Abstract

The function approximators employed by traditional image based Deep Reinforcement Learning (DRL) algorithms usually lack a temporal learning component and instead focus on learning the spatial component. We propose a technique wherein both temporal as well as spatial components are jointly learned. Our tested was tested with a generic DQN and it outperformed it in terms of maximum rewards as well as sample complexity. This algorithm has implications in the robotics as well as sequential decision making domains.

1 Introduction

Developing Reinforcement Learning (RL) algorithms that can make effective decisions using high dimensional observations is quite challenging. While a lot of work has been devoted to extracting positional information from image inputs, very little investigation has been done on learning from temporal information [2]. A recurring heuristic used by many papers is to stack sequential observations together while inputting it to a neural network [4]. This heuristic combines frames, without processing it and therefore can be considered analogous to early fusion [1]. Recently, Shang et al. approached this problem as that of video classification [5]. This is a lucid approach, as considering multiple frames as a video, will help improve the prediction capabilities of the underlying neural network. Successful video recognition architectures use late fusion where all frames are processed, using neural networks, before they are combined together.

A video stream consists of spatial and temporal aspects. The former contains information about the video frame including objects and its surroundings. Whereas the movement of the frame and its associated objects can be learned from the temporal portion [6]. While learning the spatial aspect is enough for image recognition, video recognition requires learning both spatial and temporal components [3]. While there has been investigation done on developing efficient architectures for videos using 2D CNNs, these architectures fail to learn the temporal component.
Furthermore, training agents to learn with high dimensional inputs consumes a lot of time and energy. While it is important to maximize the performance of the agent, paying the price with large training times is expensive. \cite{2, 5, 7} have worked on developing sample efficient reinforcement learning that can directly learn from pixels.

Therefore, we propose to develop a plug and play DRL algorithm that is sample efficient and takes into account the temporal changes that occur across time steps.

2 Related Work

2.1 Latent Flow

\cite{6} investigated the use of optical flow techniques to perform video classification. They developed a dual stream architecture using ConvNets, consisting of spatial and temporal recognition components. The spatial stream was learned using a pre-trained ConvNet, wherein each frame was sent to the network as input. The input to the temporal stream was stacked optical flow displacement fields generated from consecutive frames. Movement among frames can be obtained from optical flow fields thereby eliminating the need for the network to learn it. While this technique was found to be successful, it is not feasible to integrate it with RL algorithms, due to its computation time.

2.2 Flow of Latents

Shang et al. looked for a computationally feasible technique to integrate RL with optical flow. They investigated a technique wherein each image frame was encoded using a neural network. The encodings at each time step were subtracted from its prior and this difference was fused with the latent encodings, which was then then used by the RL algorithm. This technique was analogous to the work done by \cite{6}. The optical flow was approximately using the difference in encodings, which provided the temporal information. The spatial component was obtained by encoding each of the frames. They chose Rainbow DQN and RAD \cite{2} to be their base algorithm and found that it outperformed SOTA algorithms in performance and sample efficiency.

They also investigated separately encoding frames and then stacking the encodings together, instead of the raw images. This technique yielded sub-par results and the authors hypothesized that stacking high dimensional image frames would allow CNNs to learn temporal information. However, by stacking latent frames the temporal information was lost and thereby causing the difference in results.

2.3 Temporal Shift Module

\cite{3} introduced a temporal shift architecture that could efficiently run 2D CNNs over video datasets. While working with video model activations,
A ∈ ℜ^NXCXTXHW, 2D CNNs don’t consider the dimension T, thereby ignoring the temporal dimension. However, the TSM algorithms mixes information from neighbouring frames by shifting channels within the temporal dimension. While this process doesn’t require extra parameters, they found that this technique had drawbacks - 1) The data movement generated due to the shift strategy was not efficient and would increase the latency, especially since 5D activation of videos results in large memory usage. 2) Moving channels across the temporal dimension would affect the accuracy of model, since the spatial model is distorted. The former issue was mitigated by shifting only a partial number of channels, thereby reducing the amount of data movement and latency incurred. For the latter problem, the TSM module was inserted within the residual branch of a Res-Net, thereby enabling the 2D CNN to learn spatial features without degrading.

Therefore, the TSM module is a simple modification to the 2D convolutional neural network. After encoding images using a convolutional neural network it shifts frames, in the temporal dimension, by +1, -1 and 0. However, shifting frames by -1, i.e backwards, is only possible for offline problems. For online image classification problems, the frames are moved +1

2.4 Deep Q Networks

combined Q Networks with convolutional neural networks in order to obtain an approximation of the Q values -

\[ Q^*(s, a) = \max_\pi \mathbb{E}[r_t + \gamma r_{t+1} + \gamma^2 r_{t+2} + ... | s_t = s, a_t = a, \pi] \]

The above expression maximizes the sum of discounted rewards for an agent following a policy, \( \pi = P(a|s) \), \( r \) using a discount factor, \( \gamma \) during every time step \( t \). They addressed the learning instabilities that RL presented when coupled with a deep neural network using a replay buffer and target network. They found that the sequential observations were highly correlated with each other and also that minimal changes to \( Q \) would drastically affect the policy. The use of a replay buffer mitigated this issue by randomizing the data during the training process.

3 Results and Discussion

3.1 Approach

found that the work done by combined Q Networks with convolutional neural networks in order to obtain an approximation of the Q values -

\[ Q^*(s, a) = \max_\pi \mathbb{E}[r_t + \gamma r_{t+1} + \gamma^2 r_{t+2} + ... | s_t = s, a_t = a, \pi] \]

The above expression maximizes the sum of discounted rewards for an agent following a policy, \( \pi = P(a|s) \), \( r \) using a discount factor, \( \gamma \) during every time step \( t \). They addressed the learning instabilities that RL presented when coupled with a deep neural network using a replay buffer and target network. They found that the sequential observations were highly correlated with each other and also that minimal changes to \( Q \) would drastically affect the policy. The use of a replay buffer mitigated this issue by randomizing the data during the training process.
we used a generic Conv-Net. This prevented us from performing a residual shift, as done by the paper and instead we performed an in-place shift. Also, the TSM cached the channels that were being shifted. Instead of caching, we directly rolled the channels along the temporal dimension.

A PyTorch based pseudocode for our algorithm has been given below -

```python
For each step t do
  For each convolution step do
    x = self.relu1(self.conv1(x))
    n, c, h, w = x.shape
    x = x.reshape(n//T, T, c, h, w)
    copy = torch.clone(x)
    x[:, :, :c//8, :, :] = torch.roll(x[:, :, :c//8, :, :], shifts = 1, dims = 1)
    x[:, 0, :c//8, :, :] = copy[:, 0, :c//8, :, :]
    z_t = FullyConnected(x)
  End For
End For
```

3.2 Discussion

We tested our algorithm on OpenAI Gym Pong environment as shown in Fig 1. Our algorithm (DQN-TSM) outperforms the generic DQN algorithm in terms of sample complexity as well as maximum points achieved. However, since we did not place a target network in our DQN, the results were not consistent and we plan to mitigate this problem using Duelling Deep Q Networks (D3QN).

![Figure 1: Comparing DQN with and without TSM](image.png)
4 Conclusion

We have introduced a plug and play Reinforcement Learning algorithms that takes both spatial as well as temporal observations into account. Our algorithm was tested using the OpenAI Gym simulator and it outperformed a generic DQN algorithms in terms of sample complexity and also obtained higher rewards. Future work includes integrating replacinig the DQN with a D3QN.
