A Just-In-Time Networking Framework for Minimizing Request-Response Latency of Wireless Time-Sensitive Applications

Lihao Zhang, Soung Chang Liew, Fellow, IEEE, and He Chen, Member, IEEE

Abstract—This paper puts forth a networking paradigm, referred to as just-in-time (JIT) communication, to support client-server applications with stringent request-response latency requirement. Of interest is not just the round-trip delay of the network, but the actual request-response latency experienced by the application. The JIT framework contains two salient features. At the client side, the communication layer will “pull” a request from the client just when there is an upcoming transmission opportunity from the network. This ensures that the request contains information that is as fresh as possible (e.g., a sensor reading obtained just before the transmission opportunity). At the server side, the network ascertains that the server, after receiving and processing the request to generate a response (e.g., a control command to be sent to the client), will have a transmission opportunity at just this time. We realize the JIT system, including the protocol stack, over a Time-Division-Multiple-Access (TDMA) network implemented on a System-on-Chip (SoC) platform. We prove that a TDMA network with a power-of-2 time slots per superframe is optimal for realizing the server-side JIT function. Our experimental results validate that JIT networks can yield significantly lower request-response latency than networks without JIT support can.

Index Terms—wireless time-sensitive networking, application-to-application round trip time, just in time, TDMA

1 INTRODUCTION

The emerging time-sensitive applications in automotive, avionics, building management, and industrial automation [1]–[4] are revolutionizing the way we think about information. These applications may consist of distributed devices that communicate with each other to perform a task. In particular, they may send information to each other. It is essential to keep the information fresh among them, because outdated information can degrade performance and even compromise human safety.

These applications can be made more flexible if their distributed devices communicate using a wireless network rather than a wired network [5]–[8]. Wireless networks obviate the need for installation and maintenance of wires. With a wireless network, the locations of the distributed devices can be changed in a moment without rewiring. Furthermore, many applications require the devices to be mobile and portable, and this is only possible with wireless networking. An application scenario is that of a central controller coordinating the movements of collaborating tetherless automatic guided vehicles (AGV) [9] via a wireless network.

Many futuristic applications, such as industrial control applications, are time-sensitive in that they demand fast communication with low delays [10]. Conventional wireless networks do not cater well to the time-sensitive requirements of these applications [11]. This work investigates a new wireless networking framework to meet the time-sensitivity requirements. We set the context of framework below.

Lihao Zhang, Soung Chang Liew and He Chen are with Department of Information Engineering, The Chinese University of Hong Kong, Hong Kong SAR, China (email: zl018@ie.cuhk.edu.hk; soung@ie.cuhk.edu.hk; he.chen@ie.cuhk.edu.hk).
A client application should initiate the generation of opportunities for time slots to communicate with each other at the communication layer, mentioned clients and servers make use of the time slots to realize minimal round-trip delays between the client and the server, subject to the networking delay at the application layer – the time from the initiation of the request generation to the reception of the response at the client. We hereafter refer to this request-response latency as the application-to-application round trip time (RTT). We show via analysis and experiments that, without a mechanism to realize minimal round-trip delays between the client and server, no matter how fast and reliable the communication layer is, the application may still suffer from large and non-deterministic delays. In particular, tight coordination between the communication layer and the application layer is required to minimize the round-trip delay of the client-server interaction.

This paper puts forth two mechanisms to minimize the application-to-application RTT. Our mechanisms apply the following principles to address questions 1) and 2) above:

1) The client acquires some time-sensitive information (e.g., a measurement acquired from a sensor or an image captured from a camera) to generate a request message. It then forwards the request to its communication layer for delivery to the server.

2) Upon receiving the request, the server, acting as a controller, formulates a response message based on the request. It then forwards the response message to its communication layer for delivery to the client, so that an actuator at the client can perform a certain operation based on the command embedded in the response.

We ask two fundamental questions that delve into the inner core of the time-sensitivity issue at hand:

1) When should the client acquire the time-sensitive information and generate the request so that it can be delivered by the communication layer to the server with minimal delays, taking into account the future instant when the communication layer may have a transmission opportunity?

2) When should the communication layer offer a transmission opportunity to the server, subject to the networking construct, so that the server’s response can be delivered to the client with minimal delays?

We are interested in minimizing the request-response latency at the application layer – the time from the initiation of the request generation to the reception of the response at the client. We hereafter refer to this request-response latency as the application-to-application round trip time (RTT). We show via analysis and experiments that, without a mechanism to realize minimal round-trip delays between the client and server, no matter how fast and reliable the communication layer is, the application may still suffer from large and non-deterministic delays. In particular, tight coordination between the communication layer and the application layer is required to minimize the round-trip delay of the client-server interaction.

This paper puts forth two mechanisms to minimize the application-to-application RTT. Our mechanisms apply the following principles to address questions 1) and 2) above:

1) The client application should initiate the generation of the request just before its communication layer has a transmission opportunity, not too early and not too late.

2) The communication layer at the server should offer a transmission opportunity to the application layer just after the server has formulated and generated the response, not too early and not too late.

We refer to the two principles as the Just-in-Time (JIT) principles and to a networking system that realizes the two principles as a JIT system. For concreteness, this paper assumes a time-division-multiple-access (TDMA) wireless network, in which time is divided into time slots and a message is transmitted in a time slot [12]. Thus, the aforementioned clients and servers make use of the time slots to communicate with each other at the communication layer, and time slots correspond to the aforementioned transmission opportunities.

The main reason for assuming TDMA is that the physical-network latency can be made to be deterministic by preallocating time slots to users. For this reason, TDMA networks are often assumed to be used in time-critical networking [13]–[15]. Although this work assumes the underlying network to be a TDMA network, it does not mean JIT principles are not viable if TDMA networks are not adopted. In Appendix C, we discuss what if a Carrier Sense Multiple Access (CSMA) network (e.g., Wi-Fi) is used instead. Essentially, we will need to replace the deterministic JIT here with a probabilistic JIT given that CSMA networks do not preallocate transmission opportunities to the nodes.

To realize JIT principle A and JIT principle B, two mechanisms are elaborated as follows:

1) To realize JIT principle A, we design a JIT-triggered packet generation mechanism in which the client is informed by a JIT middleware to generate a request slightly in advance of the transmission opportunity. It takes a certain amount of time for the client to execute a function to generate the request. Informing the client too late will cause the request to miss its transmission opportunity and informing the client too early will cause the request to age (i.e., the information in it becomes stale) while the request sits in the communication layer waiting for its transmission opportunity. To do its job, the JIT middleware, designed to sit in between the application layer and the communication layer, needs to synchronize the timings at the application layer and the communication layer and informs the client at just the right time.

2) To realize JIT principle B, we design a JIT time-slot allocation mechanism that allocates a time-slot pair to each client-server pair: one time slot for the client request and one time slot for the server response. It takes a certain amount of time for the server to generate the response upon receiving a request. Thus, the two time slots must be separated by just the right interval. If the server time slot occurs too early after the client time slot, the response at the server may arrive at its communication layer after the server time slot has transpired. On the other hand, if the server time slot is way past the client time slot, the response may arrive at the communication layer well before its transmission opportunity, inducing extra waiting time at the communication layer. In particular, the separation between the two time slots must be commensurate with the server’s processing time.

Our JIT system is implemented over the Openwifi project [16] on a System-on-Chip (SoC) evaluation kit. This real-time implementation enables the overall end-to-end application-to-application communication. All the wireless signal processing and the communication between protocol stacks are executed in real-time, not offline. Our JIT implementation can serve as a useful experimental testbed for a whole host of wireless time-sensitive applications. Also, although our JIT implementation is over a special-purpose SoC evaluation kit, the JIT principles as expounded in this paper can be implemented over other platforms, including general-purpose computers.

Experimental results indicate that our JIT system: i) can ensure information freshness of time-sensitive messages; ii) can achieve minimum application-to-application RTT;
Two related works are [17], [18]. The communication layer of [17] attaches a timestamp to the head-of-line packet of a queue within the communication layer just before sending it out. The “just-in-time” timestamp facilitates the measurement of the end-to-end latency incurred by the communication layer. Unlike our work here, [17] does not have a mechanism to prevent or minimize aging of packets. In particular, the approach in [17] does not generate the packet in a just-in-time manner. The packet is generated without regard to the transmission opportunity at the communication layer and it sits in a queue in the communication layer waiting for its transmission opportunity. It is the time stamp added to the packet that is “just-in-time”, in order that end-to-end communication delay can be measured accurately. This communication delay is not the actual delay as perceived by the application, because it does not include the delay incurred by the packet while sitting in the queue.

The work in [18] shares the same spirit as our JIT mechanism in this paper in that the packet content is prepared just before its scheduled transmission. However, our work differs from [18] in the platform being used and in the problem being addressed. Specifically, the mechanisms in [18] were specially designed for the PC-based “Gnuradio+USRP” software-defined radio (SDR) platform, in which the USRP serves as the radio hardware, and the Gnuradio software running on the PC takes charge of the baseband signal processing. By contrast, our work in this paper in [18] is that the packet content is prepared just before its scheduled transmission. However, the PHY/MAC delay is much smaller and deterministic in our “ARM+FPGA” SoC platform. This is because our SoC platform provides a high-speed FPGA Mezzanine Card (FMC) [19] interface between the RF front-end and the FPGA core to support low-latency communications between them. Furthermore, our JIT middleware ensures minimal additional delay between the application layer and the PHY/MAC layer.

2.2 Work Related to JIT principle B

In the context of graph theory, the time-slot allocation problem in our JIT principle B can be regarded as a vertex arrangement problem, where the goal is to find an arrangement such that each pair of adjacent vertices satisfies a predefined minimum separation requirement (see Section 4-2 for details). Two related NP-complete problems have been previously studied: the cycle-separation problem [20] and the directed separation problem [21]. The critical difference between our problem and the above two problems lies in the definition of the distance of adjacent vertices. This difference fundamentally changes the nature of our problem, and the solution to our problem cannot be found by the approaches of [20] and [21]. We will further elaborate the fundamental differences between our problem and those of [20] and [21] in Section 4.2.

3 MOTIVATION FOR JIT: A QUANTITATIVE OVERVIEW

With respect to the use case depicted in Fig. 1 let us trace through the delay components that contribute to the overall the application-to-application RTT when the application is deployed over a TDMA network. As illustrated in Fig. 2 suppose that each TDMA round consists of N time slots. Without loss of generality, in this example, time slot 0 of all rounds is dedicated to the transmission of a request from the client to the server, and a time slot n, n ≠ 0 of all rounds is dedicated to the transmission of a response from the server to the client.

To illustrate how a conventional networking system may not do the best job in minimizing the application-to-application RTT, let us consider the sequence of events in the feedback loop. Fig. 2 shows a typical time diagram of a sensor-controller-actuator feedback loop over the TDMA network:

1. With reference to Fig. 3 the client acquires the sensed data from the sensor at time $T_0$ and generates a request $M_c$ at time $T_1$. Thus, $D_c = T_1 - T_0$ is the time required to generate $M_c$. We refer to $D_c$ as the client’s processing delay.
2. The client waits until $T_2$, the beginning of slot 0 of the next upcoming TDMA round to transmit $M_c$ to the
server, inducing an extra client’s waiting time of \( W_c = T_2 - T_1 \). The transmission of \( M_c \) takes a certain amount of transmission time, inducing a client’s transmission delay. In Fig.3 the transmission time or delay is \( T_4 - T_2 \), where \( T_2 \) is the time at which the client transmits the first bit of \( M_c \) and \( T_4 \) is the time at which of the client transmits the last bit of \( M_c \).

3) In addition, there is a client’s propagation delay from the client to the server. The server receives the first bit of \( M_c \) at \( T_3 \), and receives the last bit of \( M_c \) at \( T_5 \). We have \( T_5 - T_3 = T_4 - T_2 \), and the propagation delay is \( T_3 - T_2 = T_5 - T_3 \). We note that the physical medium is occupied for a duration of \( T_{\text{phy},c} = T_5 - T_2 \) after taking into account the propagation delay.

4) Upon receiving \( M_c \), the server takes some time to process it and to produce the control command as the response \( M_s \), thus incurring a server’s processing delay. Suppose that the controller generates \( M_s \) at \( T_0 \). Then the server’s processing delay is \( D_s = T_0 - T_5 \).

5) The server waits until \( T_7 \), the beginning of the time slot \( n \) of a TDMA round, to transmit \( M_s \) to the client, inducing an extra server’s waiting time of \( W_s = T_7 - T_6 \).

6) The first bit of response \( M_s \) arrives at the actuator at \( T_8 \), and the last bit of \( M_s \) arrives at the actuator at \( T_0 \). Thus, \( T_9 - T_7 = T_{10} - T_8 \) is the server’s transmission delay and \( T_8 - T_7 = T_{10} - T_9 \) is the server’s propagation delay. The physical medium occupied time is then \( T_{\text{phy},s} = T_10 - T_7 \). Thus, the overall application-to-application RTT is made up of a number of delay components as written below:

\[
RTT = T_{10} - T_0 = D_c + W_c + T_{\text{phy},c} + D_s + W_s + T_{\text{phy},s}.
\]

To reduce the application-to-application RTT, we need to reduce the extra waiting times \( W_c \) and \( W_s \). Let

\[
W = W_c + W_s
\]

be the total extra waiting times. In the following, we argue that \( W_c \) and \( W_s \) can be large in a conventional networking system.

Let \( t_{0,i} \) be the beginning of time slot \( k \) of round \( i \). Recall that time slot 0 of all rounds is dedicated to the client’s transmission, and time slot \( n \) of all rounds is dedicated to the server’s transmission. Let us first consider \( W_c \). Suppose that at time \( T_0 < t_{0,i} \), the client acquires a sensed data. The client then generates the corresponding request message \( M_c \) that contains the sensed data at \( T_1 \). Two cases are possible:

1) Suppose that \( T_1 < t_{0,i} \). Then the client uses its assigned time slot in the round \( i \) to transmit \( M_c \). Then \( T_2 = t_{0,i} \), and we have

\[
W_c = t_{0,i} - T_1.
\]

2) Suppose that \( T_1 > t_{0,i} \). Then the client misses its assigned time slot in the round \( i \). The client needs to wait for time slot 0 in TDMA round \( i + 1 \) to transmit \( M_c \). Thus, \( T_2 = t_{0,i+1} \), and we have

\[
W_c = t_{0,i+1} - T_1 = F + t_{0,i} - T_1,
\]

where \( F \) is the duration of one round. From (1), we can see that a larger \( F \) will induce a larger \( W_c \), leading to a larger application-to-application RTT. The worst-case maximum possible \( W_c \) is obtained when \( T_1 = t_{0,i} + \varepsilon \) where \( \varepsilon > 0 \) is a tiny quantity. In this case, the waiting time is effectively \( F \):

\[
W_c = F + t_{0,i} - t_{0,i} - \varepsilon \approx F.
\]

Let us next consider the maximum possible value of the total extra waiting time \( W_c \), denoted by \( W^* \). In this case, we have case 2) in the above. Thus, the server receives \( M_c \) at \( T_3 \) in round \( i+1 \). It takes \( D_s \) amount of time to process \( M_c \) to generate the response message \( M_s \) at \( T_6 \). The server then waits until the beginning of the next time slot \( n, T_7 \), to transmit \( M_s \). As in the analysis of \( W_c \), there are two possible cases:

1) Suppose that \( T_0 \leq t_{n,i+1} \). Then the server uses time slot \( n \) of round \( i + 1 \) to transmit \( M_s \). Thus, \( T_7 = t_{n,i+1} \), and we have

\[
W_s = t_{n,i+1} - T_6.
\]

2) Suppose that \( T_0 > t_{n,i+1} \). Then the server misses time slot \( n \) of round \( i + 1 \). Hence, the server needs to wait until time slot \( n \) of round \( i + 2 \) to transmit \( M_s \) (here we assume that \( T_3 + D_s = T_6 \leq t_{n,i+2} \)). Then \( T_7 = t_{n,i+2} \), and we have

\[
W_s = t_{n,i+2} - T_6 = F + t_{n,i+1} - T_6.
\]

The worst-case maximum possible \( W_s \) is obtained when \( T_6 = t_{n,i+1} + \varepsilon \), where \( \varepsilon > 0 \) is a tiny quantity. In this case, we have

\[
W_s = F + t_{n,i+1} - t_{n,i+1} - \varepsilon \approx F.
\]

From (3), (4), (6) and (7), we can see that in a conventional networking system, \( W_c \) and \( W_s \) are varying quantities, and depending on the situation, the application-to-application RTT could be large. From (5) and (8), when \( T_1 = t_{0,i} + \varepsilon \) and \( T_0 = t_{n,i+1} + \varepsilon \), the system incurs the maximum total extra waiting time \( W^* \) given by

\[
W^* \approx 2F.
\]

From (9), we can see that the conventional client-server applications can incur an extra delay of around \( 2F \) in the overall application-to-application RTT in the worst case. Motivated by the observation encapsulated in (1) and (9), we propose the JIT system to reduce the total extra waiting time \( W^* \). Our JIT system has two main features:

1) JIT-triggered packet generation: With this mechanism, the client can acquire the sensed data and generate \( M_c \) just slightly before the communication layer offers a
transmission opportunity at $T_2$. For example, consider the transmission opportunity at round $i$. Our JIT system notifies the client to start sensing at time $T_0 = t_{0,i} - D_c - \varepsilon$ such that $M_c$ can be generated at time $T_1$ to satisfy

$$T_1 = t_{0,i} - \varepsilon,$$  \hspace{1cm} (10)

where $\varepsilon$ is a small positive slack. This gives the minimum possible value of

$$W_c = \varepsilon.$$  \hspace{1cm} (11)

2) JIT time-slot allocation: Once the server receives $M_c$ and then generates $M_s$, it can send out $M_s$ immediately. This feature requires our JIT system to know the server’s processing delay $D_s$ in advance of the time-slot allocation. For example, suppose that in the round $i$, the controller receives $M_c$ at $T_5$, generates $M_s$ at $T_6$, and waits until $T_7$ to transmit $M_s$. Our system can assign a time slot to the server so that we have

$$T_6 = T_7 - \sigma,$$  \hspace{1cm} (12)

where $\sigma$ is the duration of one time slot in the worst case. This gives

$$W_s = \sigma.$$  \hspace{1cm} (13)

From (11) and (13), we can then bound $W$ to

$$W' = \varepsilon + \sigma,$$  \hspace{1cm} (14)

which can be much smaller than the $W^* \approx 2F$ in (9). Importantly, the $W'$ in (14) is independent of the duration of a TDMA round, $F$, which could be large for a TDMA system supporting a large number of IoT devices with each device taking up one slot of a round. Recall the JIT principle A and the principle B in Section 3. We emphasize that the JIT-triggered packet generation and the JIT time-slot allocation are the mechanisms that apply the JIT principle A and the JIT principle B, respectively. In this way, our JIT system with the above two features can be free of additional system delay, achieving minimum application-to-application RTT for client-server applications.

4 SYSTEM DESIGN

This section presents our JIT system design. The JIT system’s network protocol stack is shown in Fig. 4. The network protocol stack is partitioned into two main parts running on hardware and software, respectively. The communication layer, consisting of the MAC layer and the PHY layer, is implemented on hardware for high-speed processing and accurate timing control. The JIT middleware and the application layer are implemented in software. In particular, the JIT middleware, residing in between the application layer and the MAC layer, enables JIT-triggered packet generation at the client. Section 3.1 elaborates the JIT-triggered packet generation. And the JIT time-slot allocation for client-server applications is detailed in Section 4.2.

Fig. 4. JIT network protocol stack.

4.1 JIT-triggered packet generation

This subsection presents the design of JIT-triggered packet generation at the client. A possible but naïve design is as follows:

1) The MAC layer sends a pull signal to the JIT middleware.
2) Upon receiving the pull signal, the JIT middleware relays the pull signal to the application layer, asking for a packet.
3) Upon receiving the pull signal, the application layer starts to acquire sensed data and then generates the packet. After being generated, the packet is sent to the JIT middleware immediately.

This naïve design, however, has two limitations:

1) The MAC layer initiates the pull signal and the JIT middleware relays the pull signal to the application layer. This relaying of the signal may induce extra delay.
2) Since it takes time for the client’s application to generate a packet, the MAC layer needs to know how much ahead of the assigned time slot it should send the pull signal to the JIT middleware to achieve accurate timing. Specifically, in this design, the MAC layer needs to have explicit knowledge of relaying delay incurred at the JIT middleware plus the client’s processing delay.

To circumvent the limitations, we devise a design for JIT-triggered packet generation as follows:

(i) Only the JIT middleware initiates a pull signal to the application layer to ask for a packet. The MAC layer does not send a pull signal to the JIT middleware.
(ii) A separate synchronization mechanism is used to synchronize the timing at the JIT middleware to the timing at the TDMA MAC layer. With the synchronization mechanism, the JIT middleware can initiate the pull signal at an appropriate time without explicit knowledge of the client’s processing delay, such that the application-layer packet triggered by the pull signal can reach the TDMA MAC layer just in time for it to be transmitted.

We elaborate above mechanisms (i) and (ii) in the following. Before that, we emphasize that in a general setup, the hardware clock used for communication may be different from the software clock used for computation. For example, in many computing devices that run applications, the applications are written in software and if they need to use timing functions (e.g., the code needs to sleep for a
certain amount of time), they count on the operating system (OS) to provide these timing functions. The OS itself, in turn, makes use of the clock of the computing platform to offer the timing functions as software. Meanwhile, for communication and networking purposes, the communication platform (e.g., a Wi-Fi card attached to the computing device) uses its own internal oscillator (e.g., a voltage-controlled, temperature compensated oscillator) to provide the stable hardware clocking function for accurate communication timing.

Our JIT system is designed to cater to this general setup. Specifically, we assume that the JIT middleware uses a software clock that is different from the hardware clock used by the TDMA MAC layer. We refer to the two clocks as “JIT clock” and “MAC clock”, respectively. We note that the JIT clock is the same clock as used by the client application software.

For clarity, unless stated otherwise, all the time variables below are specified with reference to the MAC clock. Let $U_i^{MAC}$ denote the time at which the TDMA MAC layer is scheduled to begin to transmit the packet $P_i$. We have

$$U_i^{MAC} = U_0^{MAC} + iF, \ i \geq 0,$$

where $U_0^{MAC}$ is the time at which the TDMA MAC layer begins to transmit the first packet $P_0$ and $F$ is the duration of one TDMA round mentioned in Section.3. Meanwhile, let $U_i^{JIT}$ denote the time when the JIT middleware is scheduled to pull packet $P_i$ from the application layer. We have

$$U_i^{JIT} = U_0^{JIT} + iF', \ i \geq 0,$$

where $U_0^{JIT}$ is the time when the JIT middleware sends the first pull signal to the application layer asking for the first packet $P_0$ and $F'$ is the duration of one TDMA round at the JIT middleware measured using the MAC clock. Again, for exposition purposes, although the JIT middleware operates on the JIT clock, the time variables here, including $U_i^{JIT}$ and $F'$, are expressed in terms of the MAC clock, so that all variables use the same reference time. The reason that $F'$ and $F$ may not be the same is as follows. Suppose that the duration of one TDMA round is understood to be $F$ seconds. The MAC will implement the TDMA to have an exact duration of $F$ seconds according to its hardware clock. Meanwhile, the JIT middleware uses the software clock and also assumes the duration of one TDMA round is $F$ seconds. However, since the JIT layer uses the software clock for timing purposes, the resulting TDMA round at the JIT middleware may have a duration of $F'$ that is different from $F$ if $F'$ is expressed in terms of the MAC clock.

Note that we would like the differential $U_i^{MAC} - U_i^{JIT}$ to be not too small and not too large to allow sufficient time for the application to generate packet $P_i$ and then for $P_i$ to reach the TDMA MAC layer just in time for it to be transmitted by the MAC layer.

So far, all time variables have been specified with reference to the MAC clock. Now, since the operation at the JIT middleware only has access to the JIT clock, when we describe what the JIT middleware actually does in its operation, we need to assume the JIT middleware uses time variables with reference to the JIT clock. For clear notation, we put a “hat” over all time variables specified in the JIT clock. For example, for $U_i^{JIT}$ and $F'$ specified in MAC clock, $\hat{U}_i^{JIT}$ and $\hat{F}$ are their correspondences specified in the JIT clock. We further note that $\hat{F} = F$ because both the JIT middleware and the MAC layer have a common understanding of the duration of a TDMA round. Then, from the point of view of the JIT middleware, (16) can also be written as

$$\hat{U}_i^{JIT} = \hat{U}_0^{JIT} + i\hat{F}, \ i \geq 1$$

(17)

To enable synchronized JIT-triggered packet generation, we need to address two issues arising from (15), (16) and (17):

1) **Clock Offset:** The JIT clock and the MAC clock have a relative clock offset that drifts with time because of the different tick rates of the two clocks. Now, define $o_i$ to be the offset between the above two clocks when the pull signal for $P_i$ is triggered. Specifically, we have

$$\hat{U}_i^{JIT} = U_i^{JIT} + o_i.$$  

(18)

The differential $U_i^{MAC} - U_i^{JIT} = (U_i^{MAC} - \hat{U}_i^{JIT}) - (\hat{U}_i^{JIT} + i\hat{F} - o_i) = (U_i^{MAC} - \hat{U}_i^{JIT}) + (o_i - o_0)$ is not a constant and it drifts with the term $(o_i - o_0)$. Let us further focus on $(o_i - o_0)$. From (18), we have

$$o_i - o_0 \ = \ (\hat{U}_i^{JIT} - \hat{U}_0^{JIT}) - (U_i^{MAC} - \hat{U}_i^{JIT})$$

$$= \int_{U_0^{JIT}}^{U_i^{JIT}} dt - \int_{U_0^{MAC}}^{U_i^{MAC}} dt$$

(19)

where $\hat{t}$ and $\hat{t}$ are the time units of the JIT clock and the MAC clock, respectively. If the tick rate of the JIT clock is faster than that of the MAC clock then $\frac{\hat{t}}{t} \geq 1$, and vice versa. Thus, we can see from (19) that for an unsynchronized system where $\frac{\hat{t}}{t} \neq 1$, $U_i^{MAC} - U_i^{JIT}$ may grow unbounded or may become negative. For just-in-time operation, $U_i^{MAC} - U_i^{JIT}$ for all $i$ must be kept within a tight range. To achieve this, we need a synchronization mechanism. We will present our synchronization mechanism shortly.

2) **Timing Imprecision:** Rather than having precise time control as in hardware, the multitasking software architecture in the operating system may cause the JIT middleware and the application layer to experience preemptions from other tasks. As a result, $D_c$ could vary for different packets. Let $D_{c,i}$ denote the client’s processing delay for packet $P_i$. In general, $D_{c,i}$ in an actual system includes not only the time for packet generation, but also the preemption delay caused by other tasks preempting our task plus the time for the packet to be delivered from the application layer to the MAC layer. A larger preemption delay induces a larger $D_{c,i}$. Note also that $D_{c,i}$ is unknown to the JIT system.

Packet $P_i$ arrives at the MAC layer at time $U_i^{Arr} = U_i^{JIT} + D_{c,i}$. Let $ST_i$ denote the slack time for packet $P_i$ at the TDMA MAC layer. Specifically,

$$U_i^{MAC} = U_i^{Arr} + ST_i, \ i \geq 0.$$  

(20)

We have two requirements:

---

1. https://wiki.analog.com/resources/eval/user-guides/ad-fmcomms2-ebz/hardware/tuning#in_1
We want to minimize the slack time \( ST_i \) as much as possible to allow just-in-time packet transmission.

We would like to have \( ST_i \geq 0 \), so that we can prevent \( P_i \) from missing its desired transmission time at the MAC layer \( U^M_{i,1} \).

In short, we would like \( ST_i \geq 0 \), but not too much larger than 0.

### 4.1.1 Synchronization Mechanism

To meet the requirement, we devise an adaptive synchronization mechanism to synchronize \( U^J_{i,1} \) to \( U^M_{i,1} \). This adaptive synchronization mechanism involves interaction between the JIT middleware and the MAC layer.

In place of (17), the JIT middleware adjusts its transmission time for the \( i \)-th packet \( \hat{U}^J_{i,1} \) as follows:

\[
\hat{U}^J_{i,1} = \hat{U}^J_{i-1} + F + \tilde{n}_i, \quad i \geq 1,
\]

where \( \tilde{n}_i \) is a timing offset adjustment for the JIT pull signal for packet \( P_i \) computed based on feedback from the MAC layer. Specifically, based on the transmission of \( P_{i-1} \), we determine \( \tilde{n}_i \) as follows:

1) **Obtain and feed back the slack time \( ST_{i-1} \) of the packet \( P_{i-1} \)**: As illustrated in Fig.5, the JIT middleware sends a pull signal at time \( \hat{U}^J_{i-1} \) (w.r.t. the JIT clock) to the application layer. This triggers the generation of the packet \( P_i \). Upon receiving packet \( P_i \) from the application layer, the MAC layer retrieves the packet’s scheduled transmission time \( U^{MAC}_{i-1} \) (w.r.t. the MAC clock) and obtains the slack time \( ST_{i-1} \) (w.r.t. the MAC clock):

\[
ST_{i-1} = U^{MAC}_{i-1} - U^{Arr}_{i-1}, \quad i \geq 1,
\]

where \( U^{Arr}_{i-1} = U^{JIT}_{i-1} + D_{c,i-1} \) is the time when \( P_{i-1} \) arrives at the MAC layer. Note that although the MAC layer does not know \( \hat{U}^J_{i-1} \) and \( D_{c,i-1} \), it does know \( U^{Arr}_{i-1} \) since this is the time the packet arrives at the MAC layer according to the MAC clock. The MAC layer then feeds back \( ST_{i-1} \) to the JIT middleware.

2) **Set the target slack time \( ST_{target} \) for all packets at initialization**: The JIT middleware aims to achieve a target slack time \( ST_{target} \) at the MAC layer for all packets. As a conservative measure to avoid underflow at the MAC layer, we would like to set \( ST_{target} \) to the maximum preemption delay that the packet-generation process could encounter, explained as follows. We aim for a set-up such that in the worst case, when the packet \( P_i \) incurs the maximum preemption delay, it would still arrive at the MAC layer at time \( U^{MAC}_{i,1} \), just in time for it to be transmitted. Thus, if \( ST_j \) for different \( j \) hovers around \( ST_{target} \), and if a particular packet \( P_i, i > j \), suddenly incurs a worst-case preemption delay, it would still arrive at the MAC layer in time for its transmission, even if all the prior packets \( P_j, j < i \), incur the minimum preemption delay.

Since \( D_{c,i} \) for different \( i \) fluctuates with their instantaneous preemption delays, the maximum preemption delay is also the maximum time difference between the generations of two successive packets (other delay components being constant and the preemption delay being the only variable delay). To estimate the maximum preemption delay, the JIT middleware generates \( Q \) packets during initialization before real packet transmissions. For each of the packet generated, we monitor its start time and the end time, and calculate its processing delay. Since we can only use the software clock to obtain the start time of a software process, the processing delay we calculate in this way is specified in terms of the JIT clock. Let \( \tilde{D}_{c,q} \) denote the calculated processing delay using the JIT clock. We derive \( ST_{target} \) by

\[
ST_{target} = \max_{1 \leq q \leq Q, 1 \leq r \leq Q, \text{and } r \neq q} (\tilde{D}_{c,q} - \tilde{D}_{c,r}).
\]

In particular, \( ST_{target} \) approaches the maximum preemption delay when \( K \) is large.

3) **Determine the timing offset \( \tilde{n}_i \) for packet \( P_i \)**: With respect to the clock-offset issue, the JIT middleware needs to ensure that in the near future, \( ST_i \) does not deviate from \( ST_{target} \) too much. This is achieved by adjusting the timing offset \( \tilde{n}_i \) for packet \( P_i \). Specifically, we adjust \( \tilde{n}_i \) using the following dynamic equation:

\[
\tilde{n}_i = (1 - \alpha)\tilde{n}_{i-1} + \alpha(\hat{S}T_{i-1} - ST_{target}), \quad i \geq 1,
\]

where \( 0 < \alpha \leq 1 \) is a constant smoothing parameter.

For initialization, the JIT middleware sets \( \tilde{n}_0 = 0 \) for the packet \( P_0 \).

After deriving \( \tilde{n}_i \), the JIT middleware calculates \( \hat{U}^J_{i,1} \) using (21) and sends a pull signal at time \( \hat{U}^J_{i,1} \) to the application layer, asking for the next packet \( P_i \).

**Algorithm 1 Adaptive Synchronization Mechanism**

**Require**: \( ST_{target} \)

1: while \( \text{True} \) do
2: JIT middleware sends a pull signal at \( U^{JIT}_{i-1} \) for \( P_{i-1} \)
3: JIT middleware receives \( ST_{i-1} \) from MAC layer
4: \( \tilde{n}_i = (1 - \alpha)\tilde{n}_{i-1} + \alpha(\hat{S}T_{i-1} - ST_{target}) \)
5: \( \hat{U}^J_{i,1} = \hat{U}^J_{i-1} + F + \tilde{n}_i \)
6: \( i = i + 1 \)
7: end while
Algorithm 1 shows the pseudo-code of the adaptive synchronization mechanism. Note that in [24] \( S_{\text{target}} \) is specified in terms of the JIT clock. However, \( S_{\text{target}} \) in [23] is specified in terms of the MAC clock. Ideally, we would like them to be expressed in terms of the same clock, particularly when they are applied in [24]. We provide an analysis in Appendix A to show that, despite having these two terms expressed in terms of different clocks, our adaptive synchronization mechanism is still stable.

If we take \( U^{\text{JIT}}_j \) as the birth time of the information and take the term \( U^{\text{MAC}}_j - U^{\text{JIT}}_j \) as the Age-of-Information (AoI) of the information at the moment it is transmitted. We provide another analysis in Appendix B to show that our JIT system can have bounded AoI even if the JIT clocks and the MAC clock can drift apart.

### 4.2 JIT time-slot allocation in TDMA networks

We next consider issues related to time-slot allocation in a TDMA network when running the JIT system. Consider a server paired with \( N_c \) clients in the TDMA network. As related in Section 3, each client sends a request to the server. Upon receiving the request, the server sends back a response. Let \( C_j \) be the \( j \)-th client and \( S \) be the server. For clarity, we use another notation \( S_j \) to denote the server \( S \) when it communicates with client \( C_j \). Given a specific \( j, C_j \) and \( S_j \) together represent the \( j \)-th communication pair.

Let \( \Delta t \) be the duration of a time slot. We require that \( \Delta t = \max_j \max(T_{\text{PHY},c_j}, T_{\text{PHY},s_j}) \), where \( T_{\text{PHY},c_j} \) and \( T_{\text{PHY},s_j} \) are the \( j \)-th communication pair’s occupied airtime on the physical wireless medium from the client to the server and from the server to the client, respectively (see Section 3). For simplicity, we assume the request and response messages are of the same size. We further assume that the differences in the propagation delays of different communication pairs are negligible. We could then write \( T_{\text{PHY},c_j} = T_{\text{PHY},s_j} = T_{\text{PHY}} \), which is constant for different communication pairs. Thus, \( \Delta t = T_{\text{PHY}} \). To simplify discussion in the following, let us assume that all times are specified in terms of the time unit of one time slot. Thus, \( \Delta t = 1 \).

Let \( TS(C_j) \in \{0, ..., N-1\} \) be the time slot in TDMA rounds assigned to \( C_j \) and \( S_j \), where \( N \) is the number of time slots per TDMA round. At issue is the following question: what should be the pair of time slots \( \{TS(S_j), TS(C_j)\}_{j=0,1,...,N_c-1} \) allocated to the client-server pairs in order to minimize the response time of the client-server applications? To aid the understanding of the issue at hand, let us picture the progression of the time slots in successive rounds as a clockwise movement over a ring, as illustrated in Fig. 6(a), where we assume \( N = 10 \). For example, slot 1 follows slot 0; slot 0 follows slot \( N - 1 \). Recall in Fig. 6 that the JIT goal is to minimize \( T_2 - T_5 \) given the server processing delay \( D_s \). With \( \{TS(S_j), TS(C_j)\}_{j=0,1,...,N_c-1} \), the goal is equivalent to moving around the ring in a clockwise manner from \( TS(C_j) \) to \( TS(S_j) \) such that the number of time slots that has transpired is at least

\[
\tilde{\beta}_j = [D_{s,j}] + 1,
\]

where \( D_{s,j} \) is the \( j \)-th server’s worst-case processing delay.

Now, if \( \tilde{\beta}_j \geq N \), then the time slot \( TS(S_j) \) must be at a round that is later than the round at which time slot \( TS(C_j) \) is. That is, we may have to cycle around the ring a number of times. Overall, the time-slot allocation problem can be framed as an optimization problem to minimize the sum of the delays incurred by all the clients at the server, as follows:

\[
\min_{k_j, TS(S_j), TS(C_j), \forall j} \sum_{j=0}^{N_c-1} [k_j N + TS(S_j) - TS(C_j)],
\]

\[
s.t. \quad \min_{k_j} [k_j N + TS(S_j) - TS(C_j)] \geq \tilde{\beta}_j, \quad \forall j \in \{0, 1, ..., N_c - 1\},
\]

where \( k_j \) is the offset in rounds between the response and the request. This problem is equivalent to the problem as follows:

\[
\min_{TS(S_j), TS(C_j), \forall j} \sum_{j=0}^{N_c-1} \{TS(S_j) - TS(C_j)\} \mod N,
\]

\[
s.t. \quad \{TS(S_j) - TS(C_j)\} \mod N \geq \beta_j, \quad \forall j \in \{0, 1, ..., N_c - 1\},
\]

where \( \beta_j = \tilde{\beta}_j \mod N \). Note that \( TS(C_j) \) could be larger than \( TS(S_j) \) if the response is sent out at a TDMA round later than the TDMA round in which the request is received.

In the context of graph theory, our problem can be regarded as a vertex arrangement problem over indexes on a ring. Specifically, we can construct an undirected graph \( G(V, E) \) whereby the vertices are the client requests and the server responses. There is an undirected edge between the two vertices corresponding to the client request-server response pair \( j \), but there is no edge between vertices of different client request-server response pairs. The time slot assignment \( TS : V \rightarrow \{0, 1, ..., N - 1\} \) is an injective function from the vertices to the indexes (if there are \( N/2 \) client-server pairs i.e., \( N \) vertices then the function is a bijective function). The distance between a client request-server response pair under the injection is defined to be \( E_j = [TS(S_j) - TS(C_j)] \mod N \). The objective of the vertex arrangement problem is to minimize the sum distance \( \sum_j E_j \).

Ref. [21] studied a cycle-separation problem. As in our problem, the issue is arranging vertices over a ring (cycle). However, the definition of distance is \( E_j = \min([TS(S_j) - TS(C_j)] \mod N - [TS(S_j) - TS(C_j)]) \). That is, the distance is the smaller of the clockwise distance and the counter-clock distance from the client to the server on the ring. For our problem, the distance is always the clockwise distance from the client to the server. This makes our problem fundamentally different from that of [21].

Ref. [21] studied a directed separation problem where the arrangement of the vertices is over a line rather than a ring. The distance is defined to be \( E_j = TS(S_j) - TS(C_j) \). Again, the different definition of the distance makes this problem fundamentally different from ours.

#### 4.2.1 Optimal Packing - A Special Combinatorial Problem

Rather than going into the details of the general optimization problem here, let us consider a simplified set-up of the problem to gain some insights. Let us assume that there are \( N/2 \) client-server pairs, and that \( \beta_j = \beta \) for all \( j \).
4.2.2 General Optimal Packing Construction

We give a general method to construct optimal packing. Any optimal packing, if it exists, can be discovered by this general method. The method also tells us the condition under which optimal packing is possible and the condition under it is not possible. Consider time slots indexed by \(0, 1, \ldots, N-1\) on the ring, where \(N\) is even. From any index \(l, 0 \leq l \leq N-1\) on the ring, we can induce a subring by enumerating the indexes \((l, l+\beta) \mod N, (l+2\beta) \mod N, \ldots, (l+k\beta) \mod N\). Note that somewhere in this sequence, the index \(l\) must repeat, since there is only a finite number of indexes on the ring. Let \(k\) be the smallest integer such that \((l+k\beta) \mod N = l\). The period of this subring is said to be \(k\) and there are \(k\) unique indexes on the sequence.

Case 1:

If the period \(k = N\), the subring is the full ring. Fig. 6(b) illustrates the full ring induced in the case of \(l = 0\), \(\beta = 3\) and \(N = 10\). Any \(l \in \{0, \ldots, 9\}\) will induce the same full ring. With the full ring, we have found two possible optimal packings: \(\{(l, (l+\beta) \mod N), [(l+2\beta) \mod N, (l+3\beta) \mod N, \ldots, (l+(k-2)\beta) \mod N, (l+(k-1)\beta) \mod N]\} \) and \(\{(l+(k-1)\beta) \mod N, l\}, [(l+\beta) \mod N, (l+2\beta) \mod N, \ldots, (l+(k-3)\beta) \mod N, (l+(k-2)\beta) \mod N]\} \).

The first packing is to have time slot \(l\) as a client time slot, and the second packing is to have time slot \(l\) as a server time slot. There is no other possible optimal packing. The reason is simple. If we make time slot \(l\) a client time slot, then time slot \((l+\beta) \mod N\) must be a server time slot. This means time slot \((l+2\beta) \mod N\) must be a client time slot, and so on and so forth. By the same token, if we make time slot \(l\) a server time slot, then time slot \((l+\beta) \mod N\) must be a server time slot, and so on and so forth.

Case 2:

If the period \(k < N\) and \(k\) is odd, then optimal packing is not possible. Without loss of generality, suppose that we make time slot \(l\) a client time slot. Then time slot \((l+\beta) \mod N\) must be a server time slot, time slot \((l+2\beta) \mod N\) must be a client time slot, and so on and so forth. We will reach a conclusion that time slot \(l\) must also be a server time slot pairing with the client time slot \(N-\beta\), leading to a conflict. Fig. 6(c) shows the case of \(k = 2\), \(N = 10\). The subring induced by \(l = 0\) is \((0, 2, 4, 6, 8, 10)\). If we make time slot \(0\) a client time slot, then time slot \(8\) must be a client time slot, which implies that time slot \(0\) must also be a server time slot, leading to a conflict.

Case 3:

If the period \(k < N\) and \(k\) is even, then optimal packing is possible. There must be an index \(v\) not on the subring induced by index \(l\). This index \(v\) can induce another subring with \(k\) indexes that are distinct from the \(k\) indexes of the subring induced by index \(l\). By isomorphism, the period of the subring induced by \(v\) must exactly be the same as the period of the subring induced by \(l\) (i.e., on the ring there is no distinct difference between indexes as far as the situation that they are facing is concerned). The reason that these two subrings do not overlap is also obvious. If

We ask the following question: Under what setting, is it possible to have a bijection \(TS : V \rightarrow \{0, 1, \ldots, N-1\}\) such that \(E_j = \beta, \forall j \in \{0, 1, \ldots, N-1\}\)? Note that if this is possible, we have an optimal solution in that the distance between each client-server pair \(j\) meets the lower bound \(\beta\) exactly. We refer to such an optimal solution, if possible, as optimal packing. In the following, let us use the notation \((c, s)\) to denote the pair of time slots allocated to a client-server pair. For example, the following pairs give an optimal packing for the case of \(\beta = 3\) and \(N = 10\): \(\{(0, 3), (6, 9), (2, 5), (8, 1), (4, 7)\}\).
they have any overlapping index, then these two subrings will merge together to form a larger ring, contradicting the statement that index \( v \) is not on the subring induced by index \( l \). As long as the current subrings do not cover all the indexes \( 0, 1, \ldots, N - 1 \), we can discover a new subring with \( k \) indexes by inducing a subring from an indexes not yet in the existing subrings. Thus, in general, if \( k < N \), then there must be \( h \) subrings, each with \( k \) distinct indexes, where

\[ hk = N. \tag{32} \]

Proposition 2 states that the \( h \) subrings can be induced by indexes \( 0, 1, 2, \ldots, h - 1 \). On each subring, there are two possible packings. We can either let the subring-inducing index be a client time slot or a server time slot. Fig. 6(d) shows the five subrings for the case of \( \beta = 5, N = 10 \). The five subrings are \((0,5), (1,6), (2,7), (3,8), (4,9)\). Together, they cover all the indexes in the set \( 0, 1, \ldots, 9 \).

**Proposition 1.** Let \( 0 < k \leq N \) be the smallest integer such that \( k \beta \mod N = 0 \). \( \tag{33} \)

*Optimal packing is possible if and only if \( k \) is even.*

**Proof:** Obvious from the description of the above construction method. The \( h \) here is basically the period of the subring mentioned in the construction method.

**Proposition 2.** Suppose that for an \( N \) and a \( \beta \), we have \( h \) distinct subrings, each with \( k \) elements, \( hk = N \). The \( h \) distinct subrings can be found by inducing on index 0, index 1, \ldots, and index \( h - 1 \).

**Proof:** Consider two subrings induced by two arbitrarily chosen indexes \( e \) and \( f \), \( e, f \in \{0, 1, \ldots, h - 1\}, e \neq f \). If these two subrings were the same subring, then there would be two integers \( I_e \) and \( I_f \), \( I_e, I_f \in \{0, 1, \ldots, k - 1\} \), such that

\[ (e + I_e \beta) \mod N = (f + I_f \beta) \mod N \Rightarrow \tau + g_1 N = (I_e - I_f) \beta, \tag{34} \]

for some integer \( g_1 \), where \( \tau = f - e \neq 0 \). Furthermore, substituting \( 32 \) into \( 33 \), we have

\[ k \beta \mod kh = 0 \Rightarrow \beta = g_2 h, \tag{35} \]

for some integer \( g_2 \). Substituting \( 32 \) and \( 35 \) into \( 34 \), we then have

\[ \tau + g_1 kh = (I_e - I_f)g_2h, \tau = ((I_e - I_f)g_2 - g_1kh). \tag{36} \]

Given that \( 1 \leq \tau < h \), it is not possible for \( 36 \) to hold.

**4.2.3 What \( N \) for a TDMA system is the most flexible in terms of optimal packing?**

An interesting question arises from the above discussion. Suppose that we want optimal packing to be possible for all \( \beta < N \). What \( N \) will allow this? Recall from the previous discussion that we can map \( \beta \to \beta = \beta \mod N \) as far as time slot allocation is concerned. There is no loss of generality by considering \( \beta < N \).

**Corollary 1.** If \( N \) is a power of 2 (i.e., \( N = 2^n \) for some \( n \)), then optimal packing is possible with all \( \beta < N \). Conversely, if \( N \) is not a power of 2, then optimal packing is not possible for some \( \beta < N \).

**Proof:** We first prove the “if” part. First, suppose that \( \beta \) is odd. Then there is no common factor between \( \beta \) and \( N = 2^n \). The smallest \( k \) that can satisfy the condition in Proposition 1 must be \( k = N \), which is even. Therefore, all odd \( \beta \) allows for optimal packing.

Next, suppose that \( \beta \) is even. We can write \( \beta = a2^g \) for some integer \( g < n \) and for some odd integer \( a \). Thus, the common factor between \( \beta \) and \( N \) is \( 2^g \). The smallest \( k \) such that \( (33) \) is satisfied must be \( k = 2^n - g \). Since \( k \) is even, the condition in Proposition 1 is also satisfied.

We next prove the “only if” part (the converse). Since \( N \) is even, if \( N \) is not a power of 2, we can express it as \( N = m2^g \), where \( m \) is an odd integer larger than 1, and \( g \geq 1 \). Consider \( \beta = 2^g \). In this case, the smallest \( k \) that satisfies \( (33) \) is \( k = m \), which is odd. Thus, by Proposition 1, optimal packing is not possible with this \( \beta \) (note: in general, there could be other \( \beta \) for which optimal packing is not possible; this is just an example).

**5 JIT SYSTEM IMPLEMENTATION**

Our implementation is based on a modification of Openwifi [16], a free open-source IEEE 802.11 (Wi-Fi) SDR implementation on SoC platforms. Openwifi works on the Xilinx Zynq-7000 SoC that consists of a Field Programmable Gate Array (FPGA) and an ARM processor. Openwifi implements PHY and MAC functions with stringent latency requirements on FPGA [22]. The Openwifi driver for accessing these PHY and MAC functions, on the other hand, is implemented in the embedded Linux running on the ARM processor. The Openwifi driver sends packets to and receives packets from the MAC layer using the Advanced eXtensible Interface 4 (AXI-4), a parallel high-performance low-latency SoC software-hardware communication interface.

As with most Wi-Fi software implementations, the Openwifi driver instantiates Application Programming Interfaces (APIs) defined by the Linux mac80211 subsystem. Thanks to the modular design of Openwifi, researchers can study and modify this full-stack Wi-Fi implementation easily. Our modifications of Openwifi are described as follows.

To realize the JIT-triggered packet generation, we implemented the JIT middleware at the client into the Openwifi driver in the ARM processor with four realized functionalities as discussed in the following:

(i) **Registering application:** An application running in the userspace first needs to register with the JIT middleware so that the JIT middleware can send pull signals to the application. Specifically, a client application should register its unique process ID (PID) with the JIT middleware. Since the JIT middleware is implemented within the Openwifi driver...
running in the kernel, the client application uses ioctl to register its PID with the JIT middleware (see https://en.wikipedia.org/wiki/Ioctl for details on ioctl).

(ii) Scheduling pull-signal events: The JIT middleware uses a Linux’s high-resolution timer (hrtimer) with nanosecond resolution to schedule pull-signal events. The JIT system uses a reserved POSIX real-time signal as the pull signal. The reserved POSIX [25] real-time signals can be the SIGRTMIN through SIGRTMAX signals intended for use defined by the users. For each pull-signal event, the JIT middleware sends a pull signal to the client’s application using the SIGNAL Linux library.

(iii) Reacting to interrupt: The client’s application has a handler function. This handler function allows the client’s application to generate and send a new packet to the TDMA MAC layer (see Fig. 5) using the Openwifi driver API upon detecting the POSIX real-time signal.

(iv) Returning feedback information: Recall from the discussion in Section 4.1 that the MAC layer needs to return a calculated slack time to the JIT middleware. Thanks to the transmission-interrupt mechanism implemented by Openwifi in which the Openwifi driver always receives an interrupt after the TDMA MAC layer finishes a packet transmission. We use this interrupt mechanism to send the calculated slack time to the JIT middleware.

Note that the server does not need JIT middleware since the JIT-triggered packet generation mechanism is to reduce the extra client’s waiting time (see Section 3). We implemented a time-slotted TDMA MAC protocol on FPGA by overwriting the CSMA MAC protocol of Openwifi. In addition, we implemented a three-way handshake scheme based on precise time protocol (PTP) time to let each wifi. In addition, we implemented a three-way handshake on FPGA by overwriting the CSMA MAC protocol of Openwifi in which the Openwifi driver always receives an interrupt after the TDMA MAC layer finishes a packet transmission. We use this interrupt mechanism to send the calculated slack time to the JIT middleware.

6 EXPERIMENTAL RESULTS

As related in Section 3, the JIT system minimizes the application-to-application RTT for client-server applications. This is done by minimizing: i) server’s extra waiting time $W_s$ using the JIT time-slot allocation; ii) the client’s extra waiting time $W_c$ using the JIT-triggered packet generation. In the following, we perform experiments to evaluate our JIT system. We detail the experiment set-up in Section 6.1, present the JIT time allocation in Section 6.2, validate the JIT-triggered packet generation in Section 6.3, and present the application-to-application RTT results in Section 6.4.

6.1 Experiment set-up

As shown in Fig. 7, six ZYNQ boards (consisting of three Xilinx ZC706 dev boards, one ADRV9361-Z7035 board and two Xilinx zed boards [24]) were deployed as five client-server pairs. For Xilinx ZC706 dev boards and Xilinx zed boards, the AD-9361 RF evaluation boards of Analog Device Inc. were used to support wireless communication. In our experiment, Device 0 in Fig. 7 is the server, and the rest of the devices are clients.

Several settings that apply to this experiments are as follows: i) the payload size of request and response are the same; ii) the time duration of a time-slot is set to the same as that of request and response; iii) the server and clients make use of a non-real-time Linux OS. Other details related to the values of the system parameters are given in Table 1.

6.2 Deployment of JIT time-slot allocation mechanism

The time slots preallocated to the five client-server pairs are determined as follows:

(i) Obtain server processing delay $D_s$; Given the above time slot duration $\Delta t$ of our system, we find that our platform is such that the server processing delay is within one time slot, i.e., $0 < D_s < \Delta t$.

(ii) Derive inter time-slot parameter $\beta$; With $0 < D_s < \Delta t$, we derive that $\beta = 2$ from [25].

(iii) Allocate time slots: The time-slot pairs allocated to the five client-server pairs are $(0, 2)$, $(1, 3)$, $(2, 4)$, $(3, 5)$ and $(4, 6)$. Note that this is only one possible solution and that we are using five out of the 32 possible time-slot pairs in our experiments. Note also that in the context of the discussion in Section 4.2 we have two subrings over the TDMA slots given $\beta = 2$.

3. Before this experiment, we pre-estimated the maximum preemption delay $ST_{target}$ on the client as discussed in Section 4.1 and we set $ST_{target} = 30\(\mu s\)$.  

2. The PTP algorithm of the scheme is the same as that of [18]. Time synchronization error of our JIT system is in the order of micro IQ-sample time.
6.3 Validation of JIT-triggered packet generation mechanism

This subsection investigates whether the JIT-triggered packet generation can minimize $W_c$ in the face of the clock offset and timing imprecision. We benchmark our JIT system against a baseline system without the JIT-triggered packet generation mechanism. We describe the similarities and differences between the JIT system and the baseline system below:

**Similarities**

- The client’s TDMA MAC layer schedules one request transmission per TDMA frame using the MAC clock.
- Upon receiving a request, the server generates a response.
- The server’s TDMA MAC layer schedules one response transmission per TDMA frame using the MAC clock.

**Differences**

- In the JIT system, the client’s JIT middleware schedules one pull-signal event per TDMA frame using the JIT clock. A request is generated by the client’s application if and only if the client’s application is interrupted by the pull signal.
- In the baseline system, there is no pull signal. The client’s application itself schedules one request generation per TDMA frame using the JIT clock.

For a comprehensive investigation on the clock-offset issue, we compare the JIT system and baseline system under three different *controlled* settings on the clock tick rates: i) in setting 1, the JIT clock and the MAC have the same tick rate; ii) in setting 2, the JIT clock ticks more slowly than the MAC clock; iii) in setting 3, the JIT clock ticks faster than the MAC clock. For setting 2 (setting 3), we assume that the clock tick rate difference in the two clock systems is a small constant value $+0.0005\%$ ($-0.0005\%$). Most oscillators, including low-cost oscillators, have frequency accuracy better than this specification.

In practice, we cannot directly control the relative tick rates of the JIT clock and MAC clock in a general framework (see Section 4.1). However, our JIT system design is based on the Openwifi design in which the same clock source is used to drive the Linux OS and the communication layer, and there will be no asynchrony between the two clocks. Thus, for the study of the general framework, we simulated the settings in an artificial way. First, setting 1 requires no further effort since the ZYNQ boards are SoC evaluation boards in which the JIT clock and MAC clock share the same clock oscillator and tick at the same rate. To simulate the clock tick rate differences in both settings 2 and 3, we performed some adjustments as follows: i) in the JIT system, the initial TDMA frame duration of the client’s JIT middleware was adjusted to 9.6048ms and 9.5952ms to simulate $-0.0005\%$ and $0.0005\%$ clock tick rate differences.

4. If we deploy an embedded system design like Openwifi, we do not need to address the clock-offset issue discussed in Section 4.1. However, we still need the JIT middleware to address the time-imprecision issue due to preemption delays described in Section 4.1. As we will see in Section 6.3 and Section 6.4, the system could still suffer from large extra client’s waiting-times if the time-imprecision issue is not addressed.

We expect the JIT-triggered packet generation of the JIT system can still make sure that, on average, the pull-signal period is still 9.6ms for both settings 2 and 3. For clarity, we use the notation $\text{JITsystem}_a$ and the notation $\text{Baseline system}_a$ to denote the JIT system and the baseline system in the setting $a$, respectively. Meanwhile, since a non-real-time OS was deployed, both the JIT system and baseline system for all three settings could experience preemptions from other tasks. Hence, this experiment could also investigate the effect arising from the timing-imprecision issue. Without loss of generality, we use pair 1 with time-slot pair (0, 2) for the investigation.

In a general full-stack Wi-Fi system, a packet generated by an upper layer will first be stored in a FIFO buffer at a lower layer, waiting to be retrieved by a process at the lower layer for transmission. For example, in the design of Openwifi, a packet sent by the ARM first arrives at a transmission FIFO buffer in the FPGA. This packet is later retrieved by the MAC layer for RF transmission. Fig. 8 plots the number of packets in the transmission FIFO buffer for the JIT system and baseline system (the y-axes) when the time slot allocated to the client comes along (the x-axes). To avoid cluttering, Fig. 8 only plots the buffer occupancy once every 100 TDMA frames. We can see from Fig. 8 that:

(i) Both $\text{Baseline system}_1$ and $\text{JIT system}_1$ hold one packet in the transmission FIFO buffer all the time.

(ii) In $\text{Baseline system}_2$, the number of packets in the transmission FIFO buffer wraps from 0 to 1 repeatedly. The FIFO buffer may underflow in $\text{Baseline system}_2$ when the transmission opportunity comes along at the TDMA MAC layer, there is no packet in the FIFO buffer. In contrast, $\text{JIT system}_2$ holds one packet all the time.

(iii) In $\text{Baseline system}_3$, the number of packets in the transmission FIFO buffer keeps increasing. The FIFO buffer overflows in $\text{Baseline system}_3$. However, $\text{JIT system}_3$ still holds one packet all the time.

The $W_c$ in $\text{Baseline system}_3$ will eventually go to infinity, leading to an unbounded application-to-application RTT. In particular, $\text{Baseline system}_3$ could crash due to the FIFO buffer overflow. Therefore, we bypass the experimental results of $\text{Baseline system}_3$ going forward.

We next show the $W_c$ of the JIT system and baseline system (except $\text{JIT system}_3$) in Fig. 9. In Fig. 9(a), we only plot the $W_c$ once for every 100 TDMA frames. From Fig. 9(a), we have the following observations:

(i) The $W_c$ of $\text{JIT system}_1$, $\text{JIT system}_2$ and $\text{JIT system}_3$ are stable and roughly the same.

(ii) The $W_c$ of $\text{Baseline system}_2$ wraps from the minimum to the maximum repeatedly. A packet may arrive at the FIFO buffer just slightly after the last transmission opportunity. In particular, the $W_c$ in $\text{Baseline system}_2$ ranges from 0 to the value of one TDMA frame duration.

(iii) $\text{Baseline system}_1$, without the clock-tick rate difference, has a more stable $W_c$ compared with that of
Fig. 8. The number of packets in the transmission FIFO buffer. Note that the points for JITsystem\textsubscript{1}, JITsystem\textsubscript{2}, JITsystem\textsubscript{3}, and Baselinesystem\textsubscript{1} overlap – the buffer occupancy stays constant at 1 throughout.

Baselinesystem\textsubscript{2}. However, unlike the other systems, Baseline systems or JIT systems, the $W_c$ obtained in each experimental trial of Baselinesystem\textsubscript{1} can be different and subject to randomness. For example, Fig. 9 (a) shows the results of three experiments for Baselinesystem\textsubscript{1}. These observed results are explained as follows. For Baselinesystem\textsubscript{1}, the moment the application layer generates a packet is not synchronized to the moment of the next transmission opportunity. Within the same experiment, the offset in packet-generation time and transmission opportunity is constant throughout since the application layer and the MAC layer use the same clock. However, the offset itself is random from experiment to experiment. Thus, depending on this random offset, the $W_c$ experienced is also random and ranges from zero to one TDMA frame duration. Overall, the average value of Baselinesystem\textsubscript{1}’s $W_c$, which is half of a TDMA frame duration, is much larger than the stable $W_c$ of JITsystem\textsubscript{1}.

This result convinces us that the JIT-triggered packet generation mechanism maintains good synchronization between the JIT middleware and the TDMA MAC layer, addressing the clock-offset issue and ensuring each packet can be transmitted at the desired time.

To have a closer look at the shorter-term fluctuations in $W_c$, Fig. 9 (b) plots $W_c$ once every TDMA frame. We can see that despite the jitter of the fluctuations of processing delays due to preemptions, the $W_c$ of the JIT system only fluctuates within a small range around 30\,$\mu$s (the value of $ST_{target}$). This result is consistent with the discussion in Section 4.1. The experimental results confirm that the JIT system is robust against preemption jitters: it effectively addresses the timing-imprecision issue and keeps $W_c$ stable at the target slack time $ST_{target}$.

6.4 Application-to-Application RTT Evaluation

This subsection first investigates how $W_c$ affects the application-to-application RTT of the JIT system and the baseline system. To obtain the application-to-application RTT, we logged two kinds of timestamps on the client’s Linux system: the time when the client’s application starts to generate a request packet, denoted by $T_{start}$, and the time when the client’s application receives the corresponding response packet, denoted by $T_{end}$. The application-to-application RTT for a client-server application is $RTT = T_{end} - T_{start}$.

In this experiment, both the baseline system and JIT system use JIT time-slot allocation. And we again use client-server pair 1 assigned with the time-slot pair (0, 2) for the investigation. Fig. 10 plots the $RTT$ once every 100 TDMA frames. We have the following observations:

(i) Having a stable $W_c$, JITsystem\textsubscript{1}, JITsystem\textsubscript{2} and JITsystem\textsubscript{3} all have small and stable $RTTs$.
(ii) The $RTT$ of Baselinesystem\textsubscript{2} drifts with time due to the varying $W_c$. In particular, the maximum value of
the $RTT$ in Baselinesystem$_2$ could be more than one TDMA frame duration.

(iii) Recall that the $W_c$ of Baselinesystem$_1$ can change from experiment to experiment. Thus, the $RTT$ can also change from experiment to experiment. In Fig. 10, we plot the average $RTT$ of Baselinesystem$_1$ among these experiments. As shown, the average $RTT$ of Baselinesystem$_1$ is much larger than the stable $RTT$ of JITsystem$_1$.

Note that even with the use of JIT time-slot allocation here, the $RTTs$ of all the three baseline systems are still larger than that of the JIT systems. If the baseline systems did not use the JIT-time slot allocation, then their $RTTs$ would be even larger due to the effect of $W_c$. For example, if we assign the time-slot pair $(0, 1)$ to the two baseline systems, then their $RTT$ will increase by 62 TDMA slots (around one TDMA frame) which is $9.3ms$ in our system. This case corresponds to the case in which the conventional networking system has the worst-case maximum possible server’s waiting time $W_s$, as shown in (5) of Section 3. In short, the worst-case $RTT$ of baseline systems depends on the TDMA frame duration. The larger the TDMA frame duration a baseline system has, the larger the worst-case $RTT$. However, this situation does not happen in our JIT system. That is, the $RTT$ of our JIT system is independent of the TDMA frame duration. As seen in Fig. 10, the $RTT$ of the JIT system is stable at around $510µs$.

We further decompose this $510µs$ of $RTT$ into several components as listed in the following:

(i) $30µs$ for the client to generate a request packet, as given in Table 1.

(ii) $30µs$ of the target slack time $ST_{target}$ for each request packet. Note that the value of $ST_{target}$ depends on the maximum preemption delay that a system could experience.

(iii) $450µs$ of the elapsed time between a request packet transmitted by the client at the beginning of time slot 0 and the corresponding response packet received by the client at around the end of time slot 2.

(iv) Some other minor time that the client took to return the response back to the application.

The above discussions indicate that the JIT system as we implemented has achieved the minimum possible $RTT$.

In summary, the JIT system enables synchronized JIT-triggered packet generation with which a packet can be sent shortly after being generated by the application. Together with an optimal time-slot allocation derived from our JIT time-slot allocation scheme, our JIT system pushes the application-to-application $RTT$ of a client-server application to the limit.

7 Conclusion

Due to loose coordination between the communication and application layers, client-server applications running on conventional networking systems could suffer from large request-response latency. This round-trip latency includes the extra waiting time incurred by the request while it waits for a transmission opportunity at the client side, and the extra waiting incurred by the response while it waits for a transmission opportunity at the server side. What is even worse for the conventional networking systems is that, in a TDMA system, these two extra waiting times depend on the duration of the TDMA frame: the larger the TDMA frame, the larger the worst-case request-response latency the client-server application can suffer from.

To reduce request-response latency, we put forth a JIT framework with two mechanisms to minimize the two extra waiting times: i) a JIT-triggered packet generation at the client side to inform the client application of an upcoming transmission opportunity so that the client application can generate a just-in-time request; ii) a JIT time-slot allocation that caters to the delay in between the reception of the request and the arrival of the response at the communication layer at the server, so that when the response is generated by the server application, there is a just-in-time transmission opportunity to send out the response. Our mathematical analysis indicates that: i) the total extra waiting times in conventional networking systems can be as large as two times the duration of the TDMA frame; ii) the JIT-triggered packet generation mechanism is robust against the preemption delay in multitasking software architecture and against the timing offset among different system components; iii) a TDMA network with a power-of-2 time slots per superframe is optimal for realizing the JIT time-slot allocation.

We implemented our JIT system on the Xilinx SoC platform. The experimental results validate our analysis, and show that: i) the total extra waiting times in our JIT framework does not depend on the duration of the TDMA frame and only fluctuates within a small range; ii) the JIT system can achieve the minimum achievable application-to-application $RTT$. We believe that our JIT framework provides a useful paradigm for many time-sensitive industrial network applications with very stringent latency requirements for client-server interactions.
**APPENDIX A**

**Proof of Clock-Tick Difference Compensation and Stability**

In the following, we show that the adaptive synchronization mechanism in our JIT-triggered packet generation can compensate for this clock-tick difference and is stable. We first modify \( \tau \) to a more convenient form in (37) for later analytical development. Specifically, substituting (15) and (37) into (38), we have

\[
U_{i}^{JIT} = U_{i-1}^{JIT} + (o_{i-1} - o_{i}) + F + \hat{n}_{i}, i \geq 1. \tag{37}
\]

From (20), we have

\[
ST_{i} = U_{i}^{MAC} - (U_{i}^{JIT} + D_{c,i}). \tag{38}
\]

Substituting (15) and (37) into (38), we have

\[
ST_{i} = (U_{i-1}^{MAC} - U_{i-1}^{JIT}) - ((o_{i-1} - o_{i}) + \hat{n}_{i} + D_{c,i}) \tag{39}
\]

\[
= (ST_{i-1} + D_{c,i-1}) - ((o_{i-1} - o_{i}) + \hat{n}_{i} + D_{c,i}) \tag{40}
\]

\[
= ST_{i-1} + \Delta o_{i} - \hat{n}_{i} - \Delta D_{c,i}, i \geq 1. \tag{41}
\]

where \( \Delta o_{i} = o_{i} - o_{i-1} \) and \( \Delta D_{c,i} = D_{c,i} - D_{c,i-1} \). From (41), we also have

\[
\hat{n}_{i} = \begin{cases} 
  a(ST_{i-1} - ST_{\text{target}}) & n = 1 \\
  a(ST_{i-1} - ST_{\text{target}}) + a(1 - a)(ST_{i-2} - ST_{\text{target}}) + \ldots & n > 1 \\
  + a(1 - a)^{n-1}ST_{0} - ST_{\text{target}} & \end{cases} \tag{42}
\]

In general, we see that the deviation \( \hat{ST}_{i} \) fluctuates with the instantaneous clock offset increment \( \Delta o_{i} \) and the instantaneous preemption delay increment \( \Delta D_{c,i} \). We next show that the system is stable.

First, define our system input as \( x_{i} = \Delta o_{i} - \Delta D_{c,i} \) and our system output as \( y_{i} = ST_{i} \). Then, we can rewrite (42) in the form of difference equations as

\[
y_{i} = \begin{cases} 
  x_{i} + (1 - a)y_{0} & i = 1 \\
  x_{i} + (1 - a)y_{i-1} - a \sum_{j=0}^{i-2} (1 - a)^{i-j-1}y_{j} & i > 1 \\
\end{cases} \tag{43}
\]

where \( y_{0} = ST = C < \infty \) is the initial state of the system.

From (43), we can see that this system is a discrete-time linear feedback system where the output is generated not only from the input but also from the previous outputs. From (43), we can write the \( z \)-transform of the system response as

\[
H(z) = \frac{Y(z)}{X(z)} = \frac{1}{1 - (1-a)z^{-1} + a(1-a)z^{-2} + a(1-a)z^{-3} + \ldots} = \frac{1}{1 - z^{-1} + az^{-2}} = \frac{z^{-2} - (1-a)z^{-1} + (1-a)}{z^{-2} - (1-a)z^{-1} + (1-a)} \tag{45}
\]

From (45), we can derive the \( Z \)-plane’s poles \( r_{1} = (1 - a) + j\sqrt{a(1-a)} \) and \( r_{2} = (1 - a) - j\sqrt{a(1-a)} \). Since the input signal of our system \( x_{i} \) is a right-sided sequence and is rational, the region of convergence (ROC) of our system is the region in the \( z \)-plane outside the outermost pole. Also, since \( |r_{1}| = |r_{2}| < 1 \), our system’s ROC includes the unit circle. According to the stability sufficient condition (25), our system is hence stable. Furthermore, if \( x_{i} = \Delta o_{i} - \Delta D_{c,i} = \Delta \) is constant, \( ST_{i} \) will finally converge to \( \Delta + ST_{\text{target}} \).

**APPENDIX B**

**Proof of bounded AoI**

In the following, we show that the adaptive synchronization mechanism in our JIT-triggered packet generation can have bounded AoI (49) even if the JIT clock and the MAC clock are not synchronized and can drift apart.

Recall that \( U_{i}^{JIT} \) is the time when the system generates a pull signal for requesting the information, \( U_{i}^{MAC} \) is the time when the system transmits the information, and \( U_{i}^{MAC} - U_{i}^{JIT} \) is the AoI of the information at the moment it is transmitted. When the system reaches convergence where \( ST_{i} = \Delta + ST_{\text{target}}, \) from (48) we have \( U_{i}^{MAC} - U_{i}^{JIT} = \Delta + ST_{\text{target}} + D_{c,i} = \Delta o_{i} + D_{c,i-1} + ST_{\text{target}} \). If \( \Delta o_{i} - \Delta D_{c,i} = \Delta \) is constant, we have two particular extreme cases in terms of the system’s AoI:

(i) If \( \Delta D_{c,i} = 0 \) and \( \Delta o_{i} = \Delta \), the system has no jitter in preemption delay and \( U_{i}^{MAC} - U_{i}^{JIT} \) is constant. In this case, the system’s AoI is fixed.

(ii) If \( \Delta D_{c,i} = -\Delta \) and \( \Delta o_{i} = 0 \), \( U_{i}^{MAC} - U_{i}^{JIT} \) drifts with \( D_{c,i-1} \). In particular, when \( \Delta D_{c,i} = -\Delta \geq 0 \), \( U_{i}^{MAC} - U_{i}^{JIT} \) increases as the value of preemption delay increases. In this case, the system’s AoI becomes larger and larger even though \( ST_{i} \) converges.

In general, if the preemptive delay is bounded, case (ii) is only a hypothetical scenario. The discussion of case (i) indicates that the system can have bounded AoI even if the JIT clock and the MAC clock can drift apart. That is, our system can deal with the clock asynchronies between two different clock systems.

**APPENDIX C**

**JIT in CSMA networks**

This appendix considers what if a CSMA network is used instead of a TDMA network. Instead of a deterministic JIT system, we can aim for a probabilistic JIT system, since the underlying network does not guarantee communication resources to the users. For CSMA networks such as Wi-Fi, the MAC layer has a back-off counter to regulate when a node gets a transmission opportunity. When the counter value reaches zero, then the node gets to transmit. For JIT principle A, when the counter reaches a value equivalent to the max turn-around time for the application to generate a packet and deliver it to the PHY layer, then the JIT middleware can send a pull signal to the application layer. This maneuver is probabilistic in that the counter may still get frozen because the node senses another node transmitting before the counter value reaches zero. In this case, the packet would have arrived at the PHY layer too early. However, we...
remark that using the probabilistic JIT pull is still better than not using it. If the application layer just pushes data to the MAC layer regardless of the counter value, and if a packet arrives at the MAC layer with a large counter value, the chances for the counter to be repeatedly frozen by a series of packets would be even higher, resulting in an even higher wait time at the MAC layer.

For JIT principle B, a possibility is to set the counter value at the server to correspond to the maximum turnaround time for the server to process the request and generate a response to be delivered to the MAC layer. That is, upon receiving a response packet, the counter value is set to this value. Again, this is a best-attempt probabilistic maneuver.

Yet another approach is to redesign the back-off mechanism of the CSMA network (assuming it only supports one server and multiple clients as in our use case here) so as to minimize the delay experienced by the client and the delay experienced by the server, taking into account the JIT mechanisms. This line of work awaits future investigation.

In general, we believe that the JIT principles are applicable to all networks in which (i) the MAC layer of a client has a sense of when the next transmission opportunity may be upcoming (for JIT principle A), and (ii) the MAC layer of the server has a certain priority in scheduling the next transmission opportunity for itself (for JIT principle B). For example, a network that allocates resources based on polling or reservation can also adopt the JIT principles.
