Abstract

Out-of-distribution (OOD) detection and lossless compression constitute two problems that can be solved by the training of probabilistic models on a first dataset with subsequent likelihood evaluation on a second dataset, where data distributions differ. By defining the generalization of probabilistic models in terms of likelihood we show that, in the case of image models, the OOD generalization ability is dominated by local features. This motivates our proposal of a Local Autoregressive model that exclusively models local image features towards improving OOD performance. We apply the proposed model to OOD detection tasks and achieve state-of-the-art unsupervised OOD detection performance without the introduction of additional data. Additionally we employ our model to build a new lossless image compressor: NeLLoC (Neural Local Lossless Compressor) and report state-of-the-art compression rates and model size.

1 Introduction

Probabilistic modeling has achieved great success in the modeling of images. Likelihood based models, e.g. Variational Auto-Encoders (VAE) \textsuperscript{19}, Flow \textsuperscript{18}, Pixel CNN \textsuperscript{38, 46} are shown to successfully generate high quality images, in addition to estimating underlying densities.

Further to image generation, there also exists a close connection between probabilistic models and lossless compression \textsuperscript{30}. Let \(\{x_1, \ldots, x_M\}\) be an image dataset to compress, where \(x_m\) is sampled i.i.d from some underlying distribution with probability mass function (pmf) \(p_d\). If \(p_d\) is known, we can design a compression scheme to compress each data \(x_m\) to a bit string with length approximately \(-\log_2 p_d(x_m)\). The total length of the compressed dataset can therefore be approximated as \(\sum_{m=1}^{M} -\log_2 p_d(x_m)\). As \(M \to \infty\), the total compression length will approach the entropy of the distribution \(p_d\), that is: \(\sum_{m=1}^{M} -\log_2 p_d(x_m) \to H(p_d)\) where \(H(\cdot)\) denotes entropy. In this case, the compression length is optimal under Shannon’s source coding theorem \textsuperscript{42}, i.e. we cannot find another compression scheme with compression length less than \(H(p_d)\). In practice, however, the true data distribution \(p_d\) is unknown and we must find a suitable model \(p_\theta\) to approximate \(p_d\), typically by

\textsuperscript{*}Co-first author, the work was done during an internship in Huawei Noah’s Ark Lab.
\textsuperscript{2}For a compression method like Arithmetic Coding \textsuperscript{47}, the message length is always within two bits of \(-\log_2 p_d(x_m)\) \textsuperscript{50}, also see Section 5.1.

Preprint. Under review.
minimizing some difference between $p_d$ and $p_\theta$. A popular choice for this is the KL divergence

$$\text{KL}(p_d || p_\theta) = -\text{H}(p_d) - \int \log p_\theta(x)p_d(x)dx,$$

(1)

where the entropy of the data distribution is a constant. Since we only have access to finite $p_d$ data samples, $x_1, \ldots, x_N$ the second term is typically approximated using a Monte Carlo estimation

$$\text{KL}(p_d || p_\theta) \approx -\frac{1}{N} \sum_{n=1}^{N} \log p_\theta(x_n) - \text{const.}.\tag{2}$$

Estimation of $p_\theta$, by minimizing the KL divergence, is equivalent to Maximum Likelihood Estimation; as $\text{KL}(p_d || p_\theta) \to 0$, $p_\theta \to p_d$. We can therefore use $p_\theta$ in place of $p_d$ to build the lossless compressor.

Recent work successfully apply deep generative models such as VAEs \cite{11, 12, 46}, Flow \cite{16} \cite{13} towards conducting lossless image compression. We note that the underlying models of these methods are designed to focus on the test data and follows the same distribution as the training data: $x' \sim p_d$. However, in practical compression applications, training and test data distributions may differ: the test dataset $X'_N = \{x'_1, \ldots, x'_M\}$ where $x' \sim p_\theta \neq p_d$. Surprisingly, empirical results e.g. \cite{15} \cite{16} show that we can still use model $p_\theta$ (which is trained to approximate $p_d$) to compress test data $X'_N$ with reasonable compression rates. In this work we explore the lack of intuition as to when a model $p_\theta$, trained to approximate $p_d$, will generalize well to (i.e. will successfully compress) data from $p_\theta \neq p_d$, and what affects the generalization ability. We use the negative log-likelihood $-\frac{1}{N} \sum_{n=1}^{N} \log p_\theta(x_n')$ to indicate the Out-of-distribution (OOD) generalization ability of model $p_\theta$ on dataset $X'_N$ (lower is better). To investigate these questions, we firstly consider recent advances in likelihood-based OOD detection, leading to our proposal of a new model that we show can capture the features that dominates the generalization ability, with downstream benefits to both OOD detection and lossless compression applications.

2 Unsupervised OOD Detection

Given a set of unlabeled data points, sampled from $p_d$, and test data point $x'$ then the goal of OOD detection is to distinguish whether or not $x'$ originates from $p_d$. A natural approach involves fitting a probabilistic model $p_\theta$ to approximate $p_d$ and treat sample $x'$ as in-distribution if its (log) likelihood is larger than a threshold $\log p_\theta(x') > \epsilon$. However, recent work \cite{33} shows the surprising result that popular deep generative models including e.g. VAE \cite{19}, Flow \cite{18} and PixelCNN \cite{38} can assign OOD data higher density values than in-distribution samples, where such OOD data may contain differing semantics, c.f. the samples used for maximum likelihood training. We demonstrate this phenomenon using PixelCNN models, trained on Fashion MNIST (CIFAR10) and tested using MNIST (SVHN). Figure 1 provides histograms of model evaluation using negative bits-per-dimension (BPD), that is; the log_2 likelihood normalized by data sample dimension (larger negative BPD corresponds to larger likelihood). We corroborate previous work and observe that tested models assign higher likelihood to the OOD data, in both cases.

This counter intuitive phenomenon suggests that likelihood-based approaches may not make for good OOD image detection criterion, yet also illustrates that a probabilistic model, trained using one dataset, may be employed to compress data originating from a different distribution with a potentially higher compression rate. This intuition builds a connection between OOD detection and lossless compression. Inspired by this link, we investigate the underlying latent causes of image model generalizability, towards improving lossless compressor generalization.

Previous work studies the potential causes of the considered phenomenon; \cite{34} used a typical set to reason about the source of the effect, while the work of \cite{37} argues that likelihoods are significantly affected by image background statistics or by the size and smoothness of the background \cite{123}. In this work, we alternatively consider a recent hypothesis proposed by \cite{40} (also implicitly discussed in \cite{21} for a flow-based model); low-level local features, learned by (CNN-based) probabilistic models, are common to all images and dominate the likelihood. In their work, the authors investigated this hypothesis by studying the differences between individual pixel values and neighbourhood mean values and additionally considered the correlation between models trained on small image patches and trained, alternatively, on full images. To further investigate this hypothesis, we rather propose to
directly model the in-distribution dataset, using only local feature information. By contrasting such an approach with a standard full model, that considers both local and non-local features, we are thus able to study the contribution that local features make to the full model likelihood.

Figure 1: Left: log likelihood of FashionMNIST, MNIST test data using a full PixelCNN model, trained with FashionMNIST training set. Right: log likelihood of CIFAR10, SVHN test data using a PixelCNN model, trained with CIFAR10 training set. The x-axis indicates the value of the log-likelihood (negative BPD), the y-axis provides data sample counts.

3 Local Image Model

3.1 Local Autoregressive Model with Masked CNN

Autoregressive models have proven popular for modeling image datasets and common models are PixelCNN [46, 38], PixelRNN [46] or Transformer based models [6]. Assuming data dimension \( D \), the Autoregressive model \( p_f(x) \) can be written as

\[
p_f(x) = p(x_1) \prod_{d=2}^{D} p(x_d|x_1, \ldots, x_{d-1}),
\]

(3)

informally we refer to this type of model as a ‘full model’ since it can represent all dependencies between each dimension (pixel). Similarly, we can define a local autoregressive model \( p_l(x) \) where pixel \( x_{ij} \), at image row \( i \) column \( j \), depends on previous pixels with fixed horizon \( h \):

\[
p_l(x) = \prod_{ij} p(x_{ij}|x_{[i-h:i-1,j-h:h]+}, x_{[i,j-h:j-1]}),
\]

(4)

with zero-padding used in cases where \( i \) or \( j \) are smaller than \( h \). Figure 2b illustrates the resulting local autoregressive model dependency relationships. We implement this model using a masked CNN [46], with kernel size \( k=2 \times h+1 \) in our first network layer to mask out future pixel dependency. A full PixelCNN model would then proceed to stack multiple masked CNN layers, where increasing kernel depth affords receptive field increases. In contrast, we employ masked CNN with \( 1 \times 1 \) convolutions in subsequent layers. Such \( 1 \times 1 \) convolutions can model the correlation between channels, as in [13], and additionally prevent our local model obtaining information from pixels outwith the local feature region, defined by \( h \). Pixel dependencies are therefore defined solely using the kernel size of the first masked CNN layer, allowing for easy control over model local feature size. We note that the proposed local autoregressive model can also be implemented using alternative backbones e.g. Pixel RNN [46] or Transformers [6]. We also plot the samples of the local model, see Figure 4. Unlike the full autoregressive models [46, 38] which are used to generate semantically coherent samples, we find the samples from the local model are locally consistent yet have no clear semantic meaning.

3.2 Local Model Generalization

To investigate the generalization ability of our local autoregressive model, we fit the model to Fashion MNIST (grayscale) and CIFAR10 (color) training datasets and test using in-distribution (ID) images (respective dataset test images) and additional out-of-distribution (OOD) datasets: MNIST, KMNIST (grayscale) and SVHN, CelebA [3] (color). Both models use the discretized mixture of logistic distributions [38] with 10 mixtures for the predictive distribution and a ResNet architecture [46, 10].

---

\footnote{We down-sample the original CelebA to \( 32 \times 32 \times 3 \), see Appendix A.2 for details.}
We use a local horizon length $h = 3$ (kernel size $k = 7$) for both grayscale and color image data. We compare our local autoregressive model to a standard full autoregressive model (i.e., a standard PixelCNN), additional network architecture and training details can be found in Appendix A.

Tables 1, 2 report comparisons in terms of BPD (where lower values entail higher likelihood) for Fashion MNIST and CIFAR10, respectively. We observe that for in-distribution (ID) data, the full model has better generalization ability c.f. the local model ($0.21$ and $0.13$ BPD, respectively). This is unsurprising as training and test data originate from the same distribution; both local and non-local features, as learned by the full model, help ID generalization. For OOD data, we observe that the local model has generalization ability similar to the full model, exhibiting very small empirical gaps (only $\approx 0.02$ BPD on average). This phenomenon is consistent with our intuition: local features are shared between different image datasets and dominate the generalization ability of the model, whereas non-local features (e.g., semantics) does not allow for easy generalization to OOD datasets.

Further, we also empirically study the effect of varying local feature scale on generalization ability, see Table 3. We find the model has poor generalization performance when local features are too small and increasing the horizon size does not compensate for this towards improving generalization. We hypothesize that optimal local feature scale likely varies with both image semantics and resolution. We leave the study of selecting optimal local scales to future work.

In the following sections, we demonstrate how to apply our local autoregressive model to OOD detection (Section 4) and lossless compression tasks (Section 5).

### 4 OOD Detection

#### 4.1 Product of Experts Model

As was discussed in Section 2, local image features are observed to be largely common across the real-world image manifold and can be treated as a domain-prior. Therefore, in order to detect whether or not an image is out-of-distribution, we can require a partial model that only captures non-local components of the image distribution; denoted here $p_{nl}(x)$. It is not easy to build this non-local model $p_{nl}(x)$ directly, since the concept of ‘non-local’ lacks a mathematically accurate definition. Fortunately, we can define the full model $p_f(x)$ and the local model $p_l(x)$ for the image distribution.

We further assume the full model has the following structure:

$$ p_f(x) = \frac{p_l(x)p_{nl}(x)}{Z}, $$

where $Z = \int p_l(x)p_{nl}(x)dx$ is the normalizing constant. This formulation can also be thought of as a product of experts (PoE) model with two experts; $p_l$ (local expert) and $p_{nl}$ (non-local expert). An interesting property of the PoE model is that if a data sample $x'$ has high full model probability
where \( \hat{p}_n(x) \) denotes the unnormalized density. For the OOD detection task, we require only \( \hat{p}_n(x) \) in order to provide a score for classifying if test data \( x \) is OOD or not and therefore do not require to estimate the normalization constant \( Z \). We also note that as we increase the local horizon length for \( p_l \), the local model will converge to a full model \( p_l \rightarrow p_f \), and \( \hat{p}_n(x) = 1 \) becomes a constant and inadequate for OOD detection. This further suggests the importance of using a local model. Figure 3 shows histograms of \( \hat{p}_n(\cdot) \) for both ID and OOD test datasets. We observe that the majority of ID test data obtains higher likelihood than OOD data, illustrating the effectiveness of the non-local model.

![Figure 3: Unnormalized log likelihood of the non-local model](image)

Figure 3: Unnormalized log likelihood of the non-local model \( p_n(x) = \frac{p_f(x)}{p_l(x)} \) for both ID test datasets (FashionMNIST, CIFAR10) and OOD datasets (MNIST, SVHN). ID test datasets obtain significantly higher likelihoods, on average, in each case.

4.2 Connections to Related Methods

Likelihood ratio variants have been previously explored for OOD detection. We briefly discuss related works and highlight where our method differs from relevant literature.

In [37], it is assumed that each data sample \( x \) can be factorized as \( x = \{ x_b, x_s \} \), where \( x_b \) is a background component, characterized by population level background statistics: \( p_b \). Further, \( x_s \) then constitutes a semantic component, characterized by patterns belonging specifically to the in-distribution data: \( p_s \). A full model, fitted on the original data, (e.g. Flow) can then be factorized as \( p_f(x) = p_f(x_b, x_s) = p_b(x_b)p_s(x_s) \) and the semantic model can be correspondingly defined as a ratio: \( p_s(x) = \frac{p_f(x)}{p_b(x)} \), where \( p_f(x) \) is a full model. In order to estimate \( p_b(x_b) \), the authors of [37] design a perturbation scheme and construct samples from \( p_b(x_b) \) by adding random perturbation to the input data. A further full generative model is then fitted to the samples towards estimating \( p_b \). In our method, both \( p_l(x) \) and \( p_n(x) \) constitute distributions of the same sample space (that of the original image \( x \)) whereas \( p_s \) and \( p_b \) in [37] form distributions in different sample spaces (that of \( x_s \) and \( x_b \), respectively). Additionally, in comparison with our local and non-local experts factorization of the model distribution, their decomposition of an image into ‘background’ and ‘semantic’ parts may not be suitable for all image content and the construction of samples from \( p_b(x_b) \) (adding random perturbation) lacks principled explanation.

In [41, 40], the score for OOD detection is defined as \( s(x) = \frac{p_f(x)}{p_c(x)} \) where \( p_f \) is a full model and \( p_c \) is a complexity measure containing an image domain prior. In practice, \( p_c \) is estimated using a traditional lossless compressor (e.g. PNG or FLIF), or a model trained on an additional, larger dataset in an attempt to capture general domain information [40]. In comparison, our method does

---

4This PoE property differs from a Mixture of Experts (MoE) model that linearly combines experts. If data \( x' \) has high probability in the local model (e.g. \( p_l(x') = 0.9 \)) but low probability in the non-local model (e.g. \( p_n(x') = 0.1 \)), the probability in the full PoE model \( p_f(x') = 0.9 \times 0.1 \) is also small. On the contrary, if we assume \( p_f \) is a MoE: \( p_f = \frac{1}{2} p_l + \frac{1}{2} p_n \), then \( p_f(x') = 0.9 \) and \( p_n(x') = 0.1 \) results in a high full model \( p_f(x') \) value i.e. \( p_f(x') = 0.5 \times 0.9 + 0.5 \times 0.1 = 0.5 \). We refer to [13] for additional PoE model details.
not require the introduction of new datasets and our explicit local feature model, \( p_l \), can be considered more transparent than PNG of FLIF. Additionally, our likelihood ratio can be explained as the (unnormalized) likelihood of the non-local model for the in-distribution dataset whereas the score described by [40, 41] does not offer a likelihood interpretation. In the following Section 5, we discuss how the proposed local model may be utilized to build a lossless compressor, enhancing the connection between our OOD detection framework and those using traditional lossless compressors (e.g., PNG or FLIF). In Table 4, we report experimental results where we can show that a lossless compressor based on our model significantly improves compression rates c.f. PNG and FLIF, which further suggests the benefits of our OOD detection method.

4.3 Experiments

We conduct OOD detection experiments using four different dataset-pairs that are considered challenging [33]: Fashion MNIST (ID) vs. MNIST (OOD); Fashion MNIST (ID) vs. OMNIGLOT (OOD); CIFAR10 (ID) vs. SVHN (OOD); CIFAR10 (ID) vs. CelebA (OOD). We actively select not to include dataset pairs such as CIFAR10 vs. CIFAR100 or CIFAR10 vs. ImageNet since these contain duplicate classes and cannot be treated as strictly disjoint (or OOD) datasets [41]. Additional experimental details are provided in Appendix A. In Table 3, we report the ‘area under the receiver operating characteristic curve’ (AUROC), a common measure for the OOD detection task [11]. We compare against methods, some of which require additional label information \(^5\), or datasets. Our method achieves state-of-the-art performance in most cases without requiring additional information. We observed that the model-ensemble methods, WAIC [7] and MSMA [31] can achieve higher AUROC in the experiments involving color images yet are significantly outperformed by our approach in the case of grayscale data. We thus evidence that our simple method is consistently more reliable than alternative approaches and that our score function allows a principled likelihood interpretation.

5 Lossless Compression

Recent deep generative model based compressors [44, 3, 20, 14] are designed under the assumption that data to be compressed originates from the same distribution (source) as model training data. However, in practical scenarios, test images may come from a diverse set of categories or domains and training images may be comparatively limited [30]. Obtaining a single method capable of offering strong compression performance on data from different sources remains an open problem and related study involves consideration of ‘universal’ compression methods [30]. Based on our previous intuitions relating to generalization ability; for building such a ‘universal’ compressor in the image domain, we believe a promising route involves leveraging models that only depend on common local features, shared between differing image distributions. We thus propose a new ‘universal’ image lossless compressor: NeLLoC (Neural Local Lossless Compressor), built upon the proposed local autoregressive model and the concept of Arithmetic Coding [47]. In comparison with alternative recent deep generative model based compressors, we find that NeLLoC has competitive compression rates on a diverse set of data, yet requires significantly smaller model sizes which in turn reduces storage space and computation costs. We note that due to our design choices, and in contrast to alternatives, NeLLoC can compress images of arbitrary size.

In the remaining parts of this section, we firstly discuss NeLLoC implementation and then provide further details on the most important resulting properties of the method.

5.1 Implementation of NeLLoC

Our NeLLoC implementation uses the same network backbone as that of our OOD detection experiment (Section 4): a Masked CNN with kernel size \( k = 2 \times h + 1 \) (\( h \) is the horizon size) in the first layer and followed by several residual blocks with \( 1 \times 1 \) convolution, see Appendix A for the network architecture and training details. To realize the predictive distribution for each pixel, we propose to use a discretized Logistic-Uniform mixture distribution, which we now introduce.

\(^5\)In principle, methods that require labels correspond to classification, task-dependent OOD detection, which may be considered fundamentally different from task-independent OOD detection (with access to only image space information), see [1] for details. We compare against both classes of method, for completeness.
Table 3: OOD detection comparisons (AUROC) where higher values indicate improved performance and results are rounded to three decimal places. Results are reported in each case directly using the original references except in the cases of ODIN [37, 26] and VIB [7]. Results for Typicality test are from [41], corresponding to batches of two samples of the same type. (a) The MAHALANOBIS requires knowledge of the validation data (OOD distribution). (b) A full PixelCNN (see Appendix A) is trained on the ID dataset and its likelihood evaluations are then used to calculate AUROC.

**Discretized Logistic-Uniform Mixture Distribution** The discretized Logistic mixture distribution, proposed by [38], has shown promising results for the task of modeling color images. In order to ensure numerical stability, the original implementation can provide only an (accurate) approximation and therefore cannot be used for our task of lossless compression, which requires exact numerical evaluation. We therefore propose to use the discretized Logistic-Uniform Mixture distribution, which mixes the original discretized Logistic mixture distribution with a discrete uniform distribution:

\[
x \sim (1 - \alpha) \left( \sum_{i=1}^{K} \pi_i \text{Logistic}(\mu_i, s_i) \right) + \alpha U(0, \ldots, 255),
\]

where \(U(0, \ldots, 255)\) is the discrete uniform distribution over the support \(\{0, \ldots, 255\}\). The proposed mixture distribution can explicitly avoid numerical issues and its PMF and CDF can be easily evaluated without requiring approximation. We can then use this CDF evaluation in relation to Arithmetic Coding. In practice; we set \(\alpha = 10^{-4}\) to balance between numerical stability and model flexibility. We use \(K = 10\) (mixture components) for all models in the compression task.

**Arithmetic Coding** Arithmetic coding (AC) [47] is a form of entropy encoding which utilizes a (discrete) probabilistic model \(p(\cdot)\) to map a datapoint \(x\) to an interval \([0, 1]\). One fraction, lying in the interval, can then be used to represent the data uniquely. If we convert the fraction into a large message stream, the length of the message is always within two bits of \(- \log_2 p(x)\) (the Shannon Information content). For an image with size \(32 \times 32 \times 3 = 3072\), the BPD (bits per dimension) overhead of the arithmetic coding is less than \(2/3072 \approx 0.00065\) bits, which is negligible if we calculate the BPD to two decimal places. Our NeLLoC implementation, makes use of the vanilla (decimal) version of AC.
5.2 Properties of NeLLoC

Universal Image Compressor As discussed previously, the motivation for designing NeLLoC is to realize an image compressor that is applicable (generalizable) to images originating from differing distributions. Towards this, NeLLoC conducts compression depending on local features which are shown to constitute a domain prior for all images. In addition to universality properties, we next discuss other important axes towards making NeLLoC practical when considering real applications.

Arbitrary Image Size Common generative models, e.g. VAE or Flow, can only model image distributions with fixed dimension. Therefore, lossless compressors based on such models [44][15][3][14][20] can only compress images of fixed size. Recently, HiLLoC [45] explore fully convolutional networks, capable of accommodating variable size input images, yet still requiring even height and width. L3C [32], based on a multi-scale autoencoder, can compress large images yet also requires height and width to be even. NeLLoC (based on our local autoregressive model) is able to compress images with arbitrary size based on an alternative and simple intuition: we only model the conditional distribution, based on local neighbouring pixels. We thus do not model the distribution of the entire image and can therefore, in contrast to HiLLoC and L3C, compress arbitrary image sizes without padding requirements.

To validate method properties, we compare the compression performance of NeLLoC to other traditional image compressors and recently proposed generative model based compressors. We train NeLLoC with horizon length $h = 3$ on two (training) datasets: CIFAR10 ($32 \times 32$) and ImageNet32 ($32 \times 32$) and test on the previously introduced test sets, including both ID and OOD data. We also test on ImageNet64 with size $64 \times 64$ and a full ImageNet [8] test set (with average size $500 \times 374$). Table 4 provides details of the comparison. We find NeLLoC achieves better BPD in a majority of cases. Exceptions include LBB [14] having better ID generalization for CIFAR and HiLLoC [45] having better OOD generalization in the full ImageNet, when the model is trained on ImageNet32.

Small Model Size In comparison with traditional codecs such as PNG or FLIF, one major limitation of current deep generative model based compressors is that they require to generate and store models of very large size. For example, HiLLoC [45] contains 24 stochastic hidden layers, resulting in a capacity and parameter size of 156 MegaBytes (MB) using 32-bit floating point model weights. This poses practical challenges relating to both storage and transmission of such models to real, often resource-limited, edge-devices. Since NeLLoC only models the local region, a small network: three Residual blocks with $1 \times 1$ convolutions (except the first layer) is enough to achieve state-of-the-art compression performance. The parameter size requirement is only 2.75 MB accordingly. We also investigate the compression task under a NeLLoC instantiated with one residual block ($r = 1$); a resulting parameter size of 1.34 MB and yet still observe respectable performance. We report model size comparisons in Table 4. In principle, NeLLoC can be also combined with other resource saving techniques such as binary network weights to realize the generative model components. This would further reduce model size [4], which we consider a promising line of future investigation.

Computation Cost and Speed The computational complexity and speed for a neural based lossless compressor depends on two stages: 1. Inference stage: to compress or decompress the pixel $x_d$, a predictive distribution of $x_d$, needs to be generated by the probabilistic models; 2. Coding stage: uses the predictive distribution and the pixel value $x_d$ to generate the binary code representing $x_d$ (encoding) or using the predictive distribution and the binary code to recover $x_d$ (decoding). The computation cost and speed of the second stage heavily depends on the implementation (e.g. programming language) and the choice of coding algorithms. For example, there exists Integer-based AC [47][16], which can be used to achieve a trade-off between coding speed and overhead. Although the second stage is a crucial research problem for real applications, we consider it out of scope of the current work. Rather, we discuss the computational cost pertaining to the first inference stage. Our further discussion consists of two parts:

---

6 For images with odd height or width, padding is required.
7 See Table 5 for the use of other horizon size. We find when the too small horizon size: $h = 1$, will hurt both ID and OOD generalization performance, but when we increase the horizon length from $h = 3$ to $h = 5$, the ID generalization improves but OOD generalization remains roughly the same, therefore we use $h = 3$ to keep the best of both efficiency (see the discussion about Computational complexity below) and generalization.
8 Images with height or width greater than 1000 are removed, resulting in a total of 49032 test images.
1. Computational complexity: given an image with size $N \times N$, for a full autoregressive model the distribution of pixel $x_{ij}$ depends on all previous pixels $p(x_{ij} | x_{i1:j1})$, such that the computational cost of conditional distribution calculation scales as $O(N^2)$. For latent variable models (e.g. [45, 44]) or flow models (e.g. [3]) the predictive distribution of $x_i$ depends on all other pixels and therefore also scales with $O(N^2)$. In direct contrast, our local autoregressive model only depends on local regions with horizon $h$, so computation of the distribution $p(x_{ij} | x_{[i-h:i-1,j-h:j+h]; i=j-h:j-1})$ scales only with $O(h^2)$ and typically $h \ll N$ in practice. This results in significant reduction of the computational cost of our approach, pragmatically. A second key property affecting compression speed is parallelizability, discussed below.

2. Parallelizability: neural compressors that make use of latent variable models [44, 45] can allow for the distribution of each pixel to be independent (given decompressed latents). Flow models with an isotropic base distribution will also result in appealing decompression times on average. However for a full autoregressive model, the predictive distribution of each pixel must be generated in sequential order and thus the decompression stage cannot be directly parallelized. This results in the decompression stage scaling with image size. In contrast to a full autoregressive model, where sequential decompressing is inevitable, we note that with NeLLoC each pixel only depends on a local region. The fact that multiple pixels exist with non-overlapping local regions allows simultaneous decompression at each step, enabling parallelization. Alternatively, we can split an image into patches and compress each patch individually, thus parallelizing the decompression phase. Table 6 shows the compression BPD when we split full ImageNet images into patches. We find that BPD slightly increases when we increase the number of patches. This is explained by the fact that splitting an image into patches assumes each patch is independent, which will weaken the predictive performance. The scheme results in a trade-off between compression speed and rate: ≈0.1 BPD overhead can offer a ~×400 speed up in both compression, decompression (assuming infinite computation power), which may prove extremely valuable for practical applications.

6 Conclusion and Future Work

In this work, we propose the local autoregressive model to study generalization in probabilistic image modelling and establish an intriguing connection between two diverse applications: OOD detection and lossless compression. We verified and then use the considered hypothesis to design approaches towards solving these tasks:

- For OOD detection, we proposed a product of experts model which includes a local expert and a non-local expert. We further applied the non-local expert to conduct the OOD detection task and achieve consistently more reliable results in the tested datasets.

- For lossless compression, we propose a new lossless compressor: NeLLoC achieves state-of-the-art generalization results with smaller model sizes and reduced computation cost.

Future work will look to study the generalization ability of probabilistic models in other domains e.g. text or audio, in order to widen the benefits of the proposed OOD detectors and lossless compressors.

Acknowledgments

We would like to thank James Townsend and Tom Bird for discussion on the HiLLoC experiments. We thank Ning Kang for discussion regarding the parallelizability of NeLLoC.
Table 4: Lossless Compression Comparisons. We compare NeLLoC to other lossless compressors including traditional images compression methods and neural network based models. For neural models, we report the results where models are trained on CIFAR10 or ImageNet32 and tested on other ID or OOD test datasets. Results are either obtained from the original work or we test using publicly released models. We use † to represent the best ID generalization and ⋆ to represent the best OOD generalization. (a) We down-sample CelebA to 32×32, see Appendix A.2. (b) The BPD 3.15 reported in [45] is tested on 2000 random samples from the full ImageNet testset, whereas we test the HiLLoC on the whole testset with 49032 images. The reported BPD of NeLLoC has standard deviation ∼0.02 across multiple random seeds.

A Experiments Details

A.1 Machines

We conduct all our experiments on a NVIDIA GeForce RTX 2080 Ti GPU and a NVIDIA GeForce V100 GPU.

A.2 Prepossessing of CelebA

We first do a center crop of size 150 and then resize to $32 \times 32 \times 3$. We take the first 10000 images as our test set for CelebA.

A.3 Model Architecture

We first discuss the building blocks used in our experiments. All the models share the similar PixelCNN [46] architecture, which contains a masked CNN as the first layer and multiple Residual blocks as subsequence, we will detail both below.

**Masked CNN** Masked CNN structure is proposed in [46]. For our local model with dependency horizon $h$, one kernel of the CNN has size $k \times k$ with $k = 2 \times h + 1$. The masked CNN contains masks to zero out the input of the future pixels. There are two types of Masked CNN, which are referred to mask A (zero out the current pixel) and mask B (allows the connection from a color to itself), see [46] for details. The first layer of our model is using mask A and the residual blocks are using mask B.

**Residual Block** Each residual Block [46] contains following structure, we use MaskedCNN$_B$ to denote Masked CNN with mask type B.

**Algorithm 1:** Residual Block

**Input:** $x_{input}$

\[
\begin{align*}
    h &= \text{MaskedCNN}_B(x_{input}) \\
    h &= \text{ReLU}(h) \\
    h &= \text{MaskedCNN}_B(h) \\
    h &= \text{ReLU}(h) \\
    h &= \text{MaskedCNN}_B(h) \\
    h &= \text{ReLU}(h) \\
    \text{Return} : x_{input} + h
\end{align*}
\]

**Pixel CNN** Our full Pixel CNN and local pixel CNN shares the same backbone. The only difference of these two models is that the full model has kernel size $3 \times 3$ in the second masked CNN layer in the Residual Block and local model has kernel size $1 \times 1$ in all the masked CNN layers in the Residual block. Therefore, the reception field of the full model can increase when stacking multiple Residual block whereas the reception field of the local model will not increase. A typical Pixel CNN with N residual blocks has the following structure:

**Algorithm 2:** Pixel CNN

**Input:** $x_{input}$

\[
\begin{align*}
    h &= \text{MaskedCNN}_A(x_{input}) \\
    h &= \text{ReLU}(h) \\
    \text{for } i \text{ from 1 to N:} \\
    h &= \text{ResBlock}_i(h) \\
    h &= \text{MaskedCNN}_B(h) \\
    h &= \text{ReLU}(h) \\
    h &= \text{MaskedCNN}_B(h) \\
    \text{Return} : h
\end{align*}
\]

A.3.1 OOD detection

**Grey images** For grey images, our full Pixel CNN model has 5 residual blocks and channels size 256 except the final layer has 30 channels. The kernel size is 7 for the first Pixel CNN and the kernel size
is $[1 \times 1, 3 \times 3, 1 \times 1]$ for three masked CNN in the residual blocks. Our local Pixel CNN model has 1 residual blocks and channels size 256 except the final layer has 30 channels. The kernel size is 7 for the first Pixel CNN and the kernel size is $[1 \times 1, 1 \times 1, 1 \times 1]$ for three masked CNN in the residual blocks. We use the discretized mixture of logistic distribution [38] with 10 mixture components. The models are trained using Adam optimizer [17] with learning rate $3 \times 10^{-4}$ and batch size 100 for 100 epochs.

**Color images** For color images, our full Pixel CNN model has 10 residual blocks and channels size 256 except the final layer has 100 channels. The kernel size is 7 for the first Pixel CNN and the kernel size is $[1 \times 1, 3 \times 3, 1 \times 1]$ for three masked CNN in the residual blocks. Our local Pixel CNN model has 3 residual blocks and channels size 256 except the final layer has 100 channels. The kernel size is 7 for the first Pixel CNN and the kernel size is $[1 \times 1, 3 \times 3, 1 \times 1]$ for three masked CNN in the residual blocks. We use the discretized mixture of logistic distribution [38] with 10 mixture components. The models are trained using Adam optimizer [17] with learning rate $3 \times 10^{-4}$ and batch size 100 for 1000 epochs.

### A.3.2 Lossless compression

The NeLLoC is based on a Pixel CNN, since it is a local model, the kernel size is $1 \times 1$ for all the kernels in Residual block. Other details about the first layer’s kernel size and number of residual blocks are detailed in the main text. All the models are trained using Adam optimizer [17] with learning rate $3 \times 10^{-4}$ and batch size 100 for 1000 epochs for CIFAR dataset and 400 epochs for ImageNet32 dataset.

### B Samples From Local Model

We show the samples from a local model with $h = 3$ and is trained on CIFAR $32 \times 32 \times 3$, see figure. We can see the samples are locally consistent images but it doesn’t contain any semantic meaning. We also sample a $100 \times 100 \times 3$ size image, since the local model doesn’t require image to have a fixed size that is the same as the training data.

![Samples from a local autoregressive model](image)

(a) 16 samples with size $32 \times 32 \times 3$  
(b) One sample with size $100 \times 100 \times 3$

Figure 5: Samples from a local autoregressive model.

### C Datasets

The CelebA [29], ImageNet [9] and SVHN [35] dataset is available for non-commercial research purposes only. The Fashion MNIST [48] and Omniglot [24] are under MIT License. The KMNIST [8] is under CC BY-SA 4.0 license. We didn’t find licenses for CIFAR [22] and MNIST [25]. The CelebA dataset may contain personal identifications.
D Societal Impacts

In this paper, researchers introduce a novel generative model and investigate related out-of-distribution detection, generalization questions. Local autoregressive image models, such as those introduced, may find application in many down-stream tasks involving visual data. Typical use cases include classification, detection and additional tasks involving extraction of semantically meaningful information from imagery or video. With this in mind our caution must remain in the fore, when considering related technology, to avoid it being harnessed to enable dangerous or destructive ends. Identification or classification of people without their knowledge, towards control or criminalization provides an obvious example.
