Abstract

Modern neural networks are powerful predictive models. However, when it comes to recognizing that they may be wrong about their predictions, they perform poorly. For example, for one of the most common activation functions, the ReLU and its variants, even a well-calibrated model can produce incorrect but high confidence predictions. In the related task of action recognition, most current classification methods are based on clip-level classifiers that densely sample a given video for non-overlapping, same-sized clips and aggregate the results using an aggregation function - typically averaging - to achieve video level predictions. While this approach has shown to be effective, it is sub-optimal in recognition accuracy and has a high computational overhead. To mitigate both these issues, we propose the confidence distillation framework to teach a representation of uncertainty of the teacher to the student sampler and divide the task of full video prediction between the student and the teacher models. We conduct extensive experiments on three action recognition datasets and demonstrate that our framework achieves significant improvements in action recognition accuracy (up to 20%) and computational efficiency (more than 40%).

1. Introduction

Recent advancements of deep neural networks and the growth of online social platforms and portable video recording devices has lead to an ever-increasing amount of videos being captured, shared and consumed every day, making it imperative to design systems that can efficiently analyze these content without a high computational cost. With recent advances in action recognition, robust classifiers have been designed [25, 55, 57, 56, 17, 16, 15] that operate on short time spans of the video - typically spanning a few seconds - as input clips and generate video-level classification by applying an aggregation operator to all clip-level softmax predictions over the entire video; this aggregation operator is typically an average of all softmax vectors. Applying a clip classifier over all individual clips of a video stream may be reasonable when the video length is known to be short. In real-world applications, such an assumption does not hold and becomes impractical. Videos may be more than a few seconds long, providing the classifier with ample opportunity to misclassify individual clips, negatively affecting the aggregate video-level classification accuracy. To mitigate this issue, other approaches sample clips randomly, at equidistant intervals or take the redundancy of the video into account and skip redundant frames. Our fundamental intuition is that no matter which of the previous approaches is taken, the aleatoric uncertainty of data will still provide aggregation-based models with opportunities to misclassify.

Our idea is to address both challenges of computational efficiency and reduced aggregation accuracy by taking into account the ambiguity of individual clips. Many current state-of-the-art approaches to clip sampling assume that the highest probability score in the network’s output indicates high confidence and low ambiguity [34, 20, 64].

However, when deployed in the real world, machine learning models [21, 2] and ReLU networks specifically [27] often fail silently by providing high confidence predictions (giving a high probability to one class) while being incorrect. Looking at Fig. 1, this means some subsequent
clips in the same video that looks similar to the human eye can make the classifier fail due to inherent noise. Motivated by this fact, in this work, we propose the “Confidence distillation training and inference framework,” a novel distillation scheme where we propose a loss function to train a lightweight sampler with the primary function of skimming the video for the least ambiguous clips and the secondary function of classifying “easier” clips at low complexity. In other words, the student learns to output both a classification score and a score \( \tilde{z} \) for its confidence in the teacher’s correct classification of that specific input. We will only perform prediction on the best \( K \) clips using either only the teacher model - which reduces the computational cost and increases accuracy - or divide the prediction and inferencing task between the student and the teacher, to achieve higher computation savings at little cost to accuracy. Our key contributions are summarized as follows.

- We propose a novel distillation loss (Eq. (6) and Fig. 2) to train a lightweight classifier that also learns to predict which clips will likely be ambiguous for the teacher. We show that this loss outperforms state-of-the-art models in detecting ambiguous clips.

- We use the resulting student sampler model to devise a simple schema to divide the classification task between the student and the teacher (Fig. 3), at little cost to accuracy and a significant increase in computational efficiency.

- We demonstrate the scalability, efficiency (more than 40% faster inference) and accuracy (up to 20% increase in accuracy) of using the confidence distillation framework across three real-world video datasets of varying lengths, the UCF-101, Kinetics and Something-something V2.

2. Related work

**Action recognition:** Recent architectures are mostly designed by extending image classifiers with a temporal dimension while preserving the spatial properties of each frame. Among them include directly transforming 2D models [48, 35, 26, 53] such as Inception or ResNet to 3D [5, 25], adding RNNs on top of 2D CNNs [12, 37, 38, 67, 51, 66], using two identical 2D CNNs or using more sophisticated volume-based convolutions [17, 43, 54, 55, 56, 57]. The work, as mentioned earlier, focuses on building powerful models to improve action recognition without considering the computational cost, whereas we aim to perform action recognition accurately and efficiently.

**Efficient architectures:** Many innovative architectures have been proposed for efficient video classification [33, 68, 69, 62, 60, 59, 56, 52, 44, 40, 56, 30, 13, 11, 15]. The idea behind them is to optimize the classifier architecture itself, while in contrast, our framework is mostly architecture-independent. In [15, 29], a given 2D architecture is extended across as temporal dimension. Efficient architectures [29, 41] using depth-wise and channel-wise separable convolutions have recently been applied [33, 50] to video processing. These approaches are orthogonal to ours and can be applied in conjunction with the proposed method.

**Clip and frame selection:** These methods aim to train a model to do the video clip, or frame sampling [1, 34, 50, 63, 64, 65, 20]. SCSampler [34] uses compressed features with softmax confidence scores to score clips for their visual sampler and selects the top \( k \) clips. Similarly, in IMGAUD2VID [20] multiple modalities such as audio and video are used to select less redundant frames. Other state-of-the-art include using reinforcement learning [64] training single and [63] multiple agents to perform frame selection collaboratively. By contrast, our method requires neither a complex RL policy gradient nor access to audio-level features. Furthermore, in all methods, the video is assumed to be very long and redundant, and the number of sampled clips can be large. By focusing on redundancy, the effectiveness of these models diminishes as the size of the dataset becomes shorter and there are fewer irrelevant sections in the video. Nevertheless, these methods are complementary to ours. In our method, we do not make an assumption on video length, and as such, we can complement our sampler by first applying [20, 34, 64] to a long video to reduce the search space and then sample a subset of those frames with confidence distillation. Finally, most methods are using the softmax confidence score as a proxy for clip ambiguity, which is not a good surrogate for classifier confidence. Therefore, we make no such assumption and assume that the classifier can be confidently incorrect.

**Confidence estimation:** The task of determining when a network should say “I do not know,” or provide confidence estimates for its outputs. Examples include Bayesian neural networks [42], variational inference [13, 14] and simpler methods such as Monte Carlo dropout [19] where measures such as predictive entropy are used. Other methods learn unsupervised, unbounded [32] or bounded confidence values [10] for classification and regression. In [19, 27] Predictive entropy is a measure applied to capture aleatoric uncertainty; the type of uncertainty inherent in the data such as an image of a number 7 that may appear similar to a number 1. In [10], a given untrained classifier is regularized during training to detect out-of-distribution samples without supervision. We take a different approach by having the student sampler learn confidence estimates for its teacher’s output to improve computational efficiency and accuracy in the video analysis task.

**Other related works:** Compression techniques such as knowledge distillation [4, 28, 58] address the problem of distilling the knowledge of large pre-trained models into
smaller, more efficient models, which tends to perform better than having the smaller model learn from raw data \cite{chen2017}. The student is typically deployed without the teacher. Using our framework, we can optionally employ both the student sampler and the teacher to address the problem of efficient video analysis cooperatively.

3. Approach

Our goal is to perform more accurate and efficient action recognition in videos by skipping over ambiguous clips. We will formally define our problem (Sec. 3.1) and introduce the motivation behind, and how to teach the student the notion of confidence - how confident it is that the teacher will not make a mistake - using the teacher’s outputs (Sec. 3.2); finally, we present how this confidence score will be used to skip over ambiguous clips in the video (Sec. 3.3).

3.1. Problem formulation

Given a video \( V \) of arbitrary length, the goal of video classification is to map \( V \in \mathbb{R}^{T \times 3 \times H \times W} \) into a fixed set of \( C \) classes. Since \( V \) can be arbitrarily long, it is often difficult and sometimes impossible to stack all the video frames together - which can be hundreds and up to thousands - as input to a single deep network.

Due to this constraint, a majority of current approaches \cite{kuehne2016,kuehne2017,kuehne2018,kipf2016,gradwohl2017} first train a clip classifier \( F(\cdot) \) that operates on a short fixed-length video clip \( V \in \mathbb{R}^{K \times 3 \times H \times W} \) or in other words the inputs are short, \( K \) frames of size \( H \times W \). Given a full-sized video, the clip-classifier is applied to all \( N \) clips \( \{V_1, V_2, \ldots, V_N\} \) where \( N = \frac{T}{K} \) and padding is applied to the last clip when not divisible. The final video-level predictions are obtained by aggregating the clip-level predictions of all \( N \) clips, where the aggregation is usually an average pooling operation.

As the length of \( V \) grows, so does the computational cost of inferencing using the methods above. It can also result in poor prediction accuracy since every incorrect clip prediction across \( \{V_1, V_2, \ldots, V_N\} \) will negatively affect the aggregate prediction of \( V \). Given a pre-trained clip classifier \( F(\cdot) \), our goal is to train an efficient student sampler classifier \( f(\cdot) \) that can predict whether \( F(\cdot) \), the teacher, will misclassify a given clip \( V_i \).

As previously discussed, the dense sampling paradigm for classifying a video is both inaccurate and inefficient. Sampling ambiguous clips in a video is a waste of computations and will negatively affect aggregate prediction accuracy. Our idea is to firstly delegate the computationally heavy task of dense sampling typically done by \( F(\cdot) \) to the more efficient and smaller student network \( f(\cdot) \). Secondly, since the smaller student network will likely be less accurate overall than the teacher, we will use it to identify the least ambiguous clips that can be passed to the teacher for prediction to increase overall accuracy. By distilling the teacher’s knowledge to the student, we can also divide the prediction task between the student and the teacher to further increase the speed of inferencing, thereby addressing both challenges at once.

We note that during this procedure, the classifier \( F(\cdot) \) is left unmodified. This property renders our approach helpful as a post-training procedure to improve existing classifiers’ inferencing accuracy and efficiency.

3.2. Shared representation learning objective

Naively, one will independently train a lightweight network \( f(\cdot) \) separately from the classifier \( F(\cdot) \) on the same training set \( D \) with one-hot labels. This implies that without supervision signals from \( F(\cdot) \), there is no guarantee that the sampler and the classifier would agree on clip ambiguity. Therefore, it is essential to note that only the clips \( F(\cdot) \) finds ambiguous are relevant.

To provide supervision signals that denote ambiguity, we can design pseudo-ground-truth binary confidence labels on the training set \( D \) denoted \( z_i \) as follows: Given that the ground-truth classification label for each clip \( V_i \) is \( y \), we apply the softmax function to the prediction logits from \( \Omega(V_i) \) to obtain the vector of class prediction probabilities \( p \). We then find which class \( c \) has the maximum prediction probability \( p_c \) in \( p \). The confidence scores \( z_i \) for each clip \( V_i \) are then defined as:

\[
z_i = \begin{cases} 
1 & \text{if } \arg\max_{c \in \{1, \ldots, C\}}(p) = y \\
0 & \text{otherwise}
\end{cases}
\]  

(1)

In other words, a clip has a confidence score of 0 when \( F(\cdot) \) misclassifies it. Naively, the learning objective for \( f(\cdot) \) can correspond to a binary classification task on these confidence labels using a binary cross-entropy as the loss function (the task can also be formulated as a regression task, similar to \cite{wang2018}. However, we found little difference in learning a regressor vs. learning a classifier in our experiments).

It is important to note that in practice, the positive samples outnumber the negative samples significantly. We find that this imbalance, coupled with a lack of more fine-grained supervision, leads to performance in the bounds of random sampling.

Intuitively, when learning where one is likely to make mistakes, it also helps to learn about the context; here, the context is the video class where some clips belonging to more challenging classes can be more ambiguous than others. This prior could lead to sparser and more informative predictions \cite{wang2018}. Using just the one-hot training labels, we only know that a given activity clip belongs to one class, such as “running” or “jumping”. No other information is annotated about the similarity of the given video to other non-label classes. Through the use of soft labels \cite{li2017} - i.e. other than the highest probability class, other classes
also have non-zero probabilities in the categorical distribution - we can access this information and see the probability of the clip belonging to each class via a ranked list of probabilities. Our intuition is that when learning to predict instances where the teacher is likely to make mistakes, this dark knowledge about class predictions may be usefully similar to the goal of multi-task learning [8] where a shared representation is learned for multiple tasks to improve performance across both tasks.

In contrast to the naive learning objective, the idea behind learning a shared representation using knowledge distillation is that the softened output of a trained teacher network contains a lot more information about a data point than the one-hot class label. e.g., if multiple classes are assigned high probabilities for a video clip, it may lie close to a decision boundary among those classes. Thus, having the student mimic these probabilities can assimilate some of the teacher’s knowledge, providing information beyond the one-hot training labels.

Concretely, given an input video clip $V$, the teacher network $F(\cdot)$ produces a vector of logits $s^t(V)$:

$$s^t(V) = [s_1^t(V), s_2^t(V), \ldots, s_C^t(V)] \quad (2)$$

In order to produce “softened”, non-peaky and more informative probability distributions from $s^t(V)$, temperature scaling is used alongside the softmax function [28, 23] to produce $\tilde{p}^t(V)$:

$$\tilde{p}^t(V) = [\tilde{p}_1^t(V), \tilde{p}_2^t(V), \ldots, \tilde{p}_C^t(V)] \quad (3)$$

where

$$\tilde{p}_k^t(V) = \frac{e^{s_k^t(V)/\tau}}{\sum_j e^{s_j^t(V)/\tau}} \quad (4)$$

where $\tau$ is the temperature hyperparameter. The student model $f(\cdot)$ similarly produces a softened class probability distribution, $\tilde{p}^s(V)$. The student also needs to learn a confidence score $\tilde{z}^s(V) \in [0, 1]$ using the pseudo-ground-truth binary labels defined in Eq. [1]. This presents an interesting optimization issue: When the student is learning to classify, we want the overall loss to decrease when it has correctly classified the input; but in cases where the confidence score of a video clip is 0, $p^t(V)$ as provided by the teacher would be misleading. To mitigate this issue, we modify the loss function similar to [22, 24, 10], and guide the student by incorporating the confidence scores into the distillation loss.

To learn from the teacher, the student must have confidence that the teacher is right. When the student is confident, learning takes place by mimicking. When the student thinks that the teacher may be wrong, they can ask for more information; translated to the distillation mechanism, asking for more information is akin to increasing $\tau$ when the predicted confidence is low. When $\tau \to \infty$, the pseudo-probability output classes end up with a uniform distribution. When the $\tilde{z} = 0$, we need $\tau \to \infty$ and when $\tilde{z} = 1$, we need $\tau \to T$, where $T$ is also a hyperparameter.

For a given video clip $V$ we further modify the teacher’s probability scores after applying the softened softmax to $\tilde{p}^t(V)$ as follows:

$$\hat{p}^t(V) = \begin{cases} \tilde{z} \hat{p}^t(V) + (1 - \tilde{z}) \mathcal{U}([0, 1]^C) & \text{if } z = 1 \\ (1 - \tilde{z}) \hat{p}^t(V) + \tilde{z} \mathcal{U}([0, 1]^C) & \text{o.w.} \end{cases} \quad (5)$$

where $\mathcal{U}([0, 1]^C)$ is the uniform distribution between 0 and 1 over the $C$ classes (with the same shape as $\tilde{p}^t$).

In the overall loss, we include a distillation loss $L_{KD}$ to match the student and teacher outputs. Furthermore, to prevent a naive solution of $\tilde{z} = 0$ from being converged to as the training progresses, we add a binary cross-entropy loss $L_{conf}$ over the ground-truth confidence labels. The overall loss is then:

$$L = L_{KD}(\hat{p}^t, \hat{p}^s) + \lambda L_{conf} \quad \text{(6)}$$

wherein the $L_{KD}$ term is a knowledge distillation loss with modified logits from Eq. [5] $\tau$ and $\lambda$ are hyperparameters. In $L_{KD}(\hat{p}^t, \hat{p}^s)$ the similarity of the two pseudo-probability posterior distribution vectors for input $V$ of the student and the teacher is measured using the KL divergence metric:

$$L_{KD}(\hat{p}^t, \hat{p}^s) = \tau^2 \left[ -\frac{1}{n} \sum_{i=1}^n \tilde{p}_i^t(V) \log \frac{\tilde{p}_i^s(V)}{\tilde{p}_i^t(V)} \right] \quad (7)$$

which is equal to the difference between the cross entropy of the labels $H(\hat{p}^t, \hat{p}^s)$ and the empirical entropy $H(\hat{p}^s)$:

$$L_{KD}(\hat{p}^t, \hat{p}^s) = H(\hat{p}^t, \hat{p}^s) - H(\hat{p}^s) \quad (8)$$

In essence, we create an optimization problem where the most undesirable outcome is where the student-teacher confidences differ while the student learns from the teacher. We refer to this loss variant ConDi-SR (confidence distillation using a shared representation). A high-level overview of the training framework is shown in Fig. [2].

3.3. Inferencing scheme

Once $f(\cdot)$ has been trained using any of the aforementioned loss variants, we can utilize $f(\cdot)$ to sample the top $K$ clips in $V$ to be classified by $F(\cdot)$. On the other hand, in the case of ConDi-SR, we have more options other than feeding the top $K$ clips. Moreover, since $f(\cdot)$ also learns to classify

4. Experiments

Datasets: We consider the following datasets to evaluate our approach: (1) the Kinetics dataset [31][5][6], a video recognition dataset generally used to determine a model’s capacity to learn. (2) the UCF-101 dataset [49], one of the most widely used benchmark datasets; and (3) the Something-Something V2 dataset [22], a dataset containing short trimmed video clips that show humans performing complex pre-defined actions with everyday objects. A characteristic of this dataset is that even though each video belongs to a single class, that class can be a combination of two other classes semantically. It is worth noting that the videos in all datasets are less than 10 seconds long and too short for many current sampling approaches to be directly applied successfully.

In Table 1 an overview of all the datasets above is given. Models: We consider two simple backbone models for

in a separate branch, it can also be utilized to classify easier clips during inference and send only the more challenging clips to \( F(\cdot) \) for increased efficiency.

In this case, two ranked lists would be generated, one sorted by the uncertainty of the teacher (or in other words, the confidence of the student that the teacher will be right) and the other sorted by the uncertainty of the student, where we use the predictive entropy of the student’s classification output. To combine these two ranked lists, we use a hyperparameter \( K_s \) that denotes the number of ranked clips predicted by the student sampler and feed the rest \( K_t = K - K_s \) to the teacher.

Note that while ST-Conf also learns a shared representation of confidence and classification, it differs from ConDi-SR. In ST-Conf, the confidence scores represent the confidence of the model itself while in ConDi-SR the confidence scores represent the confidence of the student in correct classification by the teacher. This allows ConDi-SR to be able to produce two meaningful ranked lists.

Sampling baselines: The purpose of a sampler is to sample \( K \) clips from \( V \) instead of all (dense). We have the following trivial and non-trivial options: (1) Random sampling randomly choosing \( K \) clips from a video. In order to have reliable estimates of the performance, performance results of the random sampler are averaged over three runs. (2) Equidistant sampling chooses \( K \) clips at equidistant time intervals (similar to i-Frames in video compression). (3) Separate training (ST) of a sampler without supervision signals by using predictive entropy (which we call ST-Ent) or unsupervised confidence estimates [10] (which we call ST-Conf).

The latter, ST-Conf utilizes an out-of-distribution detector with the intuition that ambiguous clips likely contain out-of-distribution features. \( f(\cdot) \) can be trained using the method in [10] to obtain unsupervised confidence estimates. The network’s output shall have two branches, one for classification and one for confidence estimation. Given a clip \( V \) as an input, \( f_{st-conf}(\cdot) \) yields two vector for prediction and confidence logits. The confidence logit is then passed through a sigmoid function to obtain a confidence score \( \tilde{z} \in [0, 1] \). The former, ST-Ent utilizes predictive entropy [49] that captures the average amount of information contained in the possible outcomes of a random variable. The
higher the entropy, the more information the associated outcome has. The maximum predictive entropy is reached with the uniform distribution, and the minimum predictive entropy is reached with one-hot probabilities. This measure has been used \cite{27} to capture aleatoric uncertainty reliably; this uncertainty is the type of uncertainty inherent in the data, such as an image of a number 7 that may appear similar to a number 1. To sample with an entropy score, we distill a student sampler using a soft-label distillation loss \cite{28}. Other methods that train a model to do the video clip or frame sampling \cite{20, 64} can also be among baseline but are complementary to our method; in all methods, it is assumed that the video is very long and the number of sampled clips can be large. Since we do not assume the length of the video, \cite{20, 34, 64} can be applied to a long video to reduce the search space and sample a subset of the video frames, and confidence distillation can be used to choose a subset of sampled frames. This forms a stack of samplers. Since many of these methods rely on redundancy, they do not apply to all datasets, specifically those with shorter videos. We will be comparing the reported results directly where a result has been reported on the target dataset by the original authors.

It is also important to note that calculating an upper bound for classification accuracy can be helpful; as such, we construct an Oracle sampler similar to \cite{34}. To provide an upper bound, Oracle cheats by looking at the ground-truth label $y$ and only considers clips that yield the $k$ highest classification scores for $y$ to return an average prediction.

### 4.1. Implementation details

**Training:** We have implemented the models using the PyTorch package. Four to Eight Nvidia P100 GPUs have been used for training and testing the models. Both the teacher and student take stacks of $16 \times 3 \times 112 \times 112$ clip volumes. For distillation hyperparameters, we use $\tau \in \{0.9\}$. For $\lambda$ in Eq. \eqref{eq:4}, we use $\lambda = \{0.5, 1.5, 2.0\}$ and $K \in \{1, 3, 5, 7, 10\}$ where applicable. In knowledge distillation literature, $\tau$ is typically chosen to be a large number like 5 or 20 in the beginning and may be annealed. In our case, the reasoning behind using smaller $\tau$ values is that the teacher’s entropy (information) will be dynamically adjusted depending on the student’s confidence. We find that it is better to start with smaller values as the baseline $\tau$. We use $\tau = 0.9$ and see that higher values prevent the loss from converging.

The confidence branch’s learning rate starts the same as the rest of the network but is reduced faster (see Sec. \eqref{sec:4.3}) and decays by a factor of 5 every epoch after the first epoch. The models trained on Kinetics are trained from scratch without pre-training, similar to \cite{25}. On the other hand, the models trained on UCF-101 and Something-Something V2 are pre-trained on Kinetics and then fine-tuned on the target datasets.

For Kinetics, The ResNeXt-101 baseline teacher is trained on the Kinetics-600 dataset, and the R(2+1)D is trained on the Kinetics-400 dataset. Testing is performed on the same dataset. For UCF-101, we face two challenges. Firstly the size of the dataset is too small to allow model training from scratch, and therefore for our framework, the student and teacher models need to be pre-trained on the Kinetics dataset first (here, we use Kinetics-600 for ResNeXt and Kinetics-400 for R(2+1)D). Secondly, the videos are too short for current non-trivial sampling baselines \cite{34, 20} to work effectively, and they are not applicable as a baseline. For Something-something V2: We pre-train the models on...
the Kinetics dataset and perform fine-tuning using the training data of the Something-something V2 dataset.

**Evaluation:** For classification accuracy metrics, we consider the Top-1 accuracy, denoting the actual class matches with the most probable class predicted by the model. The UCF-101 dataset has three official validation folds; as such, the mean values of test results are reported over these folds for reproducibility. For the Something-something V2 dataset, since the test set annotations are unavailable, the validation set is used as the test set, and the training set is stratified into training and validation sets.

### 4.2. Experimental results

**Accuracy and efficiency:** To be comparable to baselines, in this section we use type (a) inferencing from Fig. 3 experimental results with classification accuracy are shown in Fig. 4. The Kinetics dataset is big enough to train models from scratch. However, there are different variants, and a percentage of video samples may not be available or accessible. Nevertheless, we distill a ShuffleNet-V2 based student using this dataset and report the results. Due to the lack of available teacher models, the ResNeXt-101 is trained on the Kinetics-600 dataset, and the R(2+1)D is trained on the Kinetics-400 dataset. We compare the non-trivial baselines [34][10] and it is important to note that the results reported directly from [34] have access to the audio while our method does not require audio access. The videos from UCF-101 and Something-something v2 are too short for other state-of-the-art redundancy samplers [34][20] to work effectively, leaving [10] as the only applicable baseline.

### 4.3. Ablation studies

The optimal choices of learning rate \( \alpha \), positive weight multiplier \( \mu \) and loss parameter \( \lambda \) for ConDi-SR and distillation temperature \( \tau \) are found through grid search.

**Learning rate:** Typical classification learning rates are \( \alpha \in [1e^{-1}, 1e^{-6}] \). We find that for fine-tuning the classification branch of ConDi-SR UCF-101 and Something-Something v2, \( \alpha = 0.01 \) works best and for training from scratch (Kinetics) \( \alpha = 0.1 \) works better. For training the confidence of ConDi-SR, we start with the same learning rate as the rest of the network; As shown in Fig. 5 we find that by decaying the learning rate \( \alpha \) for ConDi-SR at a faster rate than the classification branch (dividing \( \alpha \) by 5 instead of 1.25 at every epoch), a lower false positives rate (defined as \( \frac{FP}{FP + TN} \)) in the predicted confidence score is achieved.

**Positive weight multiplier:** It is important to note that deep spatio-temporal networks such as 3D ResNeXt-101 tend to be accurate. This accuracy leads to a class imbalance in the pseudo-ground-truth labels generated using Eq. 1 that are used for confidence distillation. Therefore an important challenge is to address this problem, otherwise learned confidence scores could become trivial solutions. Considering the schema from Eq. 1 there are many more positive classes than negative ones. False positives in the predicted confidence score (in other words, a bad clip being considered a good clip) will always negatively affect accuracy. Therefore during training, we want to minimize the number of false positives predicted by the student. To guide the optimizer in the correct direction, a higher weight \( \mu \) is placed on the positive component of \( L_{\text{conf}} \). Here we experiment with \( \mu = 1 \), the default value for most binary classification tasks and \( \mu = 1.5 \). We see the results of varying \( \mu \) in Fig. 5 where using \( \mu = 1 \) the confidence branch will learn a trivial solution and output uniform scores for all inputs, and a
Figure 4. Experimental results of As $K$ increases, all methods converge to the same point representing dense sampling. The oracle has a steep curve as $K$ increases suggesting the existence of label noise in the benchmark datasets [19]. While equidistant sampling shows to be highly effective in smaller videos, as the number of clips in the video increase, its accuracy drops significantly (c, f), while ConDi-SR remains consistently 10-15% higher in terms of accuracy in longer videos.

Figure 5. The positive sample weight multiplier $\mu$ directly affects achieving a reasonable false-positive rate. When $\mu = 1$ as the default state, the predicted confidence scores converge to a trivial solution. A lower false-positive rate is achieved when $\mu = 1.5$ and $\alpha$ decays faster. Results also suggest early stopping the confidence branch is useful. $\mu = 1.5$ will result in a lower false-positive rate. We also find that using a $\mu$ value higher than 1.5 will prevent the distillation loss $L_{KD}$ from decreasing.

Loss function components: To illustrate the need for using a more complex loss function defined in Eq. (6), consider a more straightforward and trivial multi-task distillation loss where a linear combination of distillation loss [28] and a cross-entropy regularizer on confidence scores is used similar to $L = \beta L_{cls} + (1 - \beta)L_{KD} + \lambda L_{conf}$.

We find that the performance of this loss is in the bounds of random sampling; $L_{cls}$ will allow the student to cheat, reducing its overall loss by learning to classify without learning a good representation of the confidence scores.

5. Conclusion

We proposed the confidence distillation framework and empirically showed its ability to increase efficiency and accuracy in classifying actions across three diverse datasets and utilized the learned shared representation to divide the workload between the student and the teacher optionally. Unlike all other state-of-the-art sampling methods, we also showed that confidence distillation could be utilized for compact video data and lengthy videos. We performed ablation studies and showed that the optimization problem is not solvable trivially. For future work directions, training the student sampler on other modalities such as audio or optical flow or extending our method to other machine learning tasks such as out of distribution detection are noted.
