, 2019). However, even these models still fail to capture something critical about the covariates: the joint distribution.

1.3 The central role of distributional balance in causal inference

Ultimately, a lack of distributional balance between groups leads to biased estimates of causal effects. If the distributions are the same between source and target samples, then all basis functions that determine the conditional mean function will also be balanced (Figure 1), and treatment effect estimates will be unbiased.
Additionally, securing distributional balance will also make outcome models more robust to misspecification.

Of course, balancing the correct basis functions is sufficient to estimate unbiased treatment effects. These estimators are also potentially more efficient than those that seek distributional balance alone since we are only balancing a finite number of basis functions—like in Hainmueller (2012), Imai and Ratkovic (2014), or Zubizarreta (2015)—or tuning a finite number of parameters—like in the RKHS balancing—rather than targeting point-wise distributional balance at an infinite number of points. But when these basis function models are misspecified, we can potentially do better by also targeting distributional balance. Fortunately, we do not have to choose just basis function or distributional balance—we can do both.

### 1.4 Causal optimal transport

We propose a new method that achieves distributional and basis function balance in one framework: causal optimal transport. Our method borrows from recent advancements in the computer science literature regarding optimal transport to directly target distributional balance. We also incorporate basis functions into our methodology to achieve the best of both worlds, as in Figure 1.

As we document, our method performs well compared to competitor weighting methods in simulation studies—especially when the propensity score and outcome models are misspecified. We also demonstrate that many methods in the literature—such as logistic regression based IPW, synthetic control methods, optimal matching, and mixed integer programming matching—are actually special cases of our method.
Thus, our framework can be seen as a non-parametric generalization of these methods. We proceed as follows: in Section 2, we describe the setting and assumptions necessary for identification. Then we discuss the relevant features of causal optimal transport such as the specific problem formulation, practical considerations for using the method, and statistical inference in Section 3. In Section 4, we demonstrate how causal optimal transport unifies many existing methods in the literature, and in Section 5, we provide simulation results demonstrating the utility of our method. Section 6 presents a case study utilizing our method on an observational study created from a multi-site randomized control trial (RCT) studying post-partum hemorrhage. Finally, we offer our concluding remarks in Section 7.

2 Setup

2.1 The potential outcomes framework

We adopt the potential outcomes framework of Neyman and Rubin (Splawa-Neyman, 1923; Rubin, 1974). Assume that we have an independent, identically distributed (iid) sample of \( n \in \mathbb{N} \) units from some population. Let \( Z \) be a binary variable that denotes receiving a treatment \( (Z = 1) \) or control \( (Z = 0) \) condition. Let \( Y(0) \) and \( Y(1) \) denote the potential outcomes, only one of which is observed. We denote the observed outcome as \( Y = Z \cdot Y(1) + (1 - Z) \cdot Y(0) \), which is defined on a space \( Y \subseteq \mathbb{R} \). Additionally, we will denote our confounders as \( X \in X \subseteq \mathbb{R}^d \). We will assume we have \( n_0 \in \mathbb{N} \) control units and \( n_1 \in \mathbb{N} \) treated units giving \( n = n_0 + n_1 \) total observations.

Suppose we also have a second sample of \( m \in \mathbb{N} \) iid units drawn from a potentially different population. We also measure covariates \( X \in X \), but the outcome \( Y \) and treatment indicator \( Z \) are completely missing in this new population. Our goal is then to use the information in the first set of samples, the source, to make inferences about the second set of samples, the target. Let \( S = 1 \) if an observation is in the source sample and \( S = 0 \) if an observation is in the target sample.

To avoid confusion, we will let \( i \in \{1, \ldots, n\} \) index units in the source sample and \( j \in \{n+1, \ldots, n+m\} \) index units in the target sample. Further denote the empirical distribution of the source sample as \( a = \frac{1}{n} \sum_i \delta_{x_i} \) and the empirical distribution in the target sample as \( b = \frac{1}{m} \sum_j \delta_{x_j} \). We will denote their population level counterparts as \( \alpha \) and \( \beta \), respectively. Since \( a \) and \( b \) are iid, we expect their empirical masses to be equal to the reciprocal of the sample size, \( i.e. \ a_i = 1/n \) and \( b_j = 1/m \), but this does not have to be the case. The empirical distribution in the treated group of the source sample will be defined as \( a_1 = \frac{1}{n_1} \sum_i \delta_{x_i} Z_i \), and the empirical distribution in the control group of the source sample will be defined as \( a_0 = \frac{1}{n_0} \sum_j \delta_{x_j} (1 - Z_j) \).

Finally, we assume the space \( X \) has a distance metric between observations, \( d_X(x_i, x_j) \in \mathbb{R}_+ \). We will
define a generic cost function as \( c(x_i, x_j) = d(x_i, x_j)^p, p \geq 1 \). This could be any number of well known functions. For example, if \( d \) is the Euclidean distance and \( p = 2 \), then \( c \) is the squared-Euclidean distance. From this function, we then construct a pairwise cost matrix \( C \in \mathbb{R}^{n \times m} \) between each unit of \( i \) and \( j \):

\[
C_{ij} = c(x_i, x_j).
\]

### 2.2 Causal estimands

There are several causal contrasts of interest over these populations. The first is of the form

\[
\tau_{\text{SATE}} = \mathbb{E}_q[Y(1) - Y(0)],
\]

or the source average treatment effect (SATE), the average treatment effect in the source population, and the second is of the form

\[
\tau_{\text{TATE}} = \mathbb{E}_p[Y(1) - Y(0)],
\]

or the average treatment effect in the target population (TATE). By definition, we cannot estimate \( \tau_{\text{TATE}} \) since the potential outcomes are completely missing.

Instead, we can define \( \mu_z(X) = \mathbb{E}_p(Y(z) | X) \) and estimate \( \tau_{\text{TATE}} \) as

\[
\tau_{\text{TATE}} = \int_X [\mu_1(x) - \mu_0(x)] d\beta.
\]

### 2.3 Identifying assumptions

To identify these estimators, we need several assumptions. First, we assume that unconfoundedness holds in the source sample \((S = 1)\) and that the sampling mechanism is independent of the potential outcomes. Next, we also assume that every unit has a non-zero probability of being in either the source or target samples. We formalize these assumptions below.

**Assumption 1** (Strong ignorability of treatment assignment)

(Rosenbaum and Rubin, 1983)

\[ i \quad Y(0), Y(1) \perp\!\!\!\perp Z | X, S = 1 \]

\[ ii \quad 0 < P(Z = 1 | X, S = 1) < 1. \]

**Assumption 2** (Strong ignorability of sampling)
i \ Y(0), Y(1) \perp S \mid X

\text{ii} \quad 0 < P(S \mid X) < 1

Assumption 1 (i) is the unconfoundedness assumption, and (ii) ensures the distributions of the controls and treated in the source population overlap, at least asymptotically. Assumption 2 (i) ensures the unconfoundedness of the sampling indicator with the potential outcomes and (ii) requires that the distributions of $\alpha$ and $\beta$ are defined over the same space with both putting positive density on the same sets. This is a slightly stronger assumption than is strictly necessary since we only require that $\beta \ll \alpha$, i.e. $\alpha(E) = 0 \Rightarrow \beta(E) = 0$ for every measurable set $E$.

Additionally, we assume the stable-unit-treatment-value assumption that there is no interference between units and no hidden version of treatments (Rubin, 1980; Rubin, 1986).

2.4 Weighting estimators

To successfully estimate (2), we need to adjust the expectations in the source population to equal the target population. That is, we desire

$$
\int_{X} \mu_x w d\alpha = \int_{X} \mu_x d\beta.
$$

A common way to do this is to use an importance sampling weight where $w = \frac{d\beta}{d\alpha}$, also known as the Radon-Nikodym derivative of $\beta$ with respect to $\alpha$. This method suggests adapting the density of $d\alpha$ point-wise so that it matches $d\beta$. In effect, we make the distributions the same to make the integrals the same. This is the idea behind using the propensity score for IPW. An alternative strategy is to find a $w$ such that the integrals are equal but not necessarily such that the densities are themselves the same. This is the idea behind the basis function balancing.

In either case, we estimate (2) as

$$
\hat{\tau}_{\text{ate}} = \sum_{i=1}^{n} w_i Y_i Z_i - \sum_{i=1}^{n} w_i Y_i (1 - Z_i),
$$

with the constraint that the weights sum to 1 in the treatment and control groups of the source sample: $\sum_{i} w_i Z_i = \sum_{i} w_i (1 - Z_i) = 1$. If the weights are not already normalized to sum to one, we take the non-normalized weights $\tilde{w} = (\tilde{w}_1, ..., \tilde{w}_n)^\top$ and divide by their sum:

$$
w_i = \frac{\tilde{w}_i Z_i}{\sum_{j=1}^{n} \tilde{w}_j Z_j} + \frac{\tilde{w}_i (1 - Z_i)}{\sum_{j=1}^{n} \tilde{w}_j (1 - Z_j)}.
$$

This will reduce the variance of the weights in exchange for the addition of some bias (Owen, 2013a), but
there is evidence that this leads to a lower mean-squared error for the target estimand (Wang and Zubizarreta, 2019a; Huling and Mak, 2020; Chattopadhyay et al., 2020).

Write \(a_z(w)\) as the weighted version of \(a_z\): \(\sum_{i=1}^{n} \delta_{x_i} w_i \mathbb{I}(Z_i = z)\). Then we decompose the error of (3) in the style of Huling and Mak (2020) as

\[
\hat{\tau}_{\text{tate}} - \tau_{\text{tate}} = \int \mu_1 d[a_1(w) - b] - \int \mu_0 d[a_0(w) - b] \tag{4}
\]

\[
- \int [\mu_1 - \mu_0] d[\beta - b] \tag{5}
\]

\[
+ \sum_{i=1}^{n} w_i Z_i [Y_i - \mu_1(X_i)] - \sum_{i=1}^{n} w_i [1 - Z_i] [Y_i - \mu_0(X_i)], \tag{6}
\]

We now examine each line of the error in turn since this will suggest how to improve the estimator in (3). Equation (5) quantifies the difference between the treatment effects in the empirical and asymptotic target distributions; unfortunately, this difference is fixed by the design of the study. As such, we must turn to the other components to seek improvements. The next line down, Equation (6), is the error between the observed \(Y\) in the source population and their conditional expectations. Since this is a mean zero quantity, the bias of \(\hat{\tau}_{\text{tate}}\) will mostly depend on (4). To improve this error, we either need to find weights that force the empirical distributions between \(a_z\) and \(b\) to be as close as possible or such that the integrals yield the same quantities.

These ideas have been discussed at length in the literature. Cochran and Rubin (1973) describe the importance of making the distributions of confounding variables similar across treatment groups and Imai and Ratkovic (2014) discuss seeking to make covariate distributions more similar, as have others (Rosenbaum and Rubin, 1983; Zubizarreta, 2015). Asymptotically, the propensity score will balance the distributions as desired; however, in finite samples, the balance may be sub-optimal. This may happen because the estimated model is incorrect or because units with disparate covariate values may have the same estimated propensity score. Other methods such as Stable Balancing Weights can directly target important distributional components such as the first or second moments, but these do not directly target the joint distribution.

Even methods that aim to target the basis functions of \(\mu_z(x)\) can be improved by also targeting the distributional difference. The reason is that the basis functions are not known in practice and if the set of considered basis functions does not include the correct model then estimates will suffer from increased bias. See Section 5 for such a case.

Before we directly target weights for distributional balance, we introduce a metric known as the optimal transport distance that measures how close two distributions are. This metric has several properties, which
we now review.

3 Optimal transport weights for causal inference

3.1 Properties of optimal transport

The popularity of optimal transport methods have exploded in recent years thanks to several theoretical and methodological advances in a variety of fields. This section will serve as a brief introduction for the uninitiated explaining some of the relevant concepts and results that have been discovered over the last few decades. For a longer treatment, see the book by Peyré and Cuturi (2019).

Also note that we will define the covariate values of the source population as \( x \) and the covariate values in the target population as \( x' \). This is to make clear that the variables in the following integrals are from different groups though they both refer to covariates which typically are denoted by the letter \( x \).

In the Kantorovich (1942) formulation, the optimal transport distance between the source distribution \( \alpha \) and the target distribution \( \beta \), is

\[
\text{OT} (\alpha, \beta) \overset{\text{def}}{=} \min_{\pi \in \Pi(\alpha, \beta)} \int_{\mathcal{X} \times \mathcal{X}} c(x, x') d\pi(x, x'), \tag{7}
\]

where \( \Pi \) is the set of probability distributions over \( \mathcal{X} \times \mathcal{X} \) with margins \( \alpha \) and \( \beta \):

\[
\Pi(\alpha, \beta) = \left\{ \pi \in \mathcal{M}^1_+ (\alpha \times \beta) : \forall E \subseteq \mathcal{X}, \int_{\mathcal{X}} \pi(E, dx') = \alpha(E), \int_{\mathcal{X}} \pi(dx, E) = \beta(E) \right\},
\]

with \( \mathcal{M}^1_+ \) being the set of measures over a given space summing to 1. As noted earlier, \( c(\cdot, \cdot) \) defines a cost between points and denotes the unit cost of moving mass from \( x \in \mathcal{X} \) in source population to \( x' \in \mathcal{X} \) in the target population. When \( c(x, x') = d_{\mathcal{X}}(x, x')^p \), as is the case for our setting, then Equation (7) is also known as the \( p \)-Wasserstein distance.

In finite samples, the problem in Equation (7) is a linear program that specifies the minimal cost of moving mass between empirical measure \( a \) with \( n \) atoms and empirical measure \( b \) with \( m \) atoms:

\[
\text{OT} (a, b) = \min_{P \succeq 0} \sum_{i,j} C_{ij}P_{ij} \tag{8}
\]

subject to

\[
P1_m = a, \tag{9}
\]

\[
P^\top 1_n = b. \tag{10}
\]
where \( C \) is a cost matrix with dimensions \( n \times m \) and entries corresponding to \( c(x_i, x_j) \), \( P \) is a matrix of weights also with dimensions \( n \times m \) and entries summing to one, and \( \mathbf{1}_n \) denotes a vector of length \( n \). The entries of \( P \) related to a matching matrix between the source and target samples. However, rather than being given integer values, the entries of the matrix can be given any value in \([0, 1]\) as long as all of the entries sum to one. Note this sum to one constraint is implied by constraints (9) and (10). Thus, this problem is similar to a relaxation of the optimal matching of Rosenbaum (1989) or more general Mahalanobis distance matching (Stuart, 2010).

Because of this connection to distance matching, the problem formulation in (8)–(10) has promise in making the distributions between source and target samples more similar. Unfortunately, there are a couple of drawbacks. First, as Weed and Bach (2017) show, this optimal transport cost converges at a rate of \( \mathcal{O}(n^{-1/d}) \), which means that this formulation suffers from the curse of dimensionality. Such a result is similar to one found by Abadie and Imbens (2006) in the case of nearest-neighbor matching. Second, the weights found in (8)–(10) may put large values on only a few matches in the transportation matrix, leading to a large dispersion in the weights and possibly leading to a larger mean-squared error in treatment effect estimates.

For these reasons, we consider adding an \( L_2 \) penalty directly on the transportation matrix:

\[
\text{OT}_\lambda (\mathbf{a}, \mathbf{b}) = \min_{P \geq 0} \sum_{i,j} C_{ij} P_{ij} + \lambda \frac{1}{2} \mathbf{P}^2
\]  

and still with constraints (9) and (10). This problem will converge to the original problem in (8)–(10) as \( \lambda \to 0 \), and as \( \lambda \to \infty \) it will put equal weight on every entry in \( P \). We expect that an intermediate value will reduce the dispersion of the weights without sacrificing too much in terms of bias, which should thus reduce the mean-squared error of the estimator in (3).

Another advantage of regularized optimal transport is that we can break the curse of dimensionality. Genevay et al. (2018) demonstrate in the case of entropically penalized optimal transport, that when \( \alpha \) and \( \beta \) are defined on subsets of \( \mathbb{R}^d \) and the cost function is \( L \)-Lipschitz and infinitely differentiable, then

\[
\mathbb{E} \{ \text{OT}_\lambda (\mathbf{a}, \mathbf{b}) - \text{OT}_\lambda (\alpha, \beta) \} = \begin{cases} \mathcal{O} \left( \frac{\kappa}{\lambda^{d/2}} \right), & \lambda \to 0 \\ \mathcal{O} \left( \frac{\lambda}{\sqrt{n}} \right), & \lambda \to \infty, \end{cases}
\]

for \( \kappa = 2L|\lambda'| + \|c\|_\infty \). This means that for \( \lambda \) large enough, we get the desired \( \sqrt{n} \)-convergence. Mena and Weed (2019) also show that this rate can be improved and the domain restrictions relaxed if the underlying measures are sub-Gaussian.
Finally, we can use the transportation plan found in (8)–(10) or (11) to construct a mapping from the target population into the source population (Ambrosio et al., 2005). Define a function \( T : \beta \mapsto \alpha \) and such that \( \int \mathcal{X} g(x)d\alpha = \int \mathcal{X} g(T(x'))d\beta \) for all measurable functions \( g \). \( T \) maps points from the target distribution, \( X' \sim \beta \), into the source distribution, \( X \sim \alpha \). In finite samples, this function can be estimated as

\[
T_{\beta \mapsto \alpha}(X'_j) = \arg \min_{v} \sum_i c(X_{i}, v)P_{ij}.
\]  

For the squared-Euclidean cost, this map equals \( \frac{1}{b_i} \sum_i P_{ij}X_i \), or the weighted mean of the observations in the source sample. For an \( L_1 \) cost, \( T_{\beta \mapsto \alpha} \) is the weighted median of the \( X_i \). This map is known as a barycentric projection in the literature (Ambrosio et al., 2005; Peyré and Cuturi, 2019).

With these general properties of optimal transport defined, we are now ready to discuss the specific formulation for causal inference.

### 3.2 Problem formulation

Our desired methodology should have three qualities. First, the method should adapt the distribution of the controls and the treated—\( a_0 \) and \( a_1 \), respectively—toward the empirical distribution of the target sample, \( b \). Second, we desire a method that will not increase imbalance along some dimensions of the covariate space. Third, the method should be able to balance basis functions that are known \( a \) priori. Thus, the formulation for obtaining weights adapting treatment group \( Z = z \) to the target sample is

\[
\text{COT}_{\lambda,z}(b) = \arg \min_{P \geq 0} \sum_{i,j} C_{ij}P_{ij} + \frac{1}{2} \lambda P_{ij}^2
\]

subject to

\[
\sum_{i,j} P_{ij}I(Z_i = z) = 1
\]

\[
P^\top 1_n = b
\]

\[
\sum_{i,j} C_{ij}^{(l)}P_{ij} \leq \epsilon_l, \ \forall l \in \{1, ..., d\}
\]

\[
\left| \sum_{i,j} B_k(X_i)P_{ij} - \frac{1}{m} \sum_{j} B_k(X'_j) \right| \leq \delta_k, \ \forall k \in \{1, ..., K\},
\]

where \( C_{ij}^{(l)} = c \left( X_{ij}^{(l)}, X_{ij}^{(l)} \right) \) is the distance between the \( i \)th and \( j \)th individuals only for the \( l \)th covariate, and \( B_k(X_i) \) denotes the \( k \)th basis function of the covariates for unit \( i \). This problem can be readily solved in quadratic solvers.

We now break down each component of the formulation in (13)–(17) in detail to help build intuition about
its purpose. The first line is the same objective as in (11) and has the same interpretation of minimizing the overall distance between observations subject to a regularization penalty. Note that the cost matrix $C$ is still the pairwise distances between individuals in the treatment group $Z = z$ and the target population such that the weights sum to 1. Next, the first constraint in (14) serves to make sure we are only adjusting the weights on the treated individuals so that we can adapt their distribution to the target sample and not the controls.

Then the second constraint in (15) allows us to preserve the original sampling distribution of the target population. After that the constraint in (16) will allow us to find solutions that do not allow the average distance between observations along the $i$th covariate to increase beyond $\epsilon_i$. This can also be scene as ensuring marginal distributional balance between groups.

Finally, a researcher may know a set of basis functions that he or she thinks are important to balance a priori for valid causal estimates. The constraint in (17) will seek to balance the chosen basis functions between target and source samples. If these functions are correct, they should improve the performance of the subsequent weighting estimators and improve convergence (Wang and Zubizarreta, 2019b).

These balancing conditions can also be useful to balance important moments of the distributions. In theory, if the distributions were exactly the same, we would expect the means of the covariates to be exactly the same in each group. However, this may not be the case in practice because while the objective of causal optimal transport will attempt to balance the overall joint distributions, it will not prioritize specific features of the covariates. As such, adding important covariate moments or other covariate functions as balance constraints may lead to better performance of the weights.

Using the weights from (13)–(17) to target the TATE defined in (2), we define the optimal transport weights as

$$P_{\text{OT}} = COT_{\lambda,1}(b) + COT_{\lambda,0}(b),$$

which will seek to minimize the regularized optimal transport distance between the controls in the source and the target population, as well as the treated and the target population, leading to better distributional balance and less biased treatment effects.

To construct the estimator examined in (3), we need the new marginal weights for each unit in the treated and control groups of the source sample. These are easily obtained:

$$w_{\text{OT}} = P_{\text{OT}}1_n.$$  

Admittedly, the formulations in (13) are difficult to interpret in their primal form, so we turn to the dual
formulation for a better understanding of the optimization problem.

### 3.3 Dual interpretation

In constrained optimization, problems can often be reformulated into a so-called “dual” problem. Under certain conditions, solving the dual leads to the same exact solution as the “primal,” the original problem of interest, and can sometimes be easier to solve as well as easier to interpret. Such is the case for our problem.

**Theorem 1**

Let \( (x)_+ = \max(x, 0) \). Then the dual of problem (13)–(17) is

\[
\max_{g, h, \xi} \left( -\frac{1}{2\lambda} \sum_{i,j} \mathbb{I}(Z_i = z) \left( g_j - \sum_{l=1}^d h_l C_{ij}^{(l)} - B(x_i)^\top \xi - C_{ij} \right) \right)^2 + g^\top b - h^\top \epsilon - \delta \|\xi\|_1 - B(x_j)^\top \xi, \tag{20}
\]

where the dual variables \( g \in \mathbb{R}^m \) correspond to constraint (15), \( h \in \mathbb{R}_+^d \) correspond to the constraint in (16), and \( \xi \in \mathbb{R}_+^k \) correspond to the constraint in (17).

Additionally, the primal solution \( P^* \) is equivalent to

\[
P^*_{ij} = \frac{1}{\lambda} \mathbb{I}(Z_i = z) \left( g_j - \sum_{l=1}^d h_l C_{ij}^{(l)} - B(x_i)^\top \xi - C_{ij} \right)_+, \tag{21}
\]

The proof of this theorem is in Appendix A. The key to forming the result is that the balance constraints in (17) can be represented as inequality constraints and then standard duality theory allows us to proceed.

From the dual, we get the following corollary.

**Corollary 1**

The problem in (13)–(17) is a convex optimization problem. Specifically, it is a quadratic program.

The corollary follows immediately from the dual objective in Equation (21) since it is a linear combination of concave functions and includes a quadratic term. The dual is thus

we also note that the dual objective looks like a penalized linear regression, which makes intuition about the parameters easier. We will now go through the interpretation of each constraint by examining each set of dual variables turn before turning to the interpretation of the model in relation to the propensity score. Note that the interpretation depends on holding all of the other variables fixed.
3.3.1 Interpreting the parameters

The marginal distributional constraints. The constraint in (15) corresponds to the typical constraints on the marginal empirical distributions found in the optimal transport literature. However, since we have relaxed one of the marginal constraints, this makes our task somewhat easier. In the dual form, there is a unique scalar $g_j$ for each column of $C$, so we may approximately think of the $g$’s correspond to estimating the column means of $C$, though this is not precisely true.

The marginal cost constraint. The marginal cost constraints in (16) correspond to the dual variables $h$, which seem more opaque at first glance. However, we note that if the joint cost $C$ is chosen such that it is linearly separable, as is the case for the squared-Euclidean distance or the $L_1$ norm, then we can write the joint cost as

$$C_{ij} = C_{ij}^{(1)} + \ldots + C_{ij}^{(d)},$$

which is a sum of the marginal costs associated with the dual variables $h$,

$$h_1 C_{ij}^{(1)} + \ldots + h_d C_{ij}^{(d)}.$$  

Combining both terms above we get

$$h_1 C_{ij}^{(1)} + \ldots + h_d C_{ij}^{(d)} + C_{ij} = C_{ij}^{(1)} (1 + h_1) + \ldots + C_{ij}^{(d)} (1 + h_d).$$

This means that the $h$ variables act as a weight on the components of the cost matrix as a kind of variable importance parameter. As $h$ increases, the term inside of the max function in (21) is less likely to be positive and put weight on the paring $i, j$. This will encourage solutions that minimize the cost on these particular margins.

The basis function constraints. The basis function constraints have been addressed in other studies, notably Wang and Zubizarreta (2019a). However, the interpretation here is slightly different. The basis function terms will penalize solutions that move too far away from balancing the desired basis functions and thereby seek weights that minimize the average of the basis functions in the source and target samples. How much additional importance these basis functions receive is determined by strength of the corresponding $L_1$ penalty on the coefficients.
3.3.2 The implied propensity score model

Combined, these parameters allow us to interpret the implied propensity score model from Equation (21). First, we note that the marginal weights, \( w_{OT} \), imply a propensity score model that models both the probability of treatment and of being sampled in the source group. Since the true importance sampling weights in the treated group are simply the inverse of the propensity score divided by \( n \), then the corresponding estimate of the propensity score is \( \mathbb{P}(Z_i = 1, S_i = 1 \mid X_i) \propto \frac{1}{n w_i} \) when the individual is in the treated group. For an observation \( i \) with \( Z_i = z \), the marginal weights as estimated from the dual will be

\[
\begin{align*}
    w_i &= \frac{1}{\lambda} \sum_j \left( g_j - B(x_i) \xi - \sum_{l=1}^{d} (1 + h_l) c_{ij} \right) + ,
\end{align*}
\]

which does not have an easy interpretation.

3.4 Convergence

Theorem 2

Under Assumptions 1 and 2 and for fixed \( \lambda, \epsilon, \) and \( \delta \), then as \( n, m \to \infty \),

\[
    w_{OT} \to \beta,
\]

where \( w_{OT} \) is defined in Eq. (19).

This result is similar to that obtained by Reygner and Touboul (2020) under un-penalized settings. For an empirical examination of the convergence of our method in a toy example, see Appendix B.2.

We also have the following corollary.

Corollary 2

Define the importance sampling weights as \( \tilde{w}_i^* = \frac{deta(x_i)}{d\alpha(x_i)} \) and define the self-normalized importance sampling weights as

\[
    w_i^* = \frac{1/n \tilde{w}_i^*}{\sum_{j=1}^{n} 1/n \tilde{w}_j^*}.
\]

Then as \( n, m \to \infty \),

\[
    w_{OT} \to w^*.
\]

Proofs of both the theorem and its corollary are provided in Appendix B.1.
3.5 Statistical Inference

For statistical inference we turn our attention to calculating the variance and confidence intervals of our method using the bootstrap.

In the spirit of authors such as Kallus (2016), Ratkovic and Tingley (2017), and Wang and Zubizarreta (2019a), we also consider a bootstrapped confidence interval detailed in Algorithm 1. Basically, one must generate a bootstrapped version of the data, re-calculate the estimate of the treatment effect, and repeat a large number of times. One consideration is that the unregularized optimal transport distances are known to not be Hadamard differentiable and Hadamard differentiability is a requirement for the bootstrap distribution to be consistent (Sommerfeld and Munk, 2016; Fang and Santos, 2019). Similar results have been found for other minimal optimal transport estimators such as nearest neighbor matching (Abadie and Imbens, 2008).

Fortunately, the \( m \)-out-of-\( n \) bootstrap is consistent for optimal transport distances (Sommerfeld and Munk, 2016), and it is the one we use here (Bickel et al., 1997). We further utilize the method for confidence intervals recommended for the \( m \)-out-of-\( n \) bootstrap by Lee (1999).

Algorithm 1: Confidence interval generation for optimal transport weight based estimators

\[
\textbf{Data:} \text{ empirical distribution and samples } b, \text{ hyperparameters } \lambda, \text{ constraints } \epsilon, \text{ and } \delta, \text{ estimate } \hat{\tau}, \text{ and coverage level } \alpha
\]

\[
\textbf{Result:} \text{ Confidence interval bounds } (L_{1-\alpha}, U_{1-\alpha})
\]

\[
\text{for } k \text{ in } 1 : K \text{ do}
\]

\[
\text{Bootstrap data } b^* \sim b \text{ of size } r_1 < m;
\]

\[
\text{Bootstrap data } a^* \sim a \text{ of size } r_2 < n;
\]

\[
\text{Calculate } w^* \text{ from } \text{COT}_{\lambda,1}(b^*) + \text{COT}_{\lambda,0}(b^*);
\]

\[
\text{Calculate } \tau^*_k;
\]

\[
\text{end}
\]

\[
\text{Calculate } L_{1-\alpha}^* \text{ and } U_{1-\alpha}^*, \text{ the empirical critical values of size } 1 - \alpha \text{ from the bootstrapped sample;}
\]

\[
\text{Set } \tau^* = K^{-1} \sum_k \tau^*_k;
\]

\[
\text{Set } L_{1-\alpha} = \hat{\tau} + \sqrt{r_2/n}(L_{1-\alpha}^* - \tau^*);
\]

\[
\text{Set } U_{1-\alpha} = \hat{\tau} + \sqrt{r_2/n}(U_{1-\alpha}^* - \tau^*);
\]

\[
\text{return } L_{1-\alpha}, U_{1-\alpha}^*;
\]

Additionally, one can also use this algorithm to estimate the variance of \( \hat{\tau} \):

\[
\text{Var}(\hat{\tau}) = \sqrt{r_2/n} \text{Var}(\tau^*_{1,k}),
\]
where \( r_2 < n \).

### 3.6 Double robustness

The causal optimal transport weights also enjoy the double robustness property (Robins and Rotnitzky, 1995), at least in the limit. This follows from Theorem 2. The augmented estimator of \( \tau \) will be equal to

\[
\hat{\tau}_{dr} = \sum_{i=1}^{n} w_i(Y_i - \hat{m}_1(X_i))Z_i - \sum_{i=1}^{n} w_i(Y_i - \hat{m}_1(X_i))(1 - Z_i) + \frac{1}{m} \sum_{j=1}^{m} \hat{m}_1(X_j) - m_0(X_j),
\]

where \( \hat{m}_z \) is an estimate of the hypothesized conditional mean function for treatment group \( Z = z \). In contrast, the Hájek estimator of \( \tau \) is

\[
\hat{\tau}_H = \sum_{i=1}^{n} w_i Y_i Z_i - w_i Y_i (1 - Z_i).
\]

A more interesting general property of weights that balance functions of the covariates \( B(\cdot) \), such as those in the constraint in Equation (17), is that when \( \delta = 0 \) and the balancing functions are equal to the hypothesized estimated conditional mean function, \( B(\cdot) = \hat{m}_z(\cdot) \), then these general balancing weights, \( w_{bal} \), will be equal to the doubly robust estimator.

**Theorem 3**

*Define the augmented estimator \( \hat{\tau}_{dr} \) and the Hájek estimator as \( \hat{\tau}_H \) as above and take \( \gamma_0 \in \mathbb{R} \), \( \gamma \in \mathbb{R}^K \), and \( B(\cdot) : \mathbb{R}^d \rightarrow \mathbb{R}^K \). If estimation of the balancing weights \( w_{bal} \) is feasible when \( \delta = 0 \) and we have that the hypothesized conditional mean function \( m_z(x) = \gamma_0 + B(x)^\top \gamma \), that is the hypothesized conditional mean function and the balancing functions are equal up to an affine linear transform, then

\[
\hat{\tau}_{dr} = \hat{\tau}_H.
\]

See Section C of the Appendix for a proof. This of course holds true for general balancing weights such as the Stable Balancing Weights of Zubizarreta (2015) or the weights proposed in this paper. This estimator appears to be like a linear regression in the theorem, which We should also note that the functions \( B(\cdot) \) can
vary for each treatment group since in practice the weights are estimated separately for each treatment.

Additionally, we note that one advantage of constructing augmented estimators using balancing weights is that they will not be prone to extrapolation as may be the case with general forms of \( \hat{\delta}_{DR} \). This is because with the sum to 1 constraint on the weights \( w_{bal} \), the estimator is forced to be within the convex hull of the data. In this case, we have the following corollary.

**Corollary 3**

*Under the assumptions of Theorem 3 and for \( \gamma \in \mathbb{R}^K \) and any \( \delta_k \geq 0 \) for all \( k \in K \), then for general balancing weights \( w_{bal} \),*

\[
|\hat{\delta}_{dr} - \hat{\gamma}_H| \leq \sum_{k=1}^{K} \delta_k |\gamma_k|
\]

This follows immediately from the constraints in Equation (17), the proof of Theorem 3, and the triangle inequality.

### 3.7 Practical considerations

In this section, we turn to the practical considerations of optimizing the optimal transport weights in Section 3.2. Namely, we discuss the tuning of the hyperparameters, presenting an algorithm to do so, and estimation of the optimal transport weights.

#### 3.7.1 Hyperparameter tuning

Our goal is to select the hyperparameters \( \lambda, \epsilon, \) and \( \delta \) so that we achieve the best distributional balance but also minimize the dispersion of the weights. To build some intuition about the effects of potential choices, we consider some limiting cases of the parameters. For example, if we set \( \lambda = \infty \) and choose very large \( \epsilon \) and \( \delta \), the algorithm will seek to remove any dispersion in the weights \( P \) by setting them exactly equal. Alternatively, \( \lambda = 0, \epsilon \gg 0, \) and \( \delta = 0 \) will seek weights such that the units are as close as possible in terms of the cost \( C \) but also such that the empirical means of the balance functions are exactly equal. While this last setting sounds like it would be great in practice, this may lead to over-fitting the observed data, leading to worse out of sample performance, and may not even be feasible in practice. To work around this
difficulty, we propose a bootstrap based tuning procedure detailed in Algorithm 2.

**Algorithm 2: Choosing hyperparameters for the optimal transport weights**

**Data:** Grid of parameter values $\Delta = \{\{\lambda_1, \epsilon_1, \delta_1\}, \{\lambda_2, \epsilon_2, \delta_2\}, \ldots\}$, number of bootstrap samples $K$,

empirical measure $b$, empirical measure $a$, treatment group of interest $z$

**Result:** Value of hyperparameters, $\hat{\lambda}, \hat{\epsilon}, \hat{\delta}$

**foreach** $\{\lambda, \epsilon, \delta\} \in \Delta$ **do**

| Estimate weights $P$ given parameters $\{\lambda, \epsilon, \delta\}$ via (13); |
| **for** $k$ in $1, \ldots, K$ **do** |
| Bootstrap new target data $b_k^* \sim b$; |
| Bootstrap new source data $a_k^* \sim a$; |
| Set weights for empirical measure in treatment group $z$ as $w_k^* = Z \odot w \odot a_k^*$, where $\odot$ is the element-wise product; |
| Set $T_{\{\lambda, \epsilon, \delta\}} = K^{-1} \sum_k^K \text{OT}(w_k^*, b_k^*)$ |

**return** $\hat{\lambda}, \hat{\epsilon}, \hat{\delta} = \arg\min_{\{\lambda, \epsilon, \delta\}} T_{\{\lambda, \epsilon, \delta\}}$;

We justify this procedure in two ways. First, while practitioners may have subject matter knowledge about the degree of desired balance in the basis functions or the selection of covariates, they probably do not have an ideal weight dispersion in mind. Second, because the minimum weights target the inverse propensity score, we can use this fact to justify a bootstrap-based algorithm to select the hyperparameters that provide the best out of sample balance.

Choosing the grid of values can also be done in a data driven manner. The $\lambda$ values can be chosen as a grid relative to the observed cost matrix: $\Lambda = \{C \cdot 1 \times 10^{-3}, \ldots, C \cdot 1 \times 10^6\}$, where $C$ is the median or mean value of the cost matrix $C$. The scaling by $C$ adjusts the $\lambda$ to the scale of the data so that an appropriate amount of penalization is considered. The values of $\epsilon$ have natural limits in the data, lower bounded by the optimal transport distance with $\lambda = 0$ performed on each margin, e.g. $\text{COT}_{\lambda=0, z}(b) \leq \min_{P} \sum_{i,j} C(l)^{[l]} P_{ij}$ with only constraint (15). Finally, the values of $\delta$ can either be chosen as a grid $\Delta = \{0, 0.01, \ldots, k^{-1/2}\}$, where $k$ is the number of basis functions, or $\delta$ can be selected by first running a stable balancing weights tuning algorithm (Wang and Zubizarreta, 2019a; Chattopadhyay et al., 2020) and then using the selected $\delta$. The $k^{-1/2}$ term in the former method is critical for the theory behind the stable balancing weights tuning algorithm to hold.
3.7.2 Weight estimation

Given the known complexity of estimating optimal transport weights, Huling and Mak (2020) raise the concern that using this methodology will be unfeasible since the computational complexity is on the order of $n^3$ (Solomon et al., 2015). Fortunately, these concerns are addressed by using regularized optimal transport. The computational complexity of regularized optimal transport is $n^2 \log(n)/\lambda^2$ (Altschuler et al., 2017; Dvurechensky et al., 2018), which suggests even bigger gains for larger penalties.

In our simulations, we find that estimating the desired quantities of (18) only take a few seconds for 1000 observations. This estimation can be done using optimization software like Mosek or using the built-in R function `optim` on the dual (MOSEK ApS, 2021; R Core Team, 2020).

Finally, we note that in practice we estimate the weights separately for each treatment group, meaning that weight estimation is embarrassingly parallel.

3.8 Multi-valued treatments

The work here-in is also easily extended to more the two treatments as long as the treatment takes on non-negative integer values $Z \in \{0, 1, 2, \ldots\}$. This is because for each treatment group we estimate the weights separately for the source population. In this way, the weights are essentially independent of each other.

For continuous treatments, this would correspond to an optimal transport problem matching an infinite set of distributions and would likely need some parametric assumptions.

4 Connections to existing methods

The optimal transport framework we propose is fairly general. In fact, many well-known and recently developed methods are in fact special cases of our method.

4.1 Synthetic control method

The synthetic control method was first proposed by Abadie and Gardeazabal (2003) as a way of performing counterfactual inference for a single treated unit. The synthetic control method (SCM) solution generates a so-called synthetic control for treated unit $j$ as

$$\hat{X}_{j}^{sc} = \sum_{i} w_{i}^{sc} X_{i},$$
with \( \sum_i w_i^{sc} = 1 \). The basic idea is to find weights that sum to 1 such that the covariates of the treated unit \( j \) are well approximated by the weighted mean of controls. If the synthetic control is close to the treated unit \( j \), then we also assume that the synthetic control will have an outcome that is close to the counterfactual outcome of unit \( j \). This, of course, is exactly the same task as forming a barycentric projection from a transportation matrix under a squared-Euclidean cost.

Recall that the barycentric projection for \( p = 2 \) is equal to

\[
T(X_j) = \frac{\sum_i P_{ij} X_i}{b_j}
\]

with \( \sum_i P_{ij} / b_j = 1 \). Clearly, these are the same estimator. Thus, the synthetic control objective for a single treated individual is estimating the barycentric projection directly with the particular constraint in causal inference that the value of \( X \) does not change in the counterfactual situation, i.e. \( T_{b \to a}(X_j) = X_j \). This is due to the fact that \( X \) temporally precedes treatment. As a consequence of this relationship, synthetic controls are simply a particular case of causal optimal transport. Moreover, causal optimal transport also generalizes synthetic controls to multiple treated units.

One potential drawback of using SCM versus optimal transport weights directly can be seen in the following simple example in Figure 2. The optimal transport weights favor the nearest point while the SCM method utilizes the points further away. This could be a problem if the response surface looks like it does in Figure 2b.

![Figure 2: A simple example where synthetic controls (SCM) would perform worse than the optimal transport weights.](image)

For this reason, synthetic control methods should incorporate a modified objective that directly models
both the barycentric projection and distance between units:

$$\sum_j \left( T(X_j) - b_j^{-1} \sum_i P_{ij}X_i \right)^2 + \lambda_{\text{OT}} \sum_i C_{ij}P_{ij},$$

where the value of $\lambda_{\text{OT}}$ can be chosen through cross-validation. Indeed, this objective is the same as the main term in Perrot et al. (2016), which suggests we can extend the synthetic control objective to perform joint weight and outcome mapping for multiple units. The special form of $T$ in the linear outcome modeling case would be

$$T_{\hat{\beta}}(X_j) = \left[ \hat{\beta}^\top \right] I_d X_j.$$

This can be estimated using conditional gradient descent (Frank and Wolfe, 1956; Jaggi, 2013).

### 4.2 Other methods

#### 4.2.1 Optimal matching

The optimal matching framework of Rosenbaum (1989) is closely related to the optimal transport weighting methodology developed in this chapter. Rosenbaum formulates his problem as a network flow problem that seeks to minimize the overall distance between matched pairs. We can obtain similar results from our program by modifying the objective like so:

$$\min_{P \in \{0, 1\}} \sum_{i,j} C_{ij}P_{ij}$$

subject to

$$\sum_{i,j} P_{ij} I(Z_i = z) = 1$$

$$0 \leq P_{1n} \leq L_{1n}$$

for $L \geq 1$. These modifications ensure that each observation is only matched once and that weights are integral, yielding the optimal matching problem. In contrast to the optimal matching problem, our solution 1) relaxes the integer nature of the weights, 2) adds a regularization penalty for improved performance, and 3) targets additional constraints on the marginal costs and basis functions.
4.2.2 Nearest neighbor matching

When done with replacement, nearest neighbor matching is simply a re-formulation of the minimal optimal transport distance problem. If we chose $\lambda=0$ and only use the constraint on the marginal distribution of the target population, then we obtain the following objective:

$$\min_{\mathbf{P} \geq 0} \sum_{i,j} C_{ij} P_{ij}$$

subject to

$$\sum_{i,j} P_{ij} I(Z_i = z) = 1$$

$$\mathbf{P} \mathbf{1}_n = b.$$  

This will seek to find the unit that is closest in terms of $C$ for each unit $j$, which is the definition of nearest neighbor matching. Since we allow the pool of donor individuals to be used multiple times, we have nearest neighbor matching with replacement. Of note is that the new marginal weights calculated for group $Z = z$ will simply be an integer that counts the number of times a unit was matched, divided by the total sample size of the target sample, $m$.

4.2.3 MIP matching

Mixed integer programming (MIP) matching seeks to match units to satisfy some balance criteria such as the mean or any other desired basis function, in additional to distributional balance (Zubizarreta, 2012). We can formulate the MIP objective as

$$\max_{\mathbf{P} \in \{0,1\}} \sum_{i,j} C_{ij} P_{ij}$$

subject to

$$\mathbf{P} \mathbf{1}_m = \mathbf{1}_n$$

$$\mathbf{P}^\top \mathbf{1}_n = L \mathbf{1}_m$$

$$\left| \frac{1}{Lm} \sum_{i,j} B_k(X_{ij}) P_{ij} - \frac{1}{m} \sum_j B_k(X_j) \right| \leq \delta_k, \forall k \in \{1, ..., K\} ,$$

for $L \geq 1$. Like optimal matching this is similar to the formulation of the full COT objective but with integer weights, and also like optimal matching, this will suffer from having weights with a larger dispersion if $L$ is too low.
4.2.4 Inverse probability weighting with generalized linear models

The goal of inverse probability weighting with weights from a generalized linear model is to re-weight the density of a particular treatment group to target either the SATE or the TATE. For instance, if the objective is to re-weight the treated to the full sample to estimate the SATE, the goal is to go from the observed density of

\[ p(y \mid x, z = 1)p(z = 1 \mid x)p(x) \]

to

\[ p(y \mid x, z = 1)p(x), \]

where \( p \) denotes the respective density functions. This can clearly be achieved by dividing the first equation by the propensity score, \( P(Z = 1 \mid X) \). However, obtaining the correct weights relies on the correct specification of the propensity score model.

In our particular example of aligning the source and target samples, the ideal IPW will be exactly equal to \( \frac{\partial p}{\partial \alpha_z} \), which is the ratio of densities of the target population to a particular treatment group of the source population. The causal optimal transport method will always converge to this value while the IPW method based on generalized linear model will only converge to this value if the model is correct (Figure 3a). Further, this means that causal optimal transport will estimate a model that is a subset of the potential generalized linear models and will include the true model. However, when the true model is not a subset of the generalized linear models, causal optimal transport will still converge to the true model (Figure 3b).

4.2.5 Stable balancing weights

We now provide a brief overview of stable balancing weights or SBW (Zubizarreta, 2015). The SBW method seeks to find weights of minimal dispersion that satisfy constraints on the balance functions. Reformulating
the problem slightly so that it matches the variables in (13) and (17) we have

\[
SBW(b) = \arg\min_{P \geq 0} \left( \sum_i \left( \sum_j P_{ij} \right)^2 \right)
\]

subject to \( \sum_{i,j} P_{ij} Z_i = z = 1 \)

\[
\left| \sum_{i,j} B_k(X_i) P_{ij} - \frac{1}{m} \sum_j B_k(X_j) \right| \leq \delta_k, \forall k \in \{1, ..., K\}.
\]

The quadratic objective seeks to minimize the variance of the marginal weights \( w \) since \( \sum_i \left( \sum_j P_{ij} \right)^2 = \sum_i w_i^2 \). Then the second part seeks those marginal weights that adapt basis functions of the source to the basis functions of the target, since \( \sum_{i,j} B_k(X_i) P_{ij} = \sum_i B_k(X_i) w_i \).

Ideally, these basis functions that are equal to \( \mu_z(\cdot) \) However, in order to converge to the correct weights the model must be correctly specified. In contrast, the causal optimal transport method will converge to the correct distribution and thus give accurate estimates of \( \mu_z \) without correctly specifying the model. Moreover, these balancing functions, if important, can be incorporated into our method via the constraint in (17).

If the selected balance functions are the sufficient statistics for the underlying distributions, then balancing these sufficient statistics will also balance the distributions, and likely in a more efficient manner than the proposed methodology. Note that this subsection and the previous one also imply that covariate balancing propensity scores are also a subset of this methodology (Imai and Ratkovic, 2014).

4.2.6 Energy distance and the MMD

For general empirical distributions \( a \) and \( b \) with \( n \) and \( m \) atoms, the energy distance is defined as

\[
\mathcal{E}(a, b) = \frac{2}{nm} \sum_{i,j} d(x_i, x_j)^p - \frac{1}{n^p} d(x_i, x_i)^p - \frac{1}{m^p} d(x_j, x_j)^p,
\]

where \( d \) is a distance metric between points and \( p > 1 \) (Ramdas et al., 2015; Feydy et al., 2018; Huling and Mak, 2020).

We can construct an interpolation between optimal transport distances and the energy distance by utilizing a penalized optimal transport divergence (Genevay et al., 2018; Feydy et al., 2018):

\[
D_\lambda(a, b) = OT_\lambda(a, b) - 0.5 OT_\lambda(a, b) - 0.5 OT_\lambda(b, b).
\]

As \( \lambda \to \infty \), then all the weights will receive the same value and we will have that \( D_\lambda(a, b) = 0.5\mathcal{E}(a, b) \)
Optimal transport is also related to the mean maximum discrepancy (MMD) through the energy distance Ramdas et al. (2015). The MMD is equal to

$$M = 0.5 \int_{X \times X} k(x, x') d\phi(x),$$

for $\phi = \alpha - \beta$. For some reproducing kernel Hilbert space $k$, such as the radial basis function, $\exp(-x||x - x'||^2/2\sigma^2)$ or $-||x - x'||$, and for a distance $d$ defined as $d(x, x') = \frac{1}{2}k(x, x') + \frac{1}{2}k(x, x') - k(x, x')$, then MMD with kernel $k$ is equivalent to the energy distance with distance $d$ (Ramdas et al., 2015; Feydy et al., 2018).

## 5 Simulation study

Now we perform a simulation study to evaluate the finite sample performance of the proposed weighting methodology when estimating the ATE. Here we use the simulation study originally presented in Hainmueller (2012). For each setting we run 500 experiments with a sample size of $n = 512$.

### 5.1 Setup

#### 5.1.1 Study design

We generate six covariates $X_1, \ldots, X_6$ from the following distributions

$$
\begin{bmatrix}
X_1 \\
X_2 \\
X_3
\end{bmatrix} \sim \mathcal{N}
\begin{bmatrix}
0 \\
0 \\
0
\end{bmatrix},
\begin{bmatrix}
2 & 1 & -1 \\
1 & 1 & -0.5 \\
-1 & -0.5 & 1
\end{bmatrix}
$$

$X_4 \sim \text{Unif}(-3, 3)$

$X_5 \sim X_1^2$

$X_6 \sim \text{Bern}(0.5)$.

In this study, the last three covariates are mutually independent and also independent of the first three covariates. Note that this is a mixture of continuous and binary variables.

The treatment indicator is generated from

$$Z = I(X_1 + 2X_2 - 2X_3 - X_4 - 0.5X_5 + X_6 + \nu > 0),$$
where \( \nu \) is drawn from one of three distributions leading to different degrees of overlap:

- **High**: \( \nu \sim \mathcal{N}(0, 100) \)
- **Medium**: \( \nu \sim g(\chi^2_5) \)
- **Low**: \( \nu \sim \mathcal{N}(0, 30) \).

\( g \) is a function that gives the \( \chi^2_5 \) draws expectation 0.5 and variance 67.6. The distribution of the propensity scores are displayed in Figure 4, which is the same information as included in Figure 1 of Hainmueller (2012). The scenarios that should be most difficult for estimation should be where there is strong separation between treatment groups, in the low overlap scenario with \( \nu \sim \mathcal{N}(0, 30) \), and in the case where the errors are leptokurtic, in the medium overlap scenario with \( \nu \sim g(\chi^2_5) \). Also note that though the high and low overlap models are drawn from a probit model, we expect a logistic regression to perform reasonably well.

Given the treatment indicator \( Z \) and the covariates \( X_1, \ldots, X_6 \), we simulate our outcome \( Y \) from one of two models

(A) \( Y(0) = Y(1) = X_1 + X_2 + X_3 - X_4 + X_5 + X_6 + \eta \)

(B) \( Y(0) = Y(1) = (X_1 + X_2 + X_3)^2 + \eta \),

with \( \eta \sim \mathcal{N}(0, 1) \). There are two things to note about these outcome models. The first is that there is no effect of treatment at the unit level and hence the ATE is 0. The second is that a linear outcome model should perform well in the first setting (A) while it should have substantial bias in setting (B).
5.1.2 Methods under examination

We compare our methodology to several other methods commonly used in the literature for weighting and we restrict our consideration to methods that do not use the outcomes in the design stage of the analysis. The first method we consider is logistic regression to estimate the propensity scores (GLM) using only first order terms. We also consider balancing methods like the covariate balancing propensity score (CBPS), ran with the default settings provided by the corresponding R package (Fong et al., 2019), and the stable balancing weights (SBW) of Zubizarreta (2015) targeting mean balance. Finally, we utilize the synthetic control method (SCM) with an $L_2$ penalty on the weights, (Abadie and Gardeazabal, 2003).

For the optimal transport weights (OT), we utilize four variations. The first only balances the joint distribution (no constraints or “none”), the second targets the joint distribution and includes a constraint on the marginal costs (“margins”), and the third targets the joint distribution and targets mean balance (“means”). Fourth, we target the joint and constrain the marginal costs and mean balance (“means + margins”). In all cases, we use an $L_1$ metric with standardized covariates.

5.2 Estimators

We consider four estimators to target the ATE estimand. Three of the estimators have the same form as the estimator in Equation (3) while the fourth is a version of the barycentric projection in Equation (12).

The first estimator uses the weights directly from the balancing methods to from a Hájek estimator (Hájek, 1971), or a weighted mean with normalized weights $w = (w_1, ..., w_n)^\top$:

$$\hat{\tau}_H = \sum_{i=1}^n w_i Y_i Z_i - \sum_{i=1}^n w_i Y_i (1 - Z_i).$$

(22)

The second estimator we consider is an augmented weight or doubly robust estimator (Robins et al., 1994; Rotnitzky et al., 1998):

$$\hat{\tau}_{dr} = \sum_{i=1}^n \hat{m}_1(X_i) + w_i(Y_i - \hat{m}_1(X_i))Z_i - \sum_{i=1}^n \hat{m}_0(X_i) + w_i(Y_i - \hat{m}_0(X_i))(1 - Z_i),$$

(23)

where $\hat{m}_z(X_i)$ is the prediction from a linear model trained on group $Z = z$ and evaluated at point $X_i$. We also assume that the weights have been normalized to sum to 1.

The third estimator is a weighted least squares estimator

$$\hat{\tau}_{wols} = \arg\min_{\tau, \gamma} \sum_{i=1}^n w_i (Y_i - \gamma_0 - Z_i \tau - X_i^\top \gamma)^2,$$

(24)
where $\gamma \in \mathbb{R}^D$ and $\tau, \gamma_0 \in \mathbb{R}$. The corresponding estimator $\hat{\tau}_{\text{wols}}$ is the value of $\tau$ at the minimum.

The fourth and final estimator is the barycentric projection of the target sample into the respective treatment groups of the source sample:

$$
\hat{Y}_j(z) = \arg\min_{\nu} \sum_{i} c(y_i, \nu) P_{ij}(Z_i = z).
$$

Then the estimate of the treatment effect is

$$
\hat{\tau}_{\text{BP}} = \frac{1}{m} \sum_{j=1}^{m} \hat{Y}_j(1) - \frac{1}{m} \sum_{j=1}^{m} \hat{Y}_j(0). \tag{25}
$$

For those methods that do not obtain an estimate of $P_{\text{OT}}$ in (18), we take their estimated marginal weights $w$ and estimate a version of $P_{\text{OT}}$ from Equation (8) to allow the estimation of (25).

### 5.3 Results

We now turn our attention to the results in the two outcome design settings: design A, where the linear outcome models are well specified, and design B, where the linear outcome models are misspecified. Due to their non- to semi-parametric formulation, we expect the optimal transport weights to be better than other methods when the propensity score and outcome models are misspecified—design B and medium overlap.

#### 5.3.1 Design A: well-specified outcome models

In this setting we expect that the methods utilizing the true linear outcome model, estimators (23) and (24), will perform well and that the other estimators, estimators (22) and (25), to have worse performance as the overlap degrades.

In Figure 5, we can see that the augmented estimator and weighted OLS that balance the correct basis functions—i.e. $X_1, ..., X_6$—perform well across all cases. Similarly, weighting estimators that balance the correct basis functions perform well in every case. Several methods such as GLM and CBS have some extreme outliers that are cut off by the bounds of the graph, but even with what we can see these methods suffer from larger outliers than the other methodologies across data generating processes. For the optimal transport methods, it is clear that the formulations not including balancing functions suffer from a significant amount of bias and in all cases the optimal transport methods have larger interquartile ranges than any other method save for SCM.

Table 1: Performance of various weighting methods under the simulation settings of Hainmueller (2012). Bold values are the values with the lowest bias or root mean-squared error (RMSE) of the methods under the same conditions. GLM refers to weighting by the inverse of the propensity score as calculated from a logistic regression model, SBW is the stable balancing weights of Zubizarreta (2015), OT is the optimal transport formulation proposed in this paper. The estimators are simple inverse probability weights (IPW), doubly-robust augmented IPW (DR), weighted least squares (WOLS), and barycentric projection (BP). All weights are normalized to sum to 1. Constraints refer to constraints in the linear program and are one of "none" for no constraints, "margins" for constraints on the marginal optimal transport distances, “mean” for mean constraints, and “m+m” for marginal and mean constraints.
For more detail, we turn to the top half of Table 1. This table indicates that SBW performs best on average in terms of root-mean-squared error (RMSE) across all settings for design A and performs favorably in terms of bias. Also note that balancing for the covariate means gives weights that perform the same in terms of bias and RMSE in the Hájek, augmented, and weighted least squares estimators. This indicates that balancing for covariate means generates weights that do not need further regression adjustment. As an additional note for the augmented and weight least squares estimators, SCM appears to do better than the other methods, though in the medium overlap scenario, some of the optimal transport methods perform better.

Of the optimal transport methods, those that constrain the means in some way appear to do better in terms of both bias and RMSE, indicating the benefit of including the correct basis function in the set of constraints. Finally, the RMSE for all optimal transport methods appear to be slightly worse than those of stable balancing weights even when including the true basis functions either as an outcome model or balancing these functions in the constraints of the problem. We expect that this is because the optimal transport methods also have an additional balancing target, the joint distribution, so there is some minor loss of efficiency.

5.3.2 Design B: misspecified outcome models

Now, we turn to the outcome setting B where linear outcome models are misspecified and where none of the balancing functions include the correct basis functions. In this setting, we expect that there will be a penalty to pay by using the incorrect outcome model in (23) and (24) relative to design A. One would guess that in these settings the optimal transport methods would do better in terms of bias and RMSE.

Indeed, the optimal transport weights perform well, having lowest mean-squared error across all overlap scenarios in the lower part of Table 1. But depending on the formulation, there is still the potential for substantial bias—see, for example, the no constraint setting (“none”) and the marginal cost constraint setting (“margins”) only using the Hájek weights in these settings.

However, as expected, the optimal transport weights perform best relative to the other methods when both the outcome and propensity score models are misspecified. This can be seen in the medium overlap scenario with leptokurtic errors in the middle column of Figure 6 and in the penultimate row of Table 1. No other methods come close to the optimal transport methods in terms of RMSE. Additionally, the bias of the constrained optimal transport methods (mean and mean with marginal constraints) are lower than all other methods regardless of the estimator.

The high and low overlap settings also demonstrate the utility of the causal optimal transport methodol-
ogy. For instance, in the high overlap setting the constrained optimal transport methods perform favorably in terms of bias (third to fourth best behind GLM, SBW, and sometimes CBPS) and dominate the other methods in terms of RMSE across all estimators and constraint formulations. Causal optimal transport also performs best in the low overlap setting in terms of RMSE and compares favorably to other methods such as CBPS, GLM, and SBW.

6 Case study

In this section, we turn to an application of our methodology to a real data set. There is growing interest in the literature to utilize libraries of RCTs to evaluate new interventions, the idea being that running RCTs to evaluate every new intervention is expensive. These studies, alternatively called an externally controlled trial or synthetic control group trial (U.S. Department of Health and Human Services Food and Drug Administration et al., 2001; Thorlund et al., 2020)—not to be confused with the synthetic control method of Abadie and Gardeazabal (2003)—compares a set of study subjects receiving a treatment to a group of individuals external to the trial at hand who did not receive the intervention of interest. The participants used for the control group can be taken from a variety of sources such as an observational study, electronic medical records, or from historical clinical trial data (Schmidli et al., 2020; Davi et al., 2020). Our methodology allows researchers adjust these potential control groups from an external data source to form a suitable control group for the individuals receiving the intervention by directly balancing the distributions between the groups. To demonstrate this method in practice, we present an analysis utilizing data from a multi-site RCT originally discussed by Blum et al. (2010).

For an additional data analysis, see Appendix D.

6.1 Misoprostol for the Treatment of Postpartum Hemorrhage

The original study was a double-blind, non-inferiority trial that exposed 31,055 women to prophylactic oxytocin during labor at 5 hospitals in Burkina Faso, Egypt, Turkey, and Vietnam. Women with uncontrolled blood-loss after delivery—a condition known as post-partum hemorrhage or PPH—were randomized to receive either 800mg misoprostol (treatment condition) or 40IU oxytocin (control condition). There were 407 and 402 women in each treatment group, respectively. The primary outcome for the study was whether blood loss was controlled in 20 minutes after PPH diagnosis. The authors discuss mean balance for several important confounders as a demonstration of the validity of the randomization. These confounders were the woman's age, whether the woman had no formal education, the number of live births, whether
Figure 5: Boxplots ATE estimation of various weighting methods under the simulation settings of Hainmueller (2012) for outcome design A, in which the outcomes are generated from a linear model. Constraints refer to constraints in the linear program and are one of “none” for no constraints, “margins” for constraints on the marginal optimal transport distances, “mean” for mean constraints, and “means + margins” for marginal and mean constraints. The black line denotes the true ATE. Note that the plots are zoomed in to better visualize the central parts of the distributions. Thus some outliers are not visible.
Figure 6: Boxplots of ATE estimation of various weighting methods under the simulation settings of Hainmueller (2012) for outcome design B, in which the outcomes are drawn from a non-linear outcome model. The dark line at 0 denotes the true treatment effect. Constraints refer to constraints in the linear program and are one of “none” for no constraints, “margins” for constraints on the marginal optimal transport distances, “mean” for mean constraints, and “means + margins” for marginal and mean constraints. Note that the plots have been zoomed in for better legibility and thus some outliers have been removed.
the woman was currently married, the fetus’ gestational age, whether the woman had a previous PPH, hemoglobin in (g/L), whether labor was induced, whether labor was augmented, whether the woman had an early cord clamp, whether there was controlled cord traction, whether the woman had a uterine massage, whether the placenta was delivered before the PPH diagnosis, and blood loss in milliliters (mL) at treatment.

6.2 Modifications and methods

We modify the study in a couple of ways to make it more similar to a new intervention with an external control group constructed from a library of RCTs. First, we modify the groups present in the study data. We do this by taking the largest site in the data, Egypt, and removing the control group. Then we take the controls from the other four sites as if they were a potential comparison group from a library of RCTs to use for analyzing a new intervention. This step is justified since all of the sites were randomized independently and so there should be no interference between units. One advantage of the current approach is that we know the original treatment effect at the Egypt site, so we can evaluate how well our method performs relative to the ground truth. If causal optimal transport can recover the original treatment effect, we know it is performing well.

Second, instead of whether blood loss was controlled after 20 minutes, we use the difference in observed blood loss between treatment groups measured after 20 minutes as our causal estimand of interest. The original treatment effect observed at the Egypt site was a difference of $0.369$ mL between treatment groups with a confidence interval of $(-27.1 \text{ mL}, 27.8 \text{ mL})$.

From the optimal transport weighting methodology, we use our method with constraints on nothing ("none"), marginal costs ("margins"), means between groups ("means"), and marginal costs and means ("margins + means"). We utilize an $m$-out-of-$n$ bootstrap with 1000 bootstrapped samples to generate the confidence intervals as in Algorithm 1. Finally, the distance metric we use is a Mahalanobis $L_1$ metric on the continuous covariates and an $L_1$ norm on the binary covariates.

For our estimates to be valid, we require that there be no unmeasured confounding but also that the estimates are “transportable,” i.e. we are able to take estimates from the other hospitals in the external control group and transport them to Egypt, which requires that conditional on the observed covariates there are no other variables that can effect the outcome and treatment indicator ($d$-separation holds, Pearl and Bareinboim, 2013).
6.3 Design diagnostics

Prior to discussing outcome results, we discuss the level of balance achieved by our methodology. Typically, researchers examine the standardized mean balances to assess performance of a weighting or matching estimator (Stuart, 2010), and we present the results for our methodology in Figure 7. We can see that mean balance is improved but substantial biases still remain. In fact, the average mean balance across all covariates is 0.21, so we might expect that the mean balancing methods will perform poorly. Of note some variables have a noticeable difference in mean balance between methods. For example, uterine massage, number of live births, whether labor was augmented, and hemoglobin concentration, mean balance is improved more with the methods that constrain differences in means between groups. In contrast, number of live births, and age have worse mean balance for methods that constrain the means.

Similarly, we present results for the change in 1-Wasserstein distance across the four methods before and after weighting, and in every case distributional balance is improved (Figure 8). For the methods without constraints on mean balance, the distributional differences are slightly less than the two methods where mean balance is constrained, indicating a slight trade-off occurs to obtain better mean balance.

6.4 Case study results

Amazingly, some of the optimal transport methods can recover the original treatment estimates, demonstrating the utility of this methodology for externally controlled trials.

For the optimal transport methods with no constraints or just marginal constraints, the Hájek estimator of (22) and the barycentric projection estimator of (25) have a small positive bias while the augmented and weighted OLS estimators of (23) and (24), respectively, have a small negative bias. Of all these estimators the weighted OLS estimators get closest to the original estimate. In all cases, the confidence intervals cover the observed estimate in the original RCT.

As we expected, the mean balancing formulations of causal optimal transport display substantial biases in their estimates. The mean constrained causal optimal transport has estimates that range from -54.1 mL to -39.8 mL and none of the confidence intervals cover the original estimate. See row 2 of Table 2. Constraining both the means and the marginal distributions does not do any better as these estimates range from -51.2 mL to -42.3 mL. As with the mean constrained method, the confidence interval does not cover the original estimate observed in the RCT. Figure 9 also displays these results for the Hájek and barycentric projection estimators.
Table 2: Estimates and confidence intervals for optimal transport weighting methods applied to a modification of the data in Blum et al. (2010). We have constructed a control group for the misoprostol receiving patients at Egyptian site using the controls from the four other sites. The original treatment effect at the Egypt site was 0.369 mL with a 95% C.I. of (−27.1, 27.8). We see that the methods not adjusting for mean balance have good performance in recovering the original treatment effect.
Figure 7: Change in the standardized difference in means between the two groups before and after weighting. An examination in the change in balance before and after utilizing the optimal transport methods with the listed constraints for the misoprostol receiving participants in Egypt versus the oxytocin receiving participants at the other sites. “none” corresponds to no constraints, “margins” corresponds to constraints on the marginal costs like in (16), “means” corresponds to constraints on the mean balance between distributions like in (17), and “margins + means”/”m+m” corresponds to constraints on both the marginal costs and mean balance.
Figure 8: Change in the 1-Wasserstein distance between the two groups before and after weighting. An examination in the change in balance before and after utilizing the optimal transport methods with the listed constraints for the misoprostol receiving participants in Egypt versus the oxytocin receiving participants at the other sites. “none” corresponds to no constraints, “margins” corresponds to constraints on the marginal costs like in (16), “means” corresponds to constraints on the mean balance between distributions like in (17), and “margins + means”/“m+m” corresponds to constraints on both the marginal costs and mean balance.
Figure 9: Results for treatment effect estimation between the treated misoprostol group in Egypt versus the control oxytocin group at four other sites. We see that methods without mean constraints are able to recover the effect estimate. Note that “none” corresponds to no constraints, “margins” corresponds to constraints on the marginal costs like in (16), “means” corresponds to constraints on the mean balance between distributions like in (17), and “margins + means” corresponds to constraints on both the marginal costs and mean balance.
7 Summary and remarks

We have provided a new tool for the estimation of causal effects in observational studies: causal optimal transport. The method provides distributional balance checks by utilizing optimal transport distances to measure if distributions are similar and utilizes this methodology to estimate weights that are robust to the misspecification of the outcome models and do not require the positing of a parametric treatment assignment model. Further, we introduced a method to account for variable importance in distance metric matching and weighting by constraining the marginal cost distributions. This parameter can be extended into a model selection parameter for the cost matrix and more work needs to be done to ascertain the properties of such a formulation.

A Proof of Theorem 1

We present the proof of the dual form provided in Theorem 1. First, some tools from convex analysis (Boyd and Vandenberghe, 2004).

**Strong duality.** If strong duality holds then the value of the primal objective at the optimal primal solution is equal to the dual objective at the optimal dual solution.

**Slater’s conditions.** Slater’s conditions are that the objective function is convex and only has equality and inequality constraints.

**Slater’s theorem.** If Slater’s condition’s hold, then strong duality holds.

We are now ready to proceed.

Proof. As a reminder, the primal optimization problem is

\[
\text{COT}_{\lambda, z}(b) = \arg\min_{P \geq 0} \sum_{i,j} C_{ij} P_{ij} + \lambda \frac{1}{2} P_{ij}^2
\]

subject to

\[
\sum_{i,j} P_{ij} \mathbb{I}(Z_i = z) = 1
\]

\[
P^\top 1_n = b
\]

\[
\sum_{i,j} C_{ij}^{(l)} P_{ij} \leq \epsilon_l, \forall l \in \{1, \ldots, l\}
\]

\[
\left| \sum_{i,j} B_k(X_i) P_{ij} - \frac{1}{m} \sum_{j'} B_k(X_{j'}) \right| \leq \delta_k, \forall k \in \{1, \ldots, K\}.
\]

We first note that we can separate the basis function constraint into the following two inequality constraints

\[
\sum_{i,j} B_k(X_i) P_{ij} - \frac{1}{m} \sum_{j'} B_k(X_{j'}) < \delta_k,
\]

\[
- \sum_{i,j} B_k(X_i) P_{ij} + \frac{1}{m} \sum_{j'} B_k(X_{j'}) < \delta_k.
\]

Further we combine the $k$ basis function upper bounds into one vector $\delta$ and similarly denote $B(X)$ as a $n \times k$ matrix of the basis function constraints and $\overline{B}$ as the average of the basis functions in the target population: $\frac{1}{m} \sum_{j'} B_k(X_{j'})$. Then we re-write the primal problem in its Lagrangian form, defining $\langle x, y \rangle = \text{tr}(x^\top y)$. 

47
\[ \mathcal{L} = \min_{P \geq 0} \max_{g, h, \xi_U, \xi_L} \langle C, P \rangle + \lambda \frac{1}{2} \langle P, P \rangle - \langle g, P^\top 1_n - b \rangle + \sum_{l} h_l \langle C^{(d)}_l, P \rangle - h_l \epsilon_l + \langle \xi_U, B(X)^\top P1_m - \delta - B \rangle + \langle \xi_L, -B(X)^\top P1_m - \delta + B \rangle. \]

Because the primal problem contains only equality and inequality constraints and the primal objective is a convex function, then strong duality holds,

\[ = \max_{g, h, \xi_U, \xi_L} \min_{P \geq 0} \langle C, P \rangle + \lambda \frac{1}{2} \langle P, P \rangle - \langle g, P^\top 1_n - b \rangle + \sum_{l} h_l \langle C^{(d)}_l, P \rangle - h_l \epsilon_l + \langle \xi_U, B(X)^\top P1_m - \delta - B \rangle + \langle \xi_L, -B(X)^\top P1_m - \delta + B \rangle \]

where we have combined the two positive dual variables \( \xi_U \) and \( \xi_L \) into one unconstrained variable. Then we can rearrange to get

\[ = \max_{g, h} \min_{P \geq 0} \langle C + \frac{1}{2} P^\top P - 1_n g^\top - h_l \epsilon_l - \delta \| \xi \|_1 - \xi^\top B + \xi^\top B(X)^\top P1_m, P \rangle + \frac{\lambda}{2} \langle P, P \rangle. \]

Then taking the derivative with respect to \( P \),

\[ \nabla P \mathcal{L} = C - 1_n g^\top + \sum_{l} h_l C^{(l)} + B(X) \xi 1_m^\top + \lambda P \]

and finding the critical point of the gradient gives

\[ P = \frac{1}{\lambda} \left( 1_n g^\top - \sum_{l} h_l C^{(l)} - B(X) \xi 1_m^\top - C \right)_+. \]

where the function \((x)_+ = \max(0, x)\) applied element-wise ensures that the weights are constrained to be...
positive. Plugging this back in, the objective is now

$$\mathcal{L} = \max_{g, h, \xi} g^\top b - \sum_l h_l \epsilon_l - \delta \|\xi\|_1 - \xi^\top \mathcal{B} - \frac{1}{2\lambda} \left( 1_n g^\top - \sum_l h_l \mathcal{C}^{(l)} - B(X)\xi 1_m^\top - \mathcal{C} \right)^2_+,$$

as desired. \qed

\section*{B Convergence}

In this section we prove the convergence of our estimator to the Radon-Nikodym derivatives and provide a simulation study that demonstrates this convergence.

\subsection*{B.1 Proof of Theorem 2}

The penalized one converges because it is bounded by $OT_\lambda(b, b) \to 0$ (use blondel paper to show upper and lower bound goes to 0) and above by $OT_\lambda(h, b)$. $OT_\lambda(a(w), b) \leq OT_\lambda(h, b)$ and $OT_\lambda(h, b) \to OT_\lambda(b, b) \to 0$.

We now offer our proof of Theorem 2. We first define some notation to make the work a little simpler. Define $\langle X, Y \rangle = \text{tr}(X^\top Y)$, the Frobenius norm between matrices $X$ and $Y$. Then let $L_\lambda(a, b)$ denote the objective in Equation (13): $\langle \mathcal{C}, \mathcal{P} \rangle + \frac{1}{2} \langle \mathcal{P}, \mathcal{P} \rangle$. The basic idea is that $L_\lambda$ using the causal optimal transport weights in Equation (15) is always less than the objective function using the importance sampling weights $\mathbf{w}^*$—which are equivalent to the Radon-Nikodym derivatives between $\alpha$ and $\beta$—and the distribution of $b$: $L_\lambda(\mathbf{w}^*, b)$. In turn, $L_\lambda(\mathbf{w}^*, b)$ goes to 0, implying that the causal optimal transport weights converge to $\beta$. To show this, we rely on a few lemmas and remarks that provide results from theorems in other works.

\subsection*{B.1.1 Results from importance sampling and optimal transport theory}

First, we give a result for the convergence of the importance sampling weights.

\emph{Lemma 1} (Theorem 9.2, Owen, 2013b)

Take $X_1, \ldots, X_n \sim \alpha$ and the existence of $\mathbb{E}_\beta(f(X))$, the expectation of $f(X)$ over the distribution $\beta$. Define the importance sampling weights as $\tilde{\mathbf{w}}^*_i = \frac{d\beta(X_i)}{d\alpha(X_i)}$ and define the self-normalized importance sampling weights as

$$\mathbf{w}^*_i = \frac{\frac{1}{n} \tilde{\mathbf{w}}^*_i}{\sum_{j=1}^n \frac{1}{n} \tilde{\mathbf{w}}^*_j}.$$
If $d\alpha(x) > 0$ whenever $d\beta(x) > 0$, then by the Strong Law of Large Numbers as $n \to \infty$

$$\sum_{i=1}^{n} f(X_i)w_i^* \overset{\text{a.s.}}{\to} \mathbb{E}_\beta(f(X)).$$

**Proof.** If $d\alpha(x) > 0$ whenever $f(x)d\beta(x) > 0$, then by the Strong Law of Large Numbers

$$\frac{1}{n} \sum_{i=1}^{n} f(X_i)w_i^* \overset{\text{a.s.}}{\to} \mathbb{E}_\beta(f(X)).$$

This is easily seen since $\sum_{i=1}^{n} f(X_i)w_i^* \overset{\text{a.s.}}{\to} \int f(x)\frac{d\beta(x)}{d\alpha(x)}d\alpha(x) = \int_X f(x)d\beta(x) = \mathbb{E}_\beta(f(X))$. Thus, the numerator of the unnormalized importance sampling weights converge to $\mathbb{E}_\beta(f(X))$. The same argument is true for the denominator if we take $f(x) = 1$. \hfill \Box

As a corollary of Lemma 1, we have that $w^* \to \beta$.

**Corollary 4** (The importance sampling weights converge to $\beta$)

Define $w^*$ as above. Then,

$$w^* \to \beta.$$ 

**Proof.** Define $P_n(X \in E) = \sum_{i=1}^{n} \mathbb{I}(X_i \in E)w_i^*$, for some $E \subset X$. Take $f(X) = \mathbb{I}(X \in E)$. By Lemma 1, $P_n(X \in E) = \sum_{i=1}^{n} f(X_i)w_i^* \overset{\text{a.s.}}{\to} \mathbb{E}_\beta(f(X)) = \int_X f d\beta = P_\beta(X \in E)$, where $P_\beta(\cdot)$ denotes the probability of $X \in E$ when $X \sim \beta$. Thus we have $\lim_{n \to \infty} P_n(X \in E) = P_\beta(X \in E)$. \hfill \Box

The basic idea is that we use the importance sampling weights to show the convergence of the unpenalized weights. Then, for fixed $\delta$ and $\epsilon$, as $\lambda$ goes to 0 while the sample of the target and source go off to infinity, the weights will converge to the Radon-Nikodym derivatives. First, we need some lemmas.

We first get a lemma about importance sampling weights—also known as the Radon-Nikodym derivatives:

With these lemmas, we turn to the weak convergence of measure implied by optimal transport distances. First, an important fact for optimal transport distances.

**Remark 1** (Proposition 2.2, Peyré and Cuturi, 2019)

The optimal transport distance of $\text{OT}(a, b) = 0$ if and only if $a = b$. Additionally, $\text{OT}(a, b)$ satisfies the triangle inequality, $\text{OT}(a, b) \leq \text{OT}(a, c) + \text{OT}(c, b)$, for empirical measures $a, b, c$.

**Remark 2** (Theorem 6.8 in Villani, 2006)
The optimal transport distance in Eqs. (8) metrizes convergence in distribution. That is

\[ a \rightarrow \alpha \]

is equivalent to

\[ \text{OT} (a, \alpha) \rightarrow 0. \]

We also have a similar result for empirical measures due to the triangle inequality.

**Remark 3** (Corollary 6.9 in Villani, 2006)

If \( a \rightarrow \alpha \), \( b \rightarrow \beta \), and \( \alpha = \beta \), then

\[ \text{OT} (a, b) \rightarrow 0. \]

Finally, we obtain our last lemma.

**Lemma 2** (Convergence of importance sampling weights)

Let \( X_1, \ldots, X_n \overset{iid}{\sim} \alpha \) and define \( w^* = (w^*_1, \ldots, w^*_n)^\top \) as the re-weighted empirical measure using the self-normalized importance sampling weights defined in Lemma 1. If \( d\alpha(X) > 0 \) whenever \( d\beta(X) > 0 \), then

\[ \text{OT} (w^*, b) \rightarrow 0. \]

**Proof.** Apply Remark 3.

We now turn our attention to the \( L_2 \) regularized optimal transport problem. Theorem 1 of Blondel et al. (2018) give bounds on \( L_\lambda (a, b) \):

\[
\frac{\lambda}{2} \sum_{i,j} \left( \frac{a_i}{n} + \frac{b_j}{m} - \frac{1}{mn} \right)^2 \leq L_\lambda (a, b) - \text{OT} (a, b) \leq \frac{\lambda}{2} \min \{ \|a\|^2, \|b\|^2 \}. \tag{26}
\]

This, in turn, gives us our final lemma.

**Lemma 3**

Define \( w^* \) as above and assume \( O(m) = n \). Further, assume \( d\alpha > 0 \) whenever \( d\beta > 0 \). Then as \( n, m \rightarrow \infty \),

\[ L_\lambda (w^*, b) \rightarrow 0. \]

**Proof.** First, the upper bounds on the regularized problem \( L_\lambda (a, b) \) are

\[ L_\lambda (w^*, b) \leq \text{OT} (w^*, b) + \frac{\lambda}{2} \|b\|. \]
where the first inequality follows from rearrangement of Eq. (26) and the fact that \( \min\{\|w^*\|_2, \|b\|_2\} \) is minimized by the measure where all the observations have the same weight.

By Lemma 2, \( \text{OT} (w^*, b) \to 0 \). Also,
\[
\|b\|^2 = \sum_j b_j^2 = \frac{1}{m} \to 0.
\]

Thus, \( L_\lambda(w^*, b) \to 0 \) as claimed.

**B.1.2 Proof of the theorem**

We are now ready to prove Theorem 2.

**Proof.** By Corollary 1, the problem is convex which means that
\[
L_\lambda(w_{\text{COT}}, b) \leq L_\lambda(c, b)
\]
for all \( c \in \Delta_n \) that satisfy the constraints of the problem in Equations (13)–(16). Next, define the self normalized importance sampling weights \( w^* \) as above. By Assumptions 1 and 2, \( w^* \) exists since \( d\alpha > 0 \) whenever \( d\beta > 0 \). Further, \( \exists n > 0 \) such that the importance sampling weights \( w^* \) also satisfy these constraints, since \( w^* \overset{a.s.}{\longrightarrow} \beta \) by Corollary 4. This means that
\[
L_\lambda(w_{\text{COT}}, b) \leq L_\lambda(w^*, b)
\]
for some \( n \) such that the importance sampling weights satisfy the problem constraints.

Now, \( L_\lambda(w_{\text{COT}}, b) = \langle C, P_{\text{COT}} \rangle + \frac{1}{2} \langle P_{\text{COT}}, P_{\text{COT}} \rangle \geq 0 \), since \( C_{ij} \geq 0 \) and \( P_{ij,\text{COT}} \geq 0 \) for all \( i,j \). Moreover, \( L_\lambda(w_{\text{COT}}, b) \) will only be 0 if both terms go to 0, which will also mean that \( w_{\text{COT}} \to \beta \).

By Lemma 2, \( L_\lambda(w^*, b) \to 0 \) Thus,
\[
L_\lambda(w_{\text{COT}}, b) \to 0,
\]
which means
\[
w_{\text{COT}} \to \beta
\]
B.2 Empirical convergence

To study the convergence of our weighting estimator, we provide two simulation studies. In the first, we rely on an example discussed in Huling and Mak (2020). In the second, we use the data generating model is Section 5 with high overlap.

B.2.1 Toy example

We draw a univariate covariate $X \sim \mathcal{N}(0, 1)$ and then create a treatment indicator $Z \sim \text{Bern}(p)$, with $\text{logit}(p) = -\frac{1}{3}X^3 + \frac{2}{3}X^2 + X - 1$. With this data we then attempt to re-weight the treated group ($Z = 1$) to approximate the distribution in the full sample.

We compare the performance of our method versus using unweighted treated sample, the true propensity scores, and the estimated propensity scores using the true model. To evaluate performance we subtract the weighted empirical CDF of the treated ($a_1(w)$) from the 1) empirical CDF of the full sample ($a$) and 2) the asymptotic CDF ($\alpha$) over a variety of sample sizes (Figure 10). We can see that our method converges faster to the empirical and asymptotic CDFs than the other methods under consideration. Empirically, our method does converge to the true distribution and, at least in a univariate setting, faster than the true model.
Figure 10: Empirical convergence of various weighted CDFs to the empirical and asymptotic CDFs
C Proof of Theorem 3

We now prove Theorem 3.

Proof. The doubly robust or augmented estimator is equal to

$$\hat{\tau}_{dr} = \sum_{i=1}^{n} w_i(Y_i - \hat{m}_1(X_i))Z_i$$

$$- \sum_{i=1}^{n} w_i(Y_i - \hat{m}_1(X_i))(1 - Z_i)$$

$$+ \frac{1}{m} \sum_{j=1}^{m} \hat{m}_1(X_j) - m_0(X_j),$$

which can be re-written as

$$\hat{\tau}_{dr} = \sum_{i=1}^{n} w_i(Y_iZ_i - Y_i(1 - Z_i))$$

$$- \left[ \sum_{i=1}^{n} w_i\hat{m}_1(X_i)Z_i - \frac{1}{m} \sum_{j=1}^{m} \hat{m}_1(X_j) \right]$$

$$+ \left[ \sum_{i=1}^{n} w_i\hat{m}_0(X_i)(1 - Z_i) - \frac{1}{m} \sum_{j=1}^{m} \hat{m}_0(X_j) \right].$$

The Hájek estimator is in turn

$$\hat{\tau}_H = \sum_{i=1}^{n} w_i(Y_iZ_i - Y_i(1 - Z_i)).$$

In general, the balancing constraints impose

$$\left| \sum_{i} \mathbb{I}(Z_i = z)w_iB_k(X_i) - \frac{1}{m} \sum_{j} B_k(X_j) \right| \leq \delta_k. \quad (27)$$

Under the assumptions of the theorem, the estimation of $w_{bal}$ is feasible when $\delta = 0$, which means that for each treatment group $z \in \{0, 1\}$

$$\left| \sum_{i} \mathbb{I}(Z_i = z)w_iB_k(X_i) - \frac{1}{m} \sum_{j} B_k(X_j) \right| = 0 \quad (28)$$

for all $k \in \{1, ..., K\}$. If the balancing functions we have chosen are equal to the hypothesized conditional...
mean function up to an affine linear transform, then

\[ m_z(X_i) = \gamma_0^{(z)} + \gamma_1^{(z)} B_1(X_i) + \ldots + \gamma_K^{(z)} B_K(X_i). \]

This means that

\[
\hat{\tau}_{dr} = \sum_{i=1}^{n} w_i (Y_i Z_i - Y_i (1 - Z_i)) \\
- \left[ \sum_{i=1}^{n} w_i (\hat{\gamma}_0^{(1)} + \hat{\gamma}_1^{(1)} B_1(X_i) + \ldots + \hat{\gamma}_K^{(1)} B_K(X_i)) Z_i \right] \\
- \frac{1}{m} \sum_{j=1}^{m} \left[ \gamma_0^{(1)} + \hat{\gamma}_1^{(1)} B_1(X_j) + \ldots + \hat{\gamma}_K^{(1)} B_K(X_j) \right] \\
+ \left[ \sum_{i=1}^{n} w_i (\hat{\gamma}_0^{(1)} + \hat{\gamma}_1^{(1)} B_1(X_i) + \ldots + \hat{\gamma}_K^{(1)} B_K(X_i)) (1 - Z_i) \right] \\
- \frac{1}{m} \sum_{j=1}^{m} \left[ \gamma_0^{(1)} + \hat{\gamma}_1^{(1)} B_1(X_j) + \ldots + \hat{\gamma}_K^{(1)} B_K(X_j) \right],
\]

which can be rearranged to

\[
\hat{\tau}_{dr} = \sum_{i=1}^{n} w_i (Y_i Z_i - Y_i (1 - Z_i)) \\
- \left[ \hat{\gamma}_0^{(1)} - \gamma_0^{(1)} + \hat{\gamma}_1^{(1)} \left\{ \sum_{i=1}^{n} w_i B_1(X_i) - \frac{1}{m} \sum_{j=1}^{m} B_1(X_j) \right\} \right] \\
+ \left[ \sum_{i=1}^{n} w_i B_K(X_i) - \frac{1}{m} \sum_{j=1}^{m} B_K(X_j) \right] \right\} + \ldots + \gamma_K^{(1)} \left\{ \sum_{i=1}^{n} w_i B_K(X_i) - \frac{1}{m} \sum_{j=1}^{m} B_K(X_j) \right\} \right] \\
+ \left[ \hat{\gamma}_0^{(0)} - \gamma_0^{(0)} + \hat{\gamma}_1^{(0)} \left\{ \sum_{i=1}^{n} w_i B_1(X_i) - \frac{1}{m} \sum_{j=1}^{m} B_1(X_j) \right\} \right] \\
+ \left[ \sum_{i=1}^{n} w_i B_K(X_i) - \frac{1}{m} \sum_{j=1}^{m} B_K(X_j) \right] \right\} + \ldots + \gamma_K^{(0)} \left\{ \sum_{i=1}^{n} w_i B_K(X_i) - \frac{1}{m} \sum_{j=1}^{m} B_K(X_j) \right\} \right].
\]

Then by Equation (28), this equals

\[
\hat{\tau}_{dr} = \sum_{i=1}^{n} w_i (Y_i Z_i - Y_i (1 - Z_i)) \\
- \left[ 0 + \hat{\gamma}_1^{(1)} \{0\} + \ldots + \hat{\gamma}_K^{(1)} \{0\} \right] \\
+ \left[ 0 + \hat{\gamma}_1^{(0)} \{0\} + \ldots + \hat{\gamma}_K^{(0)} \{0\} \right]
\]

56
\[ \sum_{i=1}^{n} w_i(Y_i Z_i - Y_i (1 - Z_i)) = \hat{f}_H. \]

D Additional case study: the LaLonde Data

We also validate our method on the LaLonde data set (LaLonde, 1986).

D.1 The National Supported Work Demonstration program

The original data come from a job training program called the National Supported Work Demonstration program (NSW) in which people were randomized to receive or not receive training from the program in the year 1976. The outcome of interest was then to look at the difference in incomes between the treatment and control groups in 1978. The original experimental estimate was a difference of $1,794 with a confidence interval of $(551, 3038)$. The variables available in the original study include 10 pre-intervention characteristics like earnings and employment in 1974 and 1975, years of education, whether the person received a high school degree, marital status, and indicators for black or Hispanic ethnicity.

D.2 LaLonde’s modification

LaLonde then proceeded to modify the original study data by removing the control group and seeing if he could recover the original treatment effect by utilizing an observational data sample taken from the Current Population Survey (CPS) with the same variables measured. This gives 185 participants from the NSM in the treated group and 15,992 non-participants from the CPS in the control group.

D.3 Methods

From the optimal transport weighting methods, we include no constraints (“none”), marginal cost constraints (“margins”), constraints on mean balance (“means”), and constraints on both the means and marginal costs (“margins + means”). Hyperparameters were tuned with the algorithm detailed in algorithm 2. The distance metric is an \( L_1 \) metric on the binary covariates and a Mahalanobis \( L_1 \) metric on the continuous covariates.

We again consider the Hajek (22), doubly robust/augmented (23), weighted least squares (24), and barycen-
tric projection (25) estimators. Finally we utilize the bootstrapped confidence intervals detailed in algorithm (1).

### D.4 Design diagnostics

We now display the before and after weighting balance in variable means as well as overall sample 1-Wasserstein distance difference to give a sense of distributional balance. We can see that for all weighting methods both means and distributions are much more similar after weighting than before (Figure 11).

### D.5 Results

We can see in Figure 12 that we are able to get very close to the original effects for both the Hájek and barycentric projection estimators. Similar results hold for the other estimators found in Table 3.

Table 3: Results for treatment effect estimation for the National Work Support demonstration treated group and the weighted set of controls from the Current Population Survey. The estimate is the difference in 1978 earnings in dollars between the two groups. Values are estimates with bootstrapped 95% confidence intervals. Note that “none” corresponds to no constraints, “margins” corresponds to constraints on the marginal costs like in (16), “means” corresponds to constraints on the mean balance between distributions like in (17), and “margins + means” corresponds to constraints on both the marginal costs and mean balance.
Figure 11: An examination in the change in balance before and after utilizing the optimal transport methods with the listed constraints for the LaLonde data. "none" corresponds to no constraints, "margins" corresponds to constraints on the marginal costs like in (16), "means" corresponds to constraints on the mean balance between distributions like in (17), and "margins + means"/"m+m" corresponds to constraints on both the marginal costs and mean balance.
Figure 12: Results for treatment effect estimation for the National Work Support demonstration treated group and the weighted set of controls from the Current Population Survey. The estimate is the difference in 1978 earnings in dollars between the two groups. We see that all optimal transport methods and both estimators displayed are able to get close to the original treatment effect, with one getting very close (Hájek estimator with marginal cost constraints). Note that “none” corresponds to no constraints, “margins” corresponds to constraints on the marginal costs like in (16), “means” corresponds to constraints on the mean balance between distributions like in (17), and “margins + means” corresponds to constraints on both the marginal costs and mean balance.
