

Designing a Competitive Monotone Signaling Equilibrium*

Seungjin Han[†] Alex Sam[‡] Youngki Shin[§]

September 4, 2021

Abstract

A decision maker (DM) determines a set of reactions that receivers can choose before senders and receivers move in a generalized competitive signaling model with two-sided matching. The DM's optimal design of the unique stronger monotone signaling equilibrium (unique D1 equilibrium) is equivalent to the choice problem of two threshold sender types, one for market entry and the other for pooling on the top. Our analysis sheds light on the impacts of a trade-off between matching efficiency and signaling costs, the relative heterogeneity of receiver types to sender types, and the productivity of the sender's action on optimal equilibrium designing.

1 Introduction

We study an equilibrium design problem¹ faced by the decision maker (DM) (e.g., a government or a policy maker) who can choose the set of feasible reactions before senders and receivers move in a generalized Spencian competitive signaling

*We thank Maxim Ivanov for his comments and suggestions. Han and Shin gratefully acknowledge support from the Social Sciences and Humanities Research Council of Canada, respectively.

¹We use the term, "equilibrium design" because the DM's choice of the set of feasible reactions affects the endogenous formation of the belief on the sender's type.

(Spence (1973)) with two-sided matching. In our model, there is a continuum of heterogeneous senders and receivers (e.g., sellers and buyers, workers and firms, and entrepreneurs and investors) in terms of their types. The DM is interested in maximizing the aggregate net surplus. She moves first by publicly announcing the set of feasible reactions that receivers can take. After that, senders take actions, followed by receivers' reaction choices as they are matched with senders. For example, the policy maker may announce the set of feasible transfers that firms can make to their employees. After that but prior to entering the job matching market, workers (senders) make investments in observable characteristics such as education. Once firms and workers enter the market, they form one-to-one matches as a firm offers its employee a wage (reaction). In a competitive signaling equilibrium, the market wage function that specifies a worker's wage conditional on her observable characteristics clears the matching market.

Signaling creates a trade-off in matching markets. It increases matching efficiency because separating induces assortative matching. It can also increase the sender's productivity to a certain extent unless signaling is a pure waste of resources. On the other hand, it is costly in that senders need to choose inefficiently high levels of equilibrium actions in order to separate themselves. Depending on which effect is dominant, a non-separating equilibrium can be more efficient.

Given the multiplicity of signaling equilibrium, we can apply Criterion D1 for restricting the receiver's off-path beliefs (Cho and Kreps (1987), Banks and Sobel (1987)). Cho and Sobel monotonicity of beliefs² (Cho and Sobel (1990)), a partial implication of Criterion D1, is instrumental for the selection of a separating equilibrium as a unique D1 equilibrium: Among those who chose the same action, the highest sender type always has a profitable upward deviation given Cho and Sobel monotonicity, so a pooled action cannot be sustained in a D1 equilibrium.

However, this argument only works when a receiver can reward such an upward deviation with a higher level of a reaction given his belief. One of difficulties the DM faces in optimal D1 equilibrium design is that if the upper bound of feasible reactions that he chooses is so low that there is no separating equilibrium, then Cho and Sobel monotonicity is not enough to derive D1 equilibria. Therefore, it

²Suppose that an action s is chosen by some sender type t on the equilibrium path. Cho and Sobel monotonicity means that a receiver should believe that $s' > s$ is not chosen by a lower sender type than t .

is not clear if there exists a unique D1 equilibrium in the absence of a separating equilibrium.

We first uncover the monotonicity of beliefs that is equivalent to Criterion D1 in terms of the stronger set order (Shannon (1995)). We establish the Stronger Monotone Signaling Equilibrium Theorem: Given monotonicity and single crossing properties of utility functions, any competitive signaling equilibrium is stronger monotone (i.e., equilibrium actions, reactions, beliefs and matching are monotone in the stronger set order if and only if it passes Criterion D1). In contrast to Cho and Sobel monotonicity, the stronger monotonicity of beliefs pins down a unique belief on the sender type conditional on any off-path action. Therefore, we can derive all stronger monotone equilibria (i.e., all possible D1 equilibria) as we vary the set of feasible reactions.

If utility functions are quasilinear and receivers can randomize their reactions, it reduces the DM's choice set significantly. She can only focus on intervals as the set of feasible reactions that she chooses without loss of generality.³ We introduce a well-behaved stronger monotone equilibrium given an interval of feasible reactions that the DM chooses. A well-behaved equilibrium is characterized by the two threshold sender types. The lower threshold sender type specifies the lowest sender type who enters the market, whereas any sender above the upper threshold sender type pools their actions. Any sender between the two threshold types separates themselves. If the two threshold types are the same, it becomes a pooling equilibrium. If the upper threshold type is the supremum of the sender types and greater than the lower threshold type, it becomes a separating equilibrium. If the upper threshold type is less than the supremum of the sender types but greater than the lower threshold type, it is a (strictly) well-behaved equilibrium, where separating and pooling coexist.

Given an interval of feasible reactions, we show that a stronger monotone equilibrium is unique and well-behaved. Therefore, the aggregate net surplus is a function of the two threshold sender types in a unique stronger monotone equilibrium. We show that in terms of the DM's point of view, choosing the two threshold types is equivalent to choosing the lower and upper bounds of the interval of feasible reactions. This makes the DM's unconstrained design problem for an optimal stronger monotone equilibrium equivalent to the design problem for an optimal stronger

³We allow the lower and upper bounds of the interval the DM chooses to be the same. In this case, the interval shrinks to a singleton.

monotone equilibrium where the DM chooses the two threshold sender types. Once she finds them out, she can retrieve the corresponding upper and lower bounds of feasible reactions that uniquely induce them.

For the optimal equilibrium design, we propose an approach that approximates the distribution of receiver types with “shift” and “relative spacing” parameters given an arbitrary distribution of sender types. We conduct substantive numerical analyses by applying various beta distributions on sender types and changing the productivity of sender action and relative spacing parameters. Note that it is optimal to set the lower threshold sender type equal to the lowest sender type in a separating equilibrium. However, it is not certain if the same argument holds in a non-separating well-behaved equilibrium because raising the lower threshold sender type also raises the pooled action chosen by sender types above the higher threshold: If the initial pooled action is lower than the (interim) efficient action for some senders who choose the pooled action, raising the lower threshold sender type may increase the efficiency for those senders’ action choice. The numerical analyses show that this is not the case and the DM always choose the lower threshold sender type equal to the lowest sender type in a non-separating well-behaved equilibrium.

The numerical analyses also show that the upper threshold sender type in the optimal equilibrium design increases in the productivity of sender action and the relative heterogeneity of receiver types. Matching efficiency increases as higher type senders separate themselves with higher action choices. However, this incurs inefficiently high costs. When the productivity of sender action and the relative heterogeneity of receivers are low, the cost of signaling outweighs matching efficiency. Thus, it is optimal to impose a binding upper bound of feasible transfers, leading to a pooled action by sender types above the upper threshold sender type.

As the productivity of sender action and the relative heterogeneity of receiver types increase, the matching efficiency becomes more important and it increases the upper threshold sender type in the DM’s optimal equilibrium design. As a result, the optimal well-behaved equilibrium eventually converges to the separating equilibrium. However, the convergence speed is quite slow and we observe a non-separating well-behaved equilibrium (i.e., the upper threshold sender type less than the highest sender type) as the optimal equilibrium in a wide range of values for the productivity of sender action and the relative heterogeneity of receivers.⁴

⁴The productivity of sender action is captured by its power $a \in (0, 1)$ in the surplus function.

For all beta distributions considered, the gain in the aggregate net surplus in the optimal well-behaved equilibrium relative to that in the separating equilibrium with no restrictions on feasible reactions increases monotonically as the productivity of sender action is lower and the relative heterogeneity of receivers is lower. Further, we find that the relative surplus gains by the first-order stochastically dominating distribution are uniformly larger than that by the dominated one.

Regardless of the type distribution (beta or not), a non-separating stronger monotone equilibrium is always more efficient than the stronger monotone separating equilibrium when the relative heterogeneity of receiver types to sender types and the productivity of sender action are not too large. It implies that a separating equilibrium is not optimal in the classical Spencian model of pure signaling with no heterogeneity of receivers (Spence 1973).

Related literature Our paper opens a new research direction to the stronger monotone equilibrium design and contributes to the literature on several fronts. While the literature has studied monotone equilibrium, exploring complementarities between actions and types, they mostly focus on games with simultaneous moves and no signaling (Athey (2001), McAdams (2003), Reny and Zamir (2004), Reny (2011), Van Zandt and Vives (2007)). Our Stronger Monotone Signaling Equilibrium Theorem is the first fully-fledged monotone equilibrium theorem in a model with sequential moves and signaling.

Recently, Liu and Pei (2020) derive the monotonicity of a sender’s equilibrium strategy in a two-period signaling game between one sender and one receiver with an assumption similar to our assumption on the sender’s utility function. However, our paper differs from theirs because ours shows (i) the equivalence between Criterion D1 and stronger monotone beliefs and its implication and (ii) the monotonicity of equilibrium matching given a monotonicity and a single crossing assumption on the receiver’s utility. Mensch (2020) shows the existence of an equilibrium where players’ strategies and beliefs are both monotone in a multi-period signaling game with multiple players and totally ordered signal spaces. However, he does not show the relation between monotone beliefs and equilibrium refinement and its implication

Even when (i) $a = 0.99$ and (ii) the heterogeneity of receiver types is ten times higher than that of sender types, the upper threshold sender type in the optimal well-behaved equilibrium in each of all shape parameter pairs for the beta distribution ranges from 0.981 to 0.988, so it is not the separating equilibrium.

on deriving all stronger monotone equilibria. It is the most important that we let the DM choose a set of feasible reactions before senders and receivers move while Liu and Pei (2020) and Mensch (2020) do not. We propose a general method that the DM can use for designing an optimal unique stronger monotone equilibrium.

Pre-match investment competition studies whether pre-match competition to match with a better partner can solve the hold-up problem of non-contractible pre-match investment that prevails when a match is considered in isolation (e.g. Grossman and Hart (1986) and Williamson (1986)). Cole, Mailath, and Postlewaite (1995), Rege (2008), and Hoppe, Moldovanu, and Sela (2009) consider pre-match investment with incomplete information and non-transferable utility without monetary transfers (i.e., no reaction choice by a receiver). Therefore, the sender-receiver framework does not apply. Pre-match investment with incomplete information in Hopkins (2012) includes the transferable-utility case but with no restrictions on transfers. A separating equilibrium is their focus.

2 Preliminaries

For any x and y in a partially ordered set Y with a transitive, reflexive, and anti-symmetric order relation \geq , let $x \vee y$ denote the least upper bound, or join, of x and y in Y if it exists and let $x \wedge y$ denote the greatest lower bound, or meet, of x and y in Y if it exists. The set Y is a lattice if for any $x, y \in Y$, the join $x \vee y$ and meet $x \wedge y$ exist as elements of Y . A partially ordered set Y is a chain if it does not contain an unordered pair of elements.

There are two distinct sets of senders and receivers. They can be interpreted as sellers and buyers, workers and firms, or entrepreneurs and investors. Receivers and senders are all heterogeneous in terms of types. A receiver's type is denoted by $x \in X$ and a sender's type by $z \in Z$. An agent's type is his or her own private information. For example, a worker's type is her ability that affects her productivity, whereas a firm's type is his production technology. For all $X' \subset X$, let $H(X')$ be the measure of receivers whose type is in X' . For all $Z' \subset Z$, let $G(Z')$ be the measure of senders whose type is in Z' . The total measures of senders and receivers are normalized as one.

Each sender can take an (observable) action s from a set S prior to matching.

As a sender and a receiver form a match, the receiver takes reaction t from a set T given his partner's action. For example, workers (senders) choose education s before entering market. A worker and a firm are matched as the worker accepts the firm's wage offer t .

Let $u(t, s, z)$ be the utility for a sender of type z when she chooses action s and her partner takes reaction t . The utility for a receiver of type x is $g(t, s, z, x)$ when he takes reaction t and is matched with the type z sender with action s .

In the example with workers and firms, the utilities for a sender (worker) of type z and a receiver (firm) of type x are $u(t, s, z) = t - c(s, z)$ and $g(t, s, z, x) = v(x, s, z) - t$, respectively. Note that t is the monetary transfer from a firm to his worker, $c(s, z)$ is the cost of choosing education $s \in S$ for a worker of type z , and $v(x, s, z)$ is the monetary value of the output produced by the worker in a match.

The reservation utility for every agent corresponds to staying out of the market and it is equal to zero. We assume that a sender takes the null action $\eta \in S$ to stay out of the market such that $\eta < s$ for all $s \neq \eta$ (e.g., $\eta = 0$ if $S = \mathbb{R}_+$). Each of S, T, X , and Z is a chain.

The rest of the paper is organized as follows. We define the notion of a competitive signaling equilibrium and analyze a monotone signaling equilibrium with general forms of utility function $u(t, s, z)$ and $g(t, s, z, x)$ in Sections 3 and 4. Note that we do not impose any specific interpretation on actions, reactions, and types. In Section 5, we characterize the unique stronger monotone equilibrium given each possible set of reactions that the DM may choose. In Section 6, we conduct numerical analyses for the optimal design of the unique stronger monotone equilibrium. Section 7 concludes. Unless specified, all proofs not in the paper can be found in the Online Appendix.

3 Competitive signaling equilibrium

After the DM publicly announces the set of feasible reactions T , senders and receivers make decisions over two periods. In the first period, senders choose actions given a reaction function τ . In the application of workers and firms, the reaction function τ is a market wage function that specifies a wage for a worker (sender) conditional on her choice of an action (e.g., education) that is observed in equilibrium.

Let $\sigma(z)$ be the optimal action chosen by a sender of type z . Given $\sigma : Z \rightarrow S$, let S^* denote the set of actions chosen by senders who enter the market for matching. The solution concept of a *competitive signaling equilibrium* is based on the reaction function $\tau : S^* \rightarrow T$, which specifies a receiver's reaction conditional on a sender's equilibrium action s . In the second period, senders and receivers who enter the market form one-to-one matches given the senders' action choices, and receivers take reactions upon forming a match with a sender.

We assume that all senders and receivers share a common belief, denoted by $\mu(s) \in \Delta(Z)$, on a sender's type conditional on her action $s \in S$. Fix a reaction function $\tau : S^* \rightarrow T$. Throughout the paper, $\mathbb{E}_{\mu(s)}[\cdot]$ is the expectation operator over Z given the probability distribution $\mu(s)$.

Consider a sender's action choice problem. Let $\sigma(z) \in S^*$ be the optimal action for a sender of type z if (i) it solves the following problem,

$$\max_{s \in S^*} u(\tau(s), s, z) \text{ s.t. } u(\tau(s), s, z) \geq 0, \quad (1)$$

and (ii) there is no profitable sender deviation to an off-path action $s' \notin \text{range } \sigma$. We define the notion of a profitable sender deviation in Definition 1 below. Note that $\sigma(z) = \eta$ becomes the optimal action for a sender of type z if there is no solution for (1) and there is no profitable sender deviation to an off-path action $s' \notin \text{range } \sigma$.

We now formulate the profitable sender deviation. Let $X^* \subset X$ be the set of receivers who enter the market. For all $s \in S^*$, let $m(s) \in P(X^*)$ be the set of receiver types who are matched with a sender with s , where $P(X^*)$ is the power set of X^* . Therefore, $m : S^* \rightarrow P(X^*)$ is a set-valued matching function. For all $x \in X^*$, $m^{-1}(x) \in S^*$ denotes the action chosen by a sender with whom a receiver of type x is matched, i.e., $x \in m(m^{-1}(x))$.

Definition 1 *Given $\{\sigma, \mu, \tau, m\}$, there is a profitable sender deviation to an off-path action if there exists z for which there are an action $s' \notin \text{range } \sigma$ and a reaction $t' \in T$ such that, for some x' ,*

$$(a) \mathbb{E}_{\mu(s')} [g(t', s', z', x')] > \mathbb{E}_{\mu(m^{-1}(x'))} [g(\tau(m^{-1}(x')), m^{-1}(x'), z', x')] \text{ and} \quad (2)$$

$$(b) \begin{aligned} u(t', s', z) &> u(\tau(\sigma(z)), \sigma(z), z) && \text{if } \sigma(z) \in S^*, \\ u(t', s', z) &> 0, && \text{otherwise.} \end{aligned} \quad (3)$$

Note that z' on each side of (2) is the random variable governed by $\mu(s')$ and $\mu(m^{-1}(x'))$ respectively.

A receiver's matching problem can be formulated as follows:

$$\max_{s \in S^*} \mathbb{E}_{\mu(s)} [g(\tau(s), s, z, x)] \text{ s.t. } \mathbb{E}_{\mu(s)} [g(\tau(s), s, z, x)] \geq 0. \quad (4)$$

We use the notation $\xi(x)$ as the action of the sender whom the receiver of type x optimally chooses as his match partner. If (4) has a solution for $x \in X$, $\xi(x)$ is the solution. Otherwise, $\xi(x) = \eta$. Note that X^* be the set of receiver types such that $\xi(x)$ is a solution for (4).

Definition 2 Given (σ, μ) , $\{\tau, m\}$ is a stable matching outcome if (i) τ clears the markets, i.e., for all $A \in P(S^*)$ such that $H(\{x|x \in m(\xi(x)), \xi(x) \in A\}) = G(\{z|\sigma(z) \in A\})$, (ii) m is stable, i.e., there is no pair of a sender with action s and a receiver of type $x \notin m(s)$ such that, for some $t' \in T$, some z with $\sigma(z) = s \in S^*$,

$$(a) \mathbb{E}_{\mu(s)} [g(t', s, z', x)] > \mathbb{E}_{\mu(m^{-1}(x))} [g(\tau(m^{-1}(x)), m^{-1}(x), z', x)], \quad (5)$$

$$(b) u(t', s, z) > u(\tau(s), s, z). \quad (6)$$

Note that z' on each side of (5) is the random variable governed by $\mu(s)$ and $\mu(m^{-1}(x))$ respectively. Condition (i) implies that the market-clearing reaction function τ induces a measure preserving matching function m . Condition (ii) implies that the induced m is stable where no two agents would like to block the outcome after every sender has chosen her action.

Definition 3 $\{\sigma, \mu, \tau, m\}$ constitutes a competitive signaling equilibrium (henceforth simply an equilibrium) with incomplete information if

1. for all $z \in Z$, $\sigma(z)$ is optimal

2. μ is consistent:

(a) if $s \in \text{range } \sigma$ satisfies $G(\{z|\sigma(z) = s\}) > 0$, then $\mu(s)$ is determined from G and σ , using Bayes' rule.

(b) if $s \in \text{range } \sigma$ but $G(\{z|\sigma(z) = s\}) = 0$, then $\mu(s)$ is any probability distribution with $\text{supp } \mu(s) = \text{cl } \{z|\sigma(z) = s\}$

(c) if $s \notin \text{range } \sigma$, then $\mu(s)$ is unrestricted.

3. given (σ, μ) , $\{\tau, m\}$ is a stable matching outcome.

Because the sender's type is not observable, Condition 2 imposes the consistency of the belief in equilibrium but it leaves the indeterminacy on the belief conditional on any off-path action (Condition 2(c)).

4 Criterion D1 and stronger monotone equilibrium

Given the indeterminacy of the off-equilibrium-path beliefs, an equilibrium refinement called *Criterion D1* was developed by Cho and Kreps (1987) and Banks and Sobel (1987). It restricts the off-equilibrium-path beliefs. Following Ramey (1996), we define Criterion D1 as follows. Given an equilibrium $\{\sigma, \mu, \tau, m\}$, we define type z 's equilibrium utility $U(z)$. If $\sigma(z) \in S^*$, then $U(z) := u(\tau(\sigma(z)), \sigma(z), z)$; otherwise, $U(z) = 0$.

Definition 4 (Criterion D1) Fix any $s \notin \text{range } \sigma$ and any $t \in T$. Suppose that there is a non-empty set $Z' \subset Z$ such that the following is true: for each $z \notin Z'$, there exists z' such that

$$u(t, s, z) \geq U(z) \implies u(t, s, z') > U(z'). \quad (7)$$

Then, the equilibrium is said to violate Criterion D1 unless it is the case that $\text{supp } \mu(s) \subset Z'$.

Intuitively, following the observation for an off-equilibrium-path action s , zero posterior weight is placed on a type z whenever there is another type z' that has a stronger incentive to deviate from the equilibrium in the sense that type z' would strictly prefer to deviate for any given t that would give type z a weak incentive to deviate.

We can equivalently define Criterion D1 by the contrapositive of (7), that is

$$u(t, s, z') \leq U(z') \implies u(t, s, z) < U(z). \quad (8)$$

Upon observing an off-equilibrium action s , zero posterior weight is placed on a type z whenever a type z is strictly worse off by deviating for any t that would make type z' weakly worse with the same deviation.

For the monotonicity of the belief, we employ the notion of the stronger set order (Shannon (1995)), which is stronger than the strong set order (Veinnott (1989)).

Definition 5 (Stronger set order) *Consider two sets A and B in the power set $P(Y)$ for Y a lattice with the given relation \geq . We say that $A \leq_c B$, read “ A is completely lower than B ” if for every $a \in A$ and $b \in B$, $a \leq b$. Given a partially ordered set K with the given relation \geq , a set-valued function $M : K \rightarrow P(Y)$ is monotone non-decreasing in the stronger set order if $k' \leq k$ implies that $M(k') \leq_c M(k)$.*

If a set-valued function is non-decreasing with respect to the stronger set order, then it is also non-decreasing with respect to the strong set order. For a single-valued function, the two set orders are identical. Importantly, if M is monotone non-decreasing in the stronger set order, $M(k)$ and $M(k')$ have at most one element in common: for any ordered pair of (k, k') , $M(k) \cap M(k')$ is \emptyset or a singleton.

Consider a belief function $\mu : S \rightarrow \Delta(Z)$. The monotonicity of a belief function is defined by the stronger set order on the supports of the probability distributions. A belief function is non-decreasing in the stronger set order if $s' \leq s$ implies $\text{supp } \mu(s') \leq_c \text{supp } \mu(s)$. We also use the stronger set order for the monotonicity of a matching function $m : S^* \rightarrow P(X^*)$. A matching function is non-decreasing in the stronger set order if $s' \leq s$ implies $m(s') \leq_c m(s)$. Now we define the stronger monotone equilibrium as follows.

Definition 6 (Stronger Monotone Equilibrium) *An equilibrium $\{\sigma, \mu, \tau, m\}$ is stronger monotone if σ, μ, τ , and m are non-decreasing in the stronger set order.*

We impose the following assumptions for u .

Assumption A $u(t, s, z)$ is (i) decreasing in s , increasing in t and z , and satisfies (ii) the strict single crossing property in $((t, s); z)$.⁵

⁵Let A be a lattice, Θ be a partially ordered set and $f : A \times \Theta \rightarrow \mathbb{R}$. Then, f satisfies the *single crossing property* in $(a; \theta)$ if for $a' > a''$ and $\theta' > \theta''$, (i) $f(a', \theta'') \geq f(a'', \theta'')$ implies $f(a', \theta') \geq f(a'', \theta')$ and (ii) $f(a', \theta') > f(a'', \theta')$ implies $f(a', \theta'') > f(a'', \theta'')$. If $f(a', \theta'') \geq f(a'', \theta'')$ implies $f(a', \theta') > f(a'', \theta')$ for every $\theta' > \theta''$, then f satisfies the *strict single crossing property* in $(a; \theta)$.

Given Assumption A, the stronger monotonicity of σ and τ comes from Lemma 10 in the Online Appendix. The stronger monotonicity of μ is equivalent to Criterion D1.

Corollary 1 *Let σ and μ be a sender action function and a belief function in equilibrium, respectively. If Assumption A is satisfied, μ passes Criterion D1 if and only if it is non-decreasing in the stronger set order.*

The stronger monotonicity of μ implies that for any s in the interval of off-path sender actions induced by the discontinuity of σ at an interior sender type z , the support of $\mu(s)$ is a singleton and it is $\{z\}$. This implication is satisfied if and only if μ satisfies Criterion D1 given Assumption A. Cho and Sobel monotonicity of μ does not lead to this implication although any belief function μ that passes Criterion D1 satisfies Cho and Sobel monotonicity.⁶ This implication plays a crucial role in deriving a non-separating stronger monotone equilibrium in the DM's optimal stronger monotone equilibrium design.

To establish the stronger monotonicity of an equilibrium, $\{\sigma, \mu, \tau, m\}$, we still need to identify sufficient conditions under which m is non-decreasing in the stronger set order. We impose Assumption B for g and apply the Milgrom-Shannon Monotone Selection Theorem (Milgrom and Shannon (1994)).

Assumption B (i) $g(t, s, z, x)$ is supermodular⁷ in (t, s, z) and satisfies the single crossing property in $((t, s, z); x)$ and the strict single crossing property in $(z; x)$ at each (s, t) . (ii) $g(t, s, z, x)$ is increasing in x .

Theorem 1 (Milgrom-Shannon Monotone Selection Theorem) *Let $f : A \times \Theta \rightarrow \mathbb{R}$, where A is a lattice and Θ is a partially ordered set. If f is quasisupermodular⁸ in a and satisfies the strict single crossing property in $(a; \theta)$, then every selection $a^*(\theta)$ from $\arg \max_{a \in A} f(a, \theta)$ is non-decreasing.*

⁶Suppose that an action s is chosen by some sender type z on the equilibrium path. Cho and Sobel monotonicity means that a receiver should believe that $s' > s$ is not chosen by a lower sender type than z .

⁷Given a lattice A , $f : A \rightarrow \mathbb{R}$ is *supermodular* if $f(a \wedge b) + f(a \vee b) \geq f(a) + f(b)$ for all a and b in A . $f : A \rightarrow \mathbb{R}$ is *strictly supermodular* if $f(a \wedge b) + f(a \vee b) > f(a) + f(b)$ for all unordered a and b in A .

⁸Given a lattice A , a function $f : A \rightarrow \mathbb{R}$ is *quasisupermodular* if (i) $f(a) \geq f(a \wedge b)$ implies $f(a \vee b) \geq f(b)$ and (ii) $f(a) > f(a \wedge b)$ implies $f(a \vee b) > f(b)$. If f is supermodular, then it is quasisupermodular.

Theorem 2 (Stronger Monotone Signaling Equilibrium Theorem) *Suppose that Assumptions A and B are satisfied. Then, an equilibrium $\{\sigma, \mu, \tau, m\}$ is stronger monotone if and only if it passes Criterion D1.*

Proof. Given Assumption A, the stronger monotonicity of σ, μ , and τ comes from Lemma 10 and Corollary 1, in the Online Appendix. Given the stronger monotonicity of σ, μ , and τ , consider a receiver's matching problem that is $\max_{s \in S^*} V(s, x)$, where $V(s, x) := \mathbb{E}_{\mu(s)} [g(\tau(s), s, z, x)]$. For any $s, s' \in S^*$ such that $s > s'$, we have that $\tau(s) > \tau(s')$ and $z \geq z'$ for any $z \in \text{supp } \mu(s)$ and $z' \in \mu(s')$. Therefore, the first three arguments in g are linearly ordered with respect to s . Given Assumption B(i), this implies that $V(s, x)$ satisfies the strict single crossing property. Choose an arbitrary selection $\xi_\circ(x) \in \arg \max_{s \in S^*} V(s, x)$. Then, by Milgrom and Shannon's Monotone Selection Theorem, $\xi_\circ(x)$ is non-decreasing in x . Note that $\max_{s \in S^*} V(s, x)$ is a maximization problem with no individual rationality. For all $x \in X$, let

$$\xi(x) = \begin{cases} \xi_\circ(x) & \text{if } V(\xi_\circ(x), x) \geq 0, \\ \eta & \text{otherwise.} \end{cases}$$

$V(s, x)$ is increasing in x because of Assumption B(ii) and hence we have that $x < x'$ for any x with $\xi(x) = \eta$ and any x' with $\xi(x') \neq \eta$. This property and the non-decreasing property of $\xi_\circ(x)$ make $\xi(x)$ non-decreasing in x .

For any $s \in S^*$, the set of receiver types who are matched with senders with s can be expressed as $m(s) = \xi^{-1}(s) := \{x | \xi(x) = s\}$. Because $\xi(x)$ is non-decreasing in x , m is non-decreasing with respect to the stronger set order. ■

Without loss of generality, we can focus on stronger monotone equilibria to derive all D1 equilibria given Assumptions A and B.

5 Unique Stronger Monotone Equilibrium

The sender's type set is $Z = [\underline{z}, \bar{z}] \subset \mathbb{R}$ and the receiver's type set is $X = [\underline{x}, \bar{x}] \subset \mathbb{R}$. X and Z do not have to be bounded. The equilibrium analysis with non-negative unbounded type sets can be analogously done. We assume that $S = \mathbb{R}_+$. Let $0 \in S$ be the null action.

The DM can choose any subset of \mathbb{R}_+ as the set of feasible reactions T . Thus, $\mathcal{P}(\mathbb{R}_+)$, the power set of \mathbb{R}_+ , is his choice set. In the example of workers and

firms, T is the set of feasible transfers that a firm (receiver) can make to his worker (sender). Utilities are transferable through a receiver's reaction t . A receiver's utility is $g(t, s, z, x) = v(x, s, z) - t$ and a sender's utility is $u(t, s, z) = t - c(s, z)$. v can be interpreted as match surplus and c is the cost of taking an action for senders. Let us start with assumptions.

Assumption 1. (i) $c(s, z)$ is increasing in s but decreasing in z and (ii) $-c(s, z)$ is strictly supermodular in (s, z) .

It is easy to see that Assumption 1 implies Assumption A given the form of the utility function, $u(t, s, z) = t - c(s, z)$.⁹

Assumption 2. (i) $v(x, s, z)$ is supermodular in (x, s, z) and strictly supermodular in (z, x) , (ii) v is increasing in x .

Lemma 1 *If Assumption 2 holds, then g satisfies Assumptions B.*

Because Assumptions A and B are implied by Assumptions 1 and 2, Theorem 2 goes through in this section. Focusing on stronger monotone equilibria, the DM maximizes the aggregate net surplus.

We impose Assumptions 3, 4, 5, and 6 below for the differentiability of the separating part of a stronger monotone equilibrium and the existence of a stronger monotone equilibrium.

Assumption 3 (i) v is non-negative, increasing in z , and non-decreasing in action s . (ii) v is differentiable and v_s and v_z are continuous.

Assumption 4 c is differentiable with $c(0, z) = 0$, $\lim_{s \rightarrow \infty} c(s, z) = \infty$ for all $z \in [\underline{z}, \bar{z}]$, and c_s is continuous.

With slight abuse of notation, let $G(z)$ and $H(x)$ denote CDFs for sender types and receiver types respectively.

Assumption 5 If $v(x, s, z)$ is increasing in s , it is concave in s with $\lim_{s \rightarrow 0} v_s(x, s, z) = \infty$ and $\lim_{s \rightarrow \infty} v_s(x, s, z) = 0$ and $c(s, z)$ is strictly convex in s with $\lim_{s \rightarrow 0} c_s(s, z) = 0$ and $\lim_{s \rightarrow \infty} c_s(s, z) = \infty$.

⁹If the domain A of a real-valued function f is a subset of \mathbb{R}^N , then the (strict) supermodularity of f is equivalent to non-decreasing (increasing) differences (Theorem 2.6.1 and Corollary 2.6.1 in Topkis (1998)), which in turn guarantees the (strict) single crossing property.

With slight abuse of notation, let $G(z)$ and $H(x)$ denote CDFs for sender types and receiver types respectively.

Assumption 6 $0 < G'(z) < \infty$ for all $z \in [\underline{z}, \bar{z}]$ and $0 < H'(x) < \infty$ for all $x \in [\underline{x}, \bar{x}]$.

We define the function n as $n \equiv H^{-1} \circ G$ so that $H(n(z)) = G(z)$ for all $z \in [\underline{z}, \bar{z}]$. A bilaterally efficient action $\zeta(x, z)$ for type z given x maximizes $v(x, s, z) - c(s, z)$ and

$$v(\underline{x}, \zeta(\underline{x}, \underline{z}), z) - c(\zeta(\underline{x}, \underline{z}), \underline{z}) \geq 0. \quad (9)$$

We normalize $\zeta(\underline{x}, \underline{z})$ to 0. The reservation utility for each agent is zero. We assume that every agent enters the market if she can get at least her reservation utility by entering the market in equilibrium

We assume that receivers can randomize their reactions on T . Given the quasi-linearity of utility functions of both receivers and senders, this implies that for the DM's point of view, choosing T is equivalent to choosing its convex hull.

This reduces the DM's choice set without loss of generality. For simplicity of notation, we expand the whole set of feasible reactions to $\mathbb{R}_+ \cup \{\infty\}$. The DM only needs to consider an interval, $[t_\ell, t_h]$ as the set of feasible reactions, where $0 \leq t_\ell \leq t_h \leq \infty$ given that receivers can randomize their reactions. If $t_\ell = 0$ and $t_h = \infty$, then there is no restrictions on feasible reactions. If $t_\ell = t_h$, then $[t_\ell, t_h]$ is a singleton that allows only one feasible reaction.

We introduce a *well-behaved stronger monotone equilibrium*, a type of stronger monotone equilibrium, that encompasses a separating equilibrium and a pooling equilibrium as well. A stronger monotone equilibrium is called well-behaved if it is characterized by two threshold sender types, z_ℓ and z_h such that every sender of type below z_ℓ stays out of the market, every sender in $[z_\ell, z_h)$ differentiates themselves with their unique action choice, and every sender in $[z_h, \bar{z}]$ pools themselves with the same action. If $z_\ell < z_h = \bar{z}$, then a well-behaved equilibrium is separating. If $z_\ell = z_h$, then a well-behaved equilibrium is pooling. If $z_\ell < z_h < \bar{z}$, then it is (strictly) well-behaved with both separating and pooling parts in the equilibrium. We shall show that any stronger monotone equilibrium (i.e., any D1 equilibrium) is unique as well as well-behaved.

We first start with a stronger monotone separating equilibrium. Once we characterize it, the characterization of any stronger monotone well-behaved equilibrium

comes naturally. For now, let us assume that the lower bound t_ℓ of the interval T that the DM chooses for feasible reactions is less than the maximal value of $v - c$ that can be created by the highest types \bar{z} and \bar{x} . Otherwise all agents would stay out of the market. Let z_ℓ be the lowest sender type who is matched in equilibrium and s_ℓ her action. The following two inequalities must be satisfied at (s_ℓ, z_ℓ) :

$$v(n(z), s, z) - t_\ell \geq 0, \quad (10)$$

$$t_\ell - c(s, z) \geq 0. \quad (11)$$

The two cases must be distinguished. If $z_\ell = \underline{z}$, then all types are matched in equilibrium. This is the *first case*. In this case, if we have a separating part in equilibrium, there is no information rent in the lowest match between type \underline{z} and type \underline{x} . Therefore, the equilibrium action s_ℓ in the lowest match is bilaterally efficient, i.e., $s_\ell = \zeta(\underline{x}, \underline{z}) = 0$. In this case, we assume that the DM sets t_ℓ to $c(\zeta(\underline{x}, \underline{z}), \underline{z}) = 0$.

If t_ℓ is so high that type \underline{x} cannot achieve a non-negative value of $v - t_\ell$ in a match with type \underline{z} who takes an action that costs her t_ℓ , then the lowest match must be between types z_ℓ and $x_\ell := n(z_\ell)$ in the interior of both type distributions. (10) and (11) must be also satisfied with equality at (s_ℓ, z_ℓ) . This is the *second case*. If either one of them, e.g., (10), is positive, then a receiver whose type is below but arbitrarily close to x_ℓ finds it profitable to be matched with type z_ℓ instead of staying out of the market.

Lemma 2 *If there is a solution (s_ℓ, z_ℓ) that solves (10) and (11), it is unique.*

Now consider the upper bound t_h of the interval T that the DM chooses for feasible reactions. What happens if it is equal to ∞ ? In any stronger monotone equilibrium with $t_h = \infty$, the first-order necessary condition for the sender's equilibrium action choice that solves her problem in (1) would satisfy that for all $z \in (z_\ell, \bar{z})$

$$\tau'(\sigma(z)) - c_s(\sigma(z), z) = 0. \quad (12)$$

On the other hand, the equilibrium reaction choice $\tau(s)$ by the receiver who is matched with a sender with action s solves his problem in (4) and its first-order necessary condition must satisfy that for all $s \in \text{Int}S^*$

$$\tau'(s) = v_s(m(s), s, \mu(s)) + v_z(m(s), s, \mu(s))\mu'(s), \quad (13)$$

where $m(s) = n(\mu(s))$ is the type of the receiver who is matched with a sender with action s . Note that the equilibrium matching function m is stronger monotone due to Theorem 2. Because all senders on the market differentiate themselves with unique action choices in a stronger monotone separating equilibrium, m is strictly increasing over S^* and the matching is assortative in terms of the receiver's type and the sender's action (and the receiver's type and the sender's type as well).

In our two-sided matching model, the market clearing conditions must be embedded into senders' action choices and the belief on sender types. In Theorem 3, the differentiability of τ comes from senders' optimal action choices and the differentiability of μ comes from receivers' optimal choice of a sender, given the market-clearing condition and both the continuity of σ and the differentiability of τ that we can derive from sender's optimal action choices. Theorem 3 is the consequence of Assumptions 1 - 5. The proof of Theorem 3 is rather long but its differentiability results contribute to the literature.¹⁰

Theorem 3 *In any well-behaved stronger monotone equilibrium with $t_h = \infty$, (i) S^* is a compact real interval, $[\sigma(\underline{z}), \sigma(\bar{z})]$, (ii) $\tau : S^* \rightarrow T$ is increasing and continuous on S^* and has continuous derivative $\tilde{\tau}'$ on $\text{Int } S^*$, and (iii) $\mu : S \rightarrow \Delta(Z)$ is increasing and continuous on S^* and has continuous derivative μ' on $\text{Int } S^*$.*

Because μ is the inverse of σ , the differentiability of σ is immediate from Theorem 3.(iii). Combining (12) and (13) yields a function $\phi(s, z)$ defined below:

$$\phi(s, z) := \frac{-[v_s(n(z), s, z) - c_s(s, z)]}{v_z(n(z), s, z)}. \quad (14)$$

This is the first-order ordinary differential equation, $\mu' = \phi(s, \mu(s))$ with the initial condition (s_ℓ, z_ℓ) .

Lemma 3 *If v and c are such that ϕ defined in (14) is uniformly Lipschitz continuous, then the solution exists and it is unique.*

¹⁰To apply the differentiability results in a model with one sender and one receiver (Mailath (1987)) to a two-sided matching model, Hopkins (2012) imposes the restriction that there is no complementarity between receiver type x and sender action s . This restriction gets rid of a matching effect on the marginal productivity of a sender's action. This restriction is not needed for establishing our differentiability result in Theorem 3 above.

Lemma 3 is the simple application of the Picard-Lindelof Theorem (See Teschl (2012)). Let $\tilde{\mu}$ be the unique solution for the differential equation.

Given z_ℓ induced by t_ℓ and $t_\ell < t_h = \infty$, $\{\tilde{\sigma}, \tilde{\mu}, \tilde{\tau}, \tilde{m}\}$ denotes a stronger monotone separating equilibrium.¹¹

Once we drive $\tilde{\mu}$, we can construct the functions $\tilde{\sigma}$, $\tilde{\tau}$, and \tilde{m} implied by $\tilde{\mu}$. $\tilde{\sigma}(z)$ for all $z \in [z_\ell, \bar{z}]$ is determined by $\tilde{\sigma}(z) = \tilde{\mu}^{-1}(z)$ for all $z \in [z_\ell, \bar{z}]$, where $\tilde{\mu}^{-1}(z)$ is the type of a sender that satisfies $z = \tilde{\mu}(\tilde{\mu}^{-1}(z))$ for all $z \in [z_\ell, \bar{z}]$. For $s \in [s_\ell, \tilde{\sigma}(\bar{z})]$, we can derive the matching function \tilde{m} according to $\tilde{m}(s) = n(\tilde{\mu}(s))$. Because $\tilde{\mu}$ is continuous everywhere and differentiable at all $s \in \text{Int } S^*$, integrating the right-hand-side of (13) with the initial condition with $\tilde{\tau}(s_\ell) = t_\ell$ induces

$$\tilde{\tau}(s) = \int_{s_\ell}^s [v_s(\tilde{m}(y), y, \tilde{\mu}(y)) + v_z(\tilde{m}(y), y, \tilde{\mu}(y))\tilde{\mu}'(y)] dy + t_\ell. \quad (15)$$

However, if $t_h < \tilde{\tau}(\tilde{\sigma}(\bar{z}))$, then we have no separating equilibrium. In this case, let $Z(s)$ denote the set of the types of senders who choose the same action s .

Lemma 4 *If $Z(s)$ has a positive measure in a stronger monotone equilibrium, then it is an interval with $\max Z(s) = \bar{z}$.*

Lemma 5 below shows that if there is pooling on the top of the sender side, the reaction to those senders pooled at the top must be the upper bound of feasible reaction t_h .

Lemma 5 *If $Z(s)$ has a positive measure in a stronger monotone equilibrium, then t_h is the reaction to the senders of types in $Z(s)$.*

We can establish Lemmas 4 and 5 using only Cho and Sobel monotonicity of μ without relying on the stronger monotonicity of μ . However, we cannot derive a D1 equilibrium with Cho and Sobel monotonicity as explained after Theorem 6.

Using Lemmas 4 and 5, we can establish that the stronger monotone separating equilibrium $\{\tilde{\sigma}, \tilde{\mu}, \tilde{\tau}, \tilde{m}\}$ is a unique stronger monotone equilibrium if $\tilde{\tau}(\tilde{\sigma}(\bar{z})) \leq t_h$.

Theorem 4 *Suppose that the DM chooses $T = [t_\ell, t_h]$ such that $0 \leq t_\ell < \tilde{\tau}(\tilde{\sigma}(\bar{z})) \leq t_h$, a unique stronger monotone equilibrium is the well-behaved stronger monotone equilibrium and it is separating.*

¹¹The characterization of the stronger monotone separating equilibrium can be found in Theorem 11 in the Online Appendix.

Proof. Lemma 3 leads to the existence of the unique stronger monotone separating equilibrium. The remaining question is whether there are other stronger monotone equilibria. Lemma 4 is still valid. Therefore, if there is bunching in sender action s , it must be among senders in a type interval $Z(s)$ with \bar{z} as its maximum. However, such bunching is not sustained because if we follow the logic in the proof of Lemma 5, we can show that there is a profitable small upward deviation from s for the sender of type- \bar{z} . Therefore, there is no additional stronger monotone equilibrium. ■

Theorem 4 extends the uniqueness result in Cho and Sobel (1990) and Ramey (1996) to a two-sided matching model. If $t_h < \tilde{\tau}(\tilde{\sigma}(\bar{z}))$, there are only two types of non-separating stronger monotone equilibria as shown in Lemma 6. The reason is that pooling can happen only among senders in an interval with \bar{z} being its maximum due to Lemma 4,

Lemma 6 *If there is an upper bound of reactions $t_h < \tilde{\tau}(\tilde{\sigma}(\bar{z}))$, then, there are two possible stronger monotone equilibria: (i) a strictly well-behaved stronger monotone equilibrium and (ii) a stronger monotone pooling equilibrium.*

Lemma 6 follows Theorem 2 (Stronger Monotone Equilibrium Theorem) and Lemmas 4 and 5. For the uniqueness of a stronger monotone equilibrium when $t_h < \tilde{\tau}(\tilde{\sigma}(\bar{z}))$, we impose an additional assumption as follows.

Assumption 7 $\lim_{z \rightarrow \underline{z}} c(s, z) = \infty$ for all $s > 0$ and either (i) or (ii) is satisfied:

(i) $v(x, s, z) = v(x, s', z)$ for all $s, s' \in \mathbb{R}_+$, $v(\underline{x}, s, z) = 0$ for all s, z , and $v(x, s, z) > 0$ for all $x > \underline{x}$, all $z > \underline{z}$, and all $s \in \mathbb{R}_+$.

(ii) $v(x, 0, z) = 0$ and $v(x, s, z)$ is increasing in s for all x and z , and $v(x, 0, z) - c(0, z) \geq 0$ for all $x > \underline{x}$, all $z > \underline{z}$.

We first consider a stronger monotone pooling equilibrium. This is a type of stronger monotone equilibrium when $t_\ell = t_h = t^*$. Every seller of type above $z_\ell = z_h = z^*$ enters the market with the pooled action s^* .

$$t^* - c(s^*, z^*) \geq 0, \tag{16}$$

$$\mathbb{E} [v(n(z^*), s^*, z') | z' \geq z^*] - t^* \geq 0, \tag{17}$$

where each condition holds with equality if $z^* > \underline{z}$.

Theorem 5 *For only a single feasible reaction $t^* > 0$, the only possible stronger monotone pooling equilibrium is a stronger monotone pooling equilibrium with $z^* > \underline{z}$ and $s^* > 0$ that satisfy (16) and (17), each with equality. For only a single feasible reaction, $t^* = 0$, the only possible stronger monotone pooling equilibrium is a stronger monotone pooling equilibrium with $z^* = \underline{z}$ and $s^* = 0$.*

Proof. Fix $t^* > 0$. We first show that $z^* > \underline{z}$. On the contrary, suppose that $z^* = \underline{z}$. Then, $s^* = 0$. Otherwise (i.e., $s^* > 0$), (16) is not satisfied because $\lim_{z \rightarrow \underline{z}} c(s, z) = \infty$ for all $s > 0$ in Assumption 7. If Assumption 7.(i) is satisfied, $\mathbb{E}[v(n(z^*), s^*, z') | z' \geq z^*] = 0$ because $n(z^*) = \underline{x}$. Therefore, (17) is not satisfied. If Assumption 7.(ii) is satisfied, $s^* = 0$ implies that $\mathbb{E}[v(n(z^*), s^*, z') | z' \geq z^*] = 0$. Therefore, (17) is not satisfied. It means that if $t^* > 0$, then $z^* > \underline{z}$.

Given $t^* > 0$, let $z^* > \underline{z}$ be the threshold sender type in a pooling equilibrium and hence (16) and (17), each with equality. It means that $s^* > 0$. If a sender reduced her action below s^* , the stronger monotone belief implies that her type is believed to be z^* and no receiver is willing to match with her at t^* . Any sender wants to choose her action above s^* because the reaction is fixed to t^* . Given binding (16) and (17), no agent who stays out of the market wants to enter it and vice versa no agent who enters the market stays out of the market.

If $t^* = 0$, then we must have $s^* = 0$. Otherwise the sender with s^* will have utility less than her reservation utility. Suppose that Assumption 7.(i) is satisfied. Because every sender on the market has $s^* = 0$, every receiver of type above \underline{x} gets positive (expected) utility by matching with a sender. Therefore, every receiver wants to enter the market. Then, every sender must enter the market as well. Therefore, $z^* = \underline{z}$. Suppose that Assumption 7.(ii) is satisfied. Because $s^* = 0$, any receiver who is matched with a sender with $s^* = 0$ gets the same utility as his reservation utility. All receivers and sender receive zero utility regardless of their decisions on market entry (So, the aggregate net surplus is always zero). Because agents enter the market whenever they are indifferent between entering the market and staying out, agents enter the market, $z^* = \underline{z}$. It is clear to see that no agent want to leave the market. ■

Now consider a (strictly) well-behaved equilibrium with both separating and pooling parts when $t_\ell < t_h < \tilde{\tau}(\tilde{\sigma}(\bar{z}))$. The system of equations represented in (18) and (19) is the *key* to understand jumping and pooling in the upper tail of the match

distribution with $t_h < \tilde{\tau}(\tilde{\sigma}(\bar{z}))$:

$$t_h - c(s, z) = \tilde{\tau}(\tilde{\sigma}(z)) - c(\tilde{\sigma}(z), z), \quad (18)$$

$$\mathbb{E}[v(n(z), s, z') | z' \geq z] - t_h = v(n(z), \tilde{\sigma}(z), z) - \tilde{\tau}(\tilde{\sigma}(z)). \quad (19)$$

Let (s_h, z_h) denote a solution of (18) and (19). Note that (18) makes the type z_h sender indifferent between choosing s_h for t_h and $\tilde{\sigma}(z_h)$ for $\tilde{\tau}(\tilde{\sigma}(z_h))$. The expression on the left hand side of (18) is the equilibrium utility for the type z_h receiver. The expression on the left hand side of (19) is the utility for the type $n(z_h)$ receiver who chooses a sender with action s_h as his partner by choosing t_h for her. This is the equilibrium utility for type $n(z_h)$. The expression on the right-hand side is his utility if he chooses a sender of type z_h with action $\tilde{\sigma}(z_h)$ as his partner by choosing the reaction $\tilde{\tau}(\tilde{\sigma}(z_h))$.

Lemma 7 *If there is a solution (s_h, z_h) of (18) and (19), it is unique.*

Lemma 8 below shows that there is jumping in reactions and actions at the threshold sender type.

Lemma 8 *If there exists a solution (s_h, z_h) of (18) and (19) with $z_\ell < z_h < \bar{z}$, then $\tilde{\tau}(\tilde{\sigma}(z_h)) < t_h < \tilde{\tau}(\tilde{\sigma}(\bar{z}))$ and $\tilde{\sigma}(z_h) < s_h < \tilde{\sigma}(\bar{z})$.*

We exploit Assumptions 1 and 2(i) for the proof of Lemma 8. Theorem 6 establishes the existence of a unique well-behaved stronger monotone equilibrium given $T = [t_\ell, t_h]$ with $0 \leq t_\ell < \tilde{\tau}(\tilde{\sigma}(\bar{z})) < t_h$. Let $x_h := n(z_h)$. Note that Theorem 6 allows for the possibility of separating or pooling as well as strictly well-behaved.

Theorem 6 *Suppose that the DM chooses a set of feasible reactions $T = [t_\ell, t_h]$ with $0 \leq t_\ell < \tilde{\tau}(\tilde{\sigma}(\bar{z})) < t_h$ under which (z_ℓ, s_ℓ) is the lower threshold sender type and her equilibrium action and (z_h, s_h) is the upper threshold sender type and her equilibrium action. Then, there exists a unique well-behaved stronger monotone equilibrium $\{\hat{\sigma}, \hat{\mu}, \hat{\tau}, \hat{m}\}$. It is characterized as follows.*

1. $\hat{\sigma}$ follows (i) $\hat{\sigma}(z) = 0$ if $z \in [\underline{z}, z_\ell)$; (ii) $\hat{\sigma}(z) = s_\ell$ if $z = z_\ell$; (iii) $\hat{\sigma}(z)$ satisfies that $\hat{\tau}'(\hat{\sigma}(z)) - c_s(\hat{\sigma}(z), z) = 0$ if $z \in (z_\ell, z_h)$; (iv) $\hat{\sigma}(z) = s_h$ if $z \in [z_h, \bar{z}]$. Further, $\hat{\sigma}(z_h) < s_h$.

pins it down as one that puts all the probability weights on z_h as specified in Condition 2(iv). Further, because the stronger monotonicity of the belief is equivalent to Criterion D1, we only need to show that the sender type z_h has no incentive to deviate to an off-path action in $[\lim_{z \nearrow z_h} \hat{\sigma}(z), s_h)$ in order to show that no sender has an incentive to deviate to such an off-path action.

Theorem 7 below shows that $\{\hat{\sigma}, \hat{\mu}, \hat{\tau}, \hat{m}\}$ is a unique stronger monotone equilibrium if $0 \leq t_\ell < t_h < \tilde{\tau}(\tilde{\sigma}(\bar{z}))$.

Theorem 7 *Suppose that the DM fixes a set of feasible reactions to $T = [t_\ell, t_h]$ with $0 \leq t_\ell < t_h < \tilde{\tau}(\tilde{\sigma}(\bar{z}))$. A unique stronger monotone equilibrium is $\{\hat{\sigma}, \hat{\mu}, \hat{\tau}, \hat{m}\}$.*

Proof. Since there is no separating equilibrium with $T = [t_\ell, t_h]$ with $t_\ell < t_h < \tilde{\tau}(\tilde{\sigma}(\bar{z}))$. Because of Lemma 6, it is sufficient to show that there is no pooling equilibrium. On contrary, suppose that there exists a pooling equilibrium. Because of Lemma 5, t_h is the equilibrium reaction for senders with pooled action s^* . Therefore, $x^* = n(z^*)$ and the following system of equations is satisfied in a pooling equilibrium:

$$t_h - c(s^*, z^*) \geq 0, \quad (20)$$

$$\mathbb{E}[v(n(z^*), s^*, z') | z' \geq z^*] - t_h \geq 0, \quad (21)$$

where both inequalities hold with equality if $z^* > \underline{z}$.

Suppose that $z^* > \underline{z}$. Then, (20) and (21) hold with equality. Further, because both t_h and z^* are positive, s^* must be positive from (20) with equality. On the other hand, there should be no profitable downward deviation for senders, that is,

$$v(n(z^*), s, z^*) - c(s, z^*) \leq \mathbb{E}[v(n(z^*), s^*, z') | z' \geq z^*] - c(s^*, z^*) \text{ for all } s < s^*$$

Because (20) and (21) hold with equality, this becomes

$$v(n(z^*), s, z^*) - c(s, z^*) \leq 0 \text{ for all } s < s^*. \quad (22)$$

If $v(x, s, z)$ satisfies Assumption 7(i), then, $v(n(z^*), 0, z^*) - c(0, z^*) = v(n(z^*), 0, z^*) > 0$. Therefore, (22) is violated. If v and c are satisfies Assumption 7(ii), then there exists $s < s^*$ such that $v(n(z^*), s, z^*) - c(s, z^*) > 0$. Therefore, (22) is violated.

Therefore, if there is a stronger monotone pooling equilibrium, it must be the case where $z^* = \underline{z}$. In this case, $s^* = 0$. Otherwise, the sender type z arbitrarily

close to 0 will get negative utility because $t_h < \infty$ and $\lim_{z \rightarrow \underline{z}} c(s, z) = \infty$ for all $s > 0$ (Assumption 7).

Given $z^* = \underline{z}$ and $s^* = 0$, every sender will get positive utility upon being matched. We distinguish the two cases. If Assumption 7(ii) is satisfied, then $s^* = 0$ makes the surplus equal to zero upon being matched, so no receiver is willing to pay $t_h > 0$. Therefore there is no pooling equilibrium. If Assumption 7(i) is satisfied, then the threshold receiver type x^* is determined by $\mathbb{E}[v(x^*, 0, z) | z \geq \underline{z}] - t_h = 0$. Because $v(\underline{x}, 0, z) = 0$ for all z , we must have $x^* > \underline{x}$. Therefore, there are more senders than receivers, and hence the market clearing condition is not satisfied. ■

Theorems 4, 5, and 7 establish the unique stronger monotone equilibrium given each type of the feasible reaction sets.

6 Optimal equilibrium design

Lemma 9 shows that the DM only needs to consider a well-behaved stronger monotone equilibrium because it also covers a stronger monotone separating equilibrium and a stronger monotone pooling equilibrium. Combining with Lemma 9, the next two propositions reduce the DM's the design problem of an optimal stronger monotone equilibrium to the choice of z_ℓ and z_h subject to $z_\ell \in Z$ and $z_h \geq z_\ell$ given that a unique well-behaved stronger monotone equilibrium is the only stronger monotone equilibrium. In other words, for the DM's optimal equilibrium design, choosing the lower and upper bounds of the feasible reaction interval is equivalent to choosing the two threshold sender types z_ℓ and z_h , one for market entry and the other for pooling on the top.

Proposition 1 (i) For any given $z_\ell \in [\underline{z}, \bar{z})$, there exists a unique solution (s_ℓ, t_ℓ) of (10) and (11). (ii) Suppose that the DM chooses t_ℓ in (i) above. Then, (z_ℓ, s_ℓ) solves (10) and (11) given t_ℓ and it is unique.

Note that $s_\ell = \zeta(\underline{x}, \underline{z}) = 0$ given $z_\ell = \underline{z}$. s_ℓ is also determined uniquely by z_ℓ when $z_\ell > \underline{z}$ because it solves

$$v(n(z_\ell), s, z_\ell) - c(s, z_\ell) = 0, \tag{23}$$

which is the sum of (10) and (11) with equality. Therefore, Proposition 1 implies

that we can retrieve t_ℓ that induces (s_ℓ, z_ℓ) from (10) with equality when $z_\ell = \underline{z}$ or either (10) or (11), each with equality when $z_\ell > \underline{z}$. Therefore, the DM's point of view, choosing z_ℓ is equivalent to choosing t_ℓ .

Proposition 2 (i) For any given $z_h \in (z_\ell, \bar{z})$, there exists a unique (s_h, t_h) of (18) and (19). (ii) Suppose that the DM chooses t_h in (i) above. Then, (z_h, s_h) solves (18) and (19) given t_h and it is unique.

Note that s_h is determined solely by z_h because it solves

$$\mathbb{E}[v(n(z_h), s, z') | z' \geq z_h] - c(s, z_h) = v(n(z_h), \tilde{\sigma}(z_h), z_h) - c(\tilde{\sigma}(z_h), z_h), \quad (24)$$

which is the sum of (18) and (19) at z_h . Therefore, Proposition 2 implies that we can retrieve t_h that induces (s_h, z_h) from either (18) or (19). The DM can first choose the threshold sender type z_h and retrieve the upper bound of feasible reactions t_h that induces z_h in a well-behaved equilibrium.

Lemma 9 As $z_h \rightarrow \bar{z}$, $\{\hat{\sigma}, \hat{\mu}, \hat{\tau}, \hat{m}\}$ converges to the stronger monotone separating equilibrium with the same lower threshold sender type z_ℓ . As $z_h \rightarrow z_\ell$, $\{\hat{\sigma}, \hat{\mu}, \hat{\tau}, \hat{m}\}$ converges to the stronger monotone pooling equilibrium in which t_ℓ is a single feasible reaction, z_ℓ is the threshold sender type for market entry, and s_ℓ is the pooled action for senders in the market.¹³

Given Propositions 1–2 and Lemma 9, we can say that for the DM's point of view, choosing an interval of feasible reactions $T = [t_\ell, t_h]$ is equivalent to choosing the corresponding z_ℓ and z_h .

Because a unique stronger monotone equilibrium is always well-behaved, this implies that the solution for the DM's unconstrained design problem of the optimal stronger monotone equilibrium is the same as the solution for the DM's design problem of the optimal stronger monotone equilibrium where the DM chooses the lower and upper threshold sender types, z_ℓ and z_h , for a well-behaved stronger monotone equilibrium.

¹³As $z_h \rightarrow z_\ell$, (18) and (19) become (16) and (17), each with equality if $z^* > \underline{z}$. From (16) and (17), we can also directly derive (t^*, s^*) given each z^* or (z^*, s^*) given each t^* for a pooling equilibrium.

Given a well-behaved stronger monotone equilibrium $\{\hat{\sigma}, \hat{\mu}, \hat{\tau}, \hat{m}\}$ with the lower and upper threshold sender types, z_ℓ and z_h , the aggregate net surplus is

$$\begin{aligned} \Pi(z_\ell, z_h) := & \int_{z_\ell}^{z_h} v(n(z), \hat{\sigma}(z), z) dG(z) - \int_{z_\ell}^{z_h} c(\hat{\sigma}(z), z) dG(z) \\ & + \int_{z_h}^{\bar{z}} \mathbb{E}[v(n(z), s_h(z_h), z') | z' \geq z_h] dG(z) - \int_{z_h}^{\bar{z}} c(s_h(z_h), z) dG(z), \end{aligned}$$

where $s_h(z_h)$ is the pooled action chosen by all sender types above z_h and it is unique given any $z_h \in [z_\ell, \bar{z}]$ because of Proposition 2(i).

Theorem 8 *The solution for the DM's unconstrained design problem of the optimal stronger monotone equilibrium is the same as the solution for the DM's design following problem of the optimal stronger monotone equilibrium:*

$$\max_{\bar{z} > z_\ell \geq z, z_h \geq z_\ell} \Pi(z_\ell, z_h)$$

If $z_\ell < z_h < \bar{z}$, then the stronger monotone equilibrium is strictly well-behaved. If $z_\ell < z_h = \bar{z}$, it is separating. If $z_\ell = z_h < \bar{z}$, it is pooling.

Generally, the aggregate equilibrium surplus depends on v , c , G , and H . For the optimal equilibrium design, we propose an approach that approximates the distribution of receiver types with the “shift” and “relative spacing” parameters given an arbitrary distribution of sender types. Consider a match surplus function that follows the form of $v(x, s, z) = As^a xz$ with $0 \leq a < 1$. The cost of choosing an action s is $c(s, z) = \beta \frac{s^2}{z}$ for the sender of type z , where $\beta > 0$. The lowest sender type is $\underline{z} = 0$. Note that v , c , and $\underline{z} = 0$ satisfy Assumption 7.

A sender's type follows a probability distribution G , whereas a receiver's type follows H . Recall that n is defined as $H^{-1} \circ G$ so that $H(n(z)) = G(z)$ for all z . We assume that n takes the following form:

$$n(z) = kz^q, \tag{25}$$

where $k > 0$ and $q \geq 0$. Note that k is the “shift” parameter and q is the “relative spacing” parameter. The relative spacing parameter q shows the relative heterogeneity of receiver types to sender types. Recall that $n(z)$ denotes the type of a receiver who is matched with the sender of type z in the stronger monotone separa-

rating equilibrium. This approach is general in the sense that it approximates the distribution of receiver types with the “shift” and “relative spacing” parameters for any arbitrary distribution of sender types.

To derive a well-behaved stronger monotone equilibrium, we first need to solve the first-order differential equilibrium $\tilde{\mu}'(s) = \phi(s, \tilde{\mu}(s))$ in (14) with the initial condition (z_ℓ, s_ℓ) . The value of s_ℓ only depends on z_ℓ . If $z_\ell = 0$, then $s_\ell(z_\ell) = \zeta(0, 0) = 0$. If $z_\ell > 0$, then $s_\ell(z_\ell)$ is determined by (23) and it is $s_\ell(z_\ell) = \left(\frac{Ak}{\beta} z_\ell^{q+2}\right)^{\frac{1}{2-a}}$. Note that $s_\ell(z_\ell)$ is continuous everywhere including at $z_\ell = 0$.

Proposition 3 *Given any initial condition $(z_\ell, s_\ell(z_\ell))$, the solution for first-order differential equation $\mu'(s) = \phi(s, \mu(s))$ is*

$$\tilde{\mu}(s) = \left[+ \left(\frac{s_\ell(z_\ell)}{s} \right)^{a(2+q)} \frac{\left(\frac{2\beta(2+q)}{Ak} \right) \frac{s^{2-a}}{2+a+aq}}{[Ak(2+a+aq)z_\ell^{2+q} - 2\beta(2+q)s_\ell(z_\ell)^{(2-a)}]} Ak(2+a+aq)} \right]^{\frac{1}{2+q}}.$$

Note that $\tilde{\sigma}(z)$ is the inverse of $\tilde{\mu}(s)$, which is derived numerically as $\tilde{\mu}(s)$ does not allow for a closed-form solution for its inverse. Given z_h , $s_h(z_h)$ is unique and it solves (24), which is

$$Aks_h^a z_h^q \mathbb{E}[z'|z' \geq z_h] - \beta \frac{s_h^2}{z_h} = Ak\tilde{\sigma}(z_h)^a z_h^{1+q} - \beta \frac{\tilde{\sigma}(z_h)^2}{z_h}. \quad (26)$$

We need to numerically derive $s_h(z_h)$ as it does not allow for a closed form solution. Given a choice of z_ℓ and z_h , the aggregate net surplus is

$$\begin{aligned} \Pi_w(z_\ell, z_h, q, a, G) &= \int_{z_\ell}^{z_h} [v(n(z), \hat{\sigma}(z), z) - c(\hat{\sigma}(z), z)] g(z) dz \\ &+ \int_{z_h}^{\bar{z}} [\mathbb{E}[v(n(z), s_h(z_h), z')|z' \geq z_h] - c(s_h(z_h), z)] g(z) dz \\ &= \int_{z_\ell}^{z_h} \left(Akz^{q+1} \hat{\sigma}(z)^a - \beta \frac{\hat{\sigma}(z)^2}{z} \right) g(z) dz \\ &+ Aks_h(z_h)^a \mathbb{E}[z'|z' \geq z_h] \int_{z_h}^{\bar{z}} z^q g(z) dz - \beta s_h(z_h)^2 \int_{z_h}^{\bar{z}} \frac{1}{z} g(z) dz, \end{aligned}$$

where $\hat{\sigma}(z) = \tilde{\sigma}(z)$ for $z \in [z_\ell, z_h]$.

Given (a, q, G) , we can find the best well-behaved equilibrium through the following maximization problem:

$$\begin{aligned} & \max_{(z_\ell, z_h)} \Pi_w(z_\ell, z_h, q, a, G) \\ & \text{subject to } 0 \leq z_\ell \leq z_h \leq \bar{z}. \end{aligned}$$

We turn our attention to numerical illustrations by considering a specific distribution of G with various combinations of q and a . The space of sender types is normalized as $[0, 1]$ and G follows the beta distribution with the following eight pairs of shape parameters:

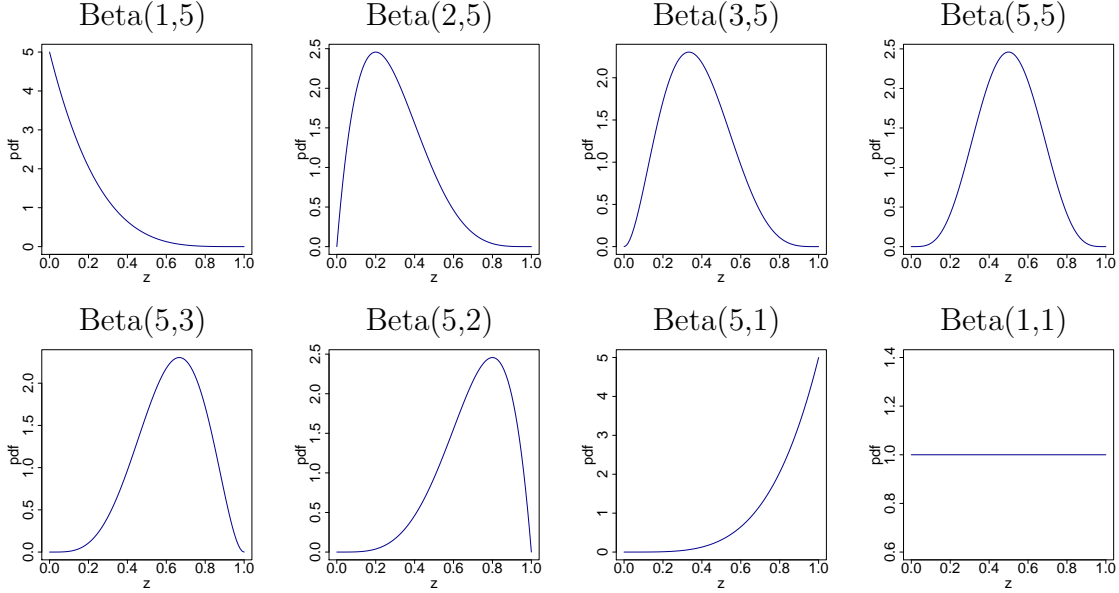

$$\{(1, 5), (2, 5), (3, 5), (5, 5), (5, 3), (5, 2), (5, 1), (1, 1)\}.$$

Figure 2 shows the probability density functions with different shape parameter values. Note that the shape parameter pair $(1, 1)$ corresponds to the uniform distribution and $(5, 5)$ to a symmetric bell-shaped distribution. If the former shape parameter is smaller than the latter, the density is right-skewed (see, e.g. Beta(1,5), Beta(2,5), and Beta(3,5)). It is left-skewed in the opposite situation (e.g. Beta(5,3), Beta(5,2), and Beta(5,1)). The model parameters q and a vary over $\{0, 0.1, \dots, 2\}$ and $\{0, 0.1, \dots, 0.9\}$, respectively. Therefore, we compute the optimal well-behaved equilibrium (i.e., optimal stronger monotone equilibrium) for 1680 ($= 10 \times 21 \times 8$) different specifications in total for shape parameters in the beta distribution, q , and a . Finally, we set the effective zero as 10^{-6} .

Figures 3–4 show the optimal solution paths and the relative surplus gains of the well-behaved equilibrium, respectively. It turns out that $z_\ell = 0$ in all specifications. Thus, in Figure 3, we only report z_h that solves the optimization problem in each design. In the graph, the horizontal axis denotes the parameter value of q . To make the graph readable, we report the solution paths of z_h for four different values of $a = 0, 0.3, 0.6$, and 0.9 .

We illustrate the well-behaved equilibrium with two examples. When G follows Beta(1,1) and $(q, a) = (1.5, 0.9)$, the optimal well-behaved equilibrium is achieved at $(z_\ell, z_h) = (0, 0.8251)$ as denoted by a circle point on the vertical line in the bottom-right graph of Figure 3. This implies that every sender enters the market and that the senders with $0 \leq z < 0.8251$ differentiate themselves with unique action choices.

Figure 2: Probability Density Functions of the Beta Distribution

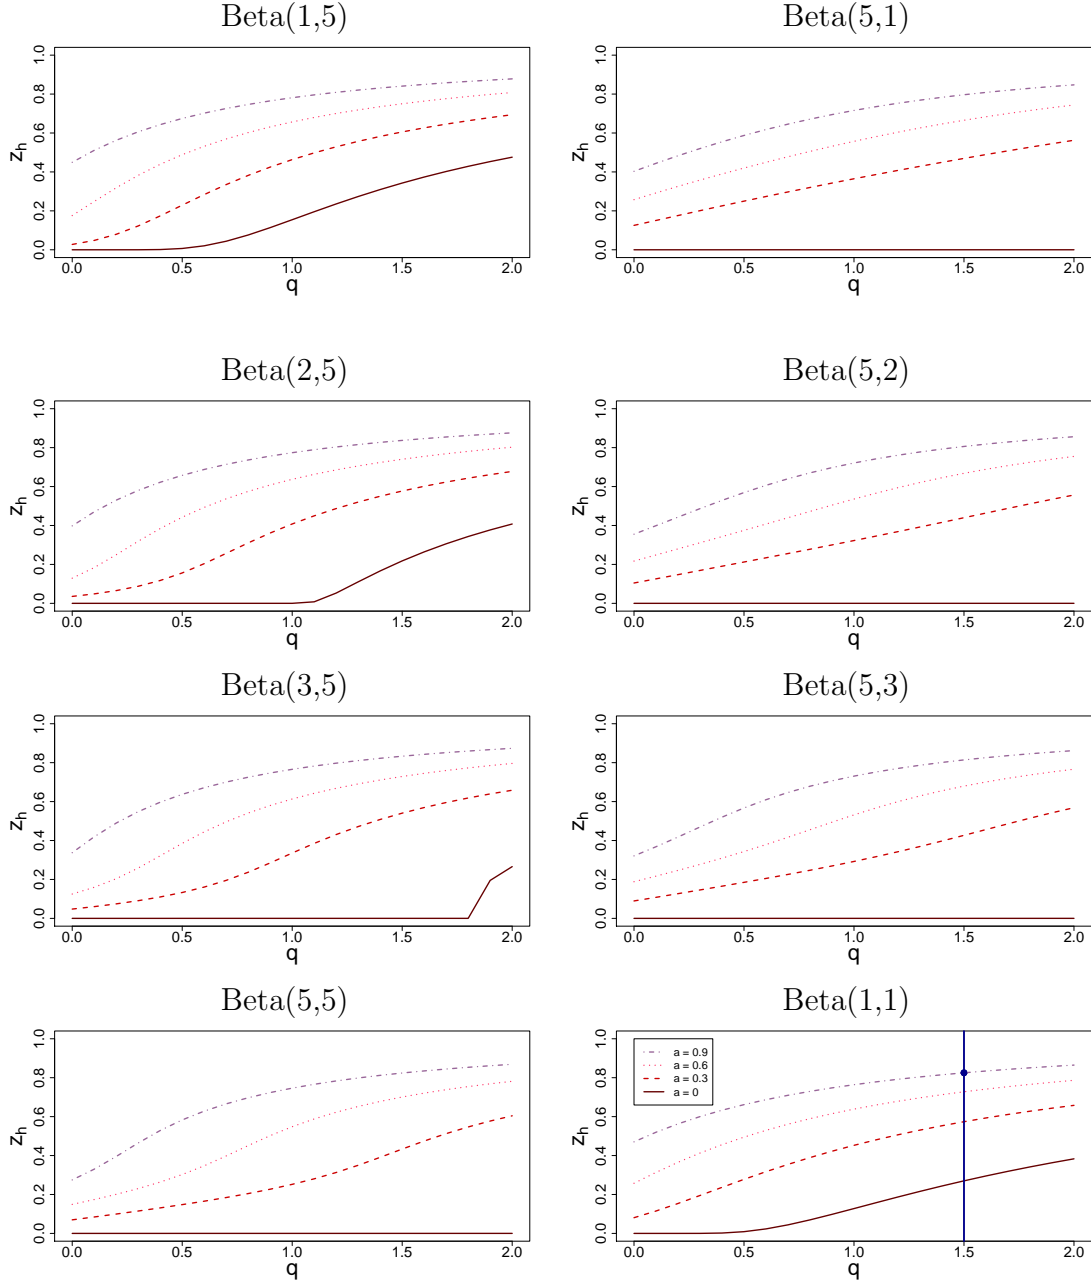

Furthermore, we can compute from (26) that those senders with $z \geq 0.8251$ choose a pooled action $s_h = 0.8211$. The upper threshold sender type $z_h = 0.8251$ is induced when the DM sets the upper bound of feasible reactions $t_h = 0.4218$ (We can derive the value of t_h from (18) or (19) given z_h and s_h). From Theorem 8, we can conclude that this is a unique optimal stronger monotone equilibrium that maximizes the aggregate net surplus and that it is reached when the DM sets the set of feasible reactions as $[t_\ell, t_h] = [0, 0.4218]$.¹⁴ The second example is in case that G follows Beta(1,1) and $(q, a) = (0.2, 0.2)$. Then, the optimal well-behaved equilibrium is achieved at $(z_\ell, z_h) = (0, 0.0921)$. Those senders with $z \geq 0.0921$ choose a pooled action $s_h = 0.0047$. This equilibrium is reached when the DM sets the set of feasible reactions as $[t_\ell, t_h] = [0, 0.0001]$.¹⁵

We have some remarks on these numerical results. First, as we have discussed

¹⁴With no restrictions on the set of feasible reactions, the action chosen by the highest sender type $\bar{z} = 1$ is $\tilde{\sigma}(1) = 1.193$ and the receiver's feasible reaction for her is $\tilde{\tau}(\tilde{\sigma}(1)) = 0.628 > t_h = 0.4218$. The aggregate net surplus in the separating equilibrium is 0.072, whereas the aggregate net surplus in the optimal well-behaved equilibrium is 0.073. Therefore, the optimal well-behaved equilibrium increases the aggregate net surplus by 1%.

¹⁵The aggregate net surplus in the optimal well-behaved equilibrium is 0.263, whereas the aggregate net surplus in the separating equilibrium is 0.201. Therefore, the optimal well-behaved equilibrium increases the aggregate net surplus by 31%.

Figure 3: Solutions z_h for Different Parameter Specifications

Notes. We show only solutions z_h since $z_l = 0$ for all designs. Each line represents solutions over $q \in [0, 2]$ for each a value. For example, when G follows Beta(1,1) and $(q, a) = (1.5, 0.9)$, the best well-behaved equilibrium is achieved at $(z_l, z_h) = (0, 0.8251)$ as denoted by a circle point on the vertical line at the figure of Beta(1,1).

above, z_ℓ is equal to zero for all specifications. In the case of the separating equilibrium, it is clear that $z_\ell = 0$ is optimal since any positive z_ℓ does not improve efficiency. With $z_\ell > 0$, we lose some positive surplus that could have been created by lower matches. At the same time, it further increases the inefficiently high equilibrium action of every sender of type $z > z_\ell$. However, this is not certain in the well-behaved equilibrium with $z_h < 1$. In this case, raising z_ℓ leads to an increase in the pooled action s_h chosen by sender types above z_h . Because s_h is lower than the equilibrium action choice for the highest sender type in a separating equilibrium, it is possible that s_h may be even lower than the efficient level of action for some senders on the top end of the type distribution. In this case, raising s_h through raising z_ℓ increases efficiency for those senders while decreasing efficiency for the other senders. Our numerical analysis shows that, when $z_\ell > 0$, the efficiency loss by lower types dominates any possible efficiency gains by higher types across all designs considered.

Second, z_h is strictly increasing in a for any given q . Also, z_h is strictly increasing in q for any given a besides $a = 0$. When $a = 0$, (i.e., the sender action is not productive at all), we observe $z_h = 0$ in a range of q values. This result implies that the optimal equilibrium becomes the pooling equilibrium. To make the well-behaved equilibrium deviate from the pooling equilibrium, the relative spacing parameter q has to be larger than a threshold that depends on the distribution of z . Otherwise, the inefficiency associated with high costs of separating themselves among lower sender types dominates matching efficiency created by separating themselves and it is the optimal equilibrium design to force every sender not to take any action by setting $z_h = 0$.

Third, the optimal well-behaved equilibrium converges to the separating equilibrium as a converges to 1 and q increases. However, the convergence speed over q is quite slow as we can conjecture from the solution path curvature for large q values in Figure 3. For example, when we compute z_h for $a = 0.99$ and $q = 10$, the solution is $z_h = 0.986$ for Beta(1,1). When we compute it for other shape parameters, the solution z_h has the value between 0.981 to 0.988. Based on this slow convergence rate, we can conclude that the (strictly) well-behaved equilibrium is the optimal design in a wide range of (q, a) for various beta distributions.

Fourth, the different shapes of the probability density function affect the curvature of the z_h paths for all a and the threshold of q that makes the well-behaved

Figure 4: Relative Surplus Gains of the Well-Behave Equilibrium

Notes. We compute the aggregate net surplus gains of the optimal well-behaved equilibrium compared to the separating equilibrium by $100 \times (\Pi_w - \Pi_s) / \Pi_s$, where Π_w and Π_s are aggregate net surplus of the well-behaved and separating equilibria.

equilibrium the optimal equilibrium for $a = 0$.

Finally, we show the relative surplus gains from the optimal well-behaved equilibrium in Figure 4. For each design, we compute the aggregate net surpluses for the optimal well-behaved and separating equilibria. Then, we compute the relative gain of the well-behaved equilibrium by $100 \times (\Pi_w - \Pi_s)/\Pi_s$. For all beta distributions considered, we confirm that the gains increase monotonically as the role of the signal is lower in production (smaller a) and the relative spacing is lower (smaller q). For example, under Beta(1,1), the relative gains are 52.8% and 0.69% when (a, q) are (0.1, 0.1) and (0.9, 2.0), respectively. We also find that the surplus gains become larger as there are relatively more high types, i.e., more density weights on higher z values (see, for example, Beta(1,5) and Beta(5,1) in Figure 4).

Figure 5: Cumulative Distribution Functions

To elaborate the final point in detail, we ordered the Beta distributions according to the first-order stochastic dominance and check whether the efficiency gains are larger in the case of a stochastically dominating distribution. In Figure 5 we draw the cumulative distribution functions (cdf) of the beta distributions. First, consider two outside cdfs, Beta(1,5) and Beta(5,1), along with Beta(1,1) that is the straight line in the middle. They show a clear relationship of stochastic dominance. Beta(5,1) dominates Beta(1,1), which again dominates Beta(1,5). In Figure 6, we show the differences of relative surplus gains between the paired beta distributions. For example, in the figure of “Beta(5,1) vs. Beta(1,1)”, we subtract the heat map of Beta(1,1) from Beta(5,1). More specifically, let $R(\beta_i) := 100 \times (\Pi_w(\beta_i) - \Pi_s(\beta_i))/\Pi_s(\beta_i)$ be

Figure 6: Differences of Relative Surplus Gains

Notes. Each cell in the graph shows the difference of efficiency gains in the corresponding cell of beta distributions. Specifically, let $R(\beta_1) := 100 \times (\Pi_w(\beta_1) - \Pi_s(\beta_1))/\Pi_s(\beta_1)$ be the ratio of the net surplus gains given a beta distribution denoted by β_1 . Then, the difference of ratios (ratio_diff) is defined as $R(\beta_1) - R(\beta_2)$ for two beta distributions β_1 and β_2 , where β_1 first-order stochastically dominates β_2 .

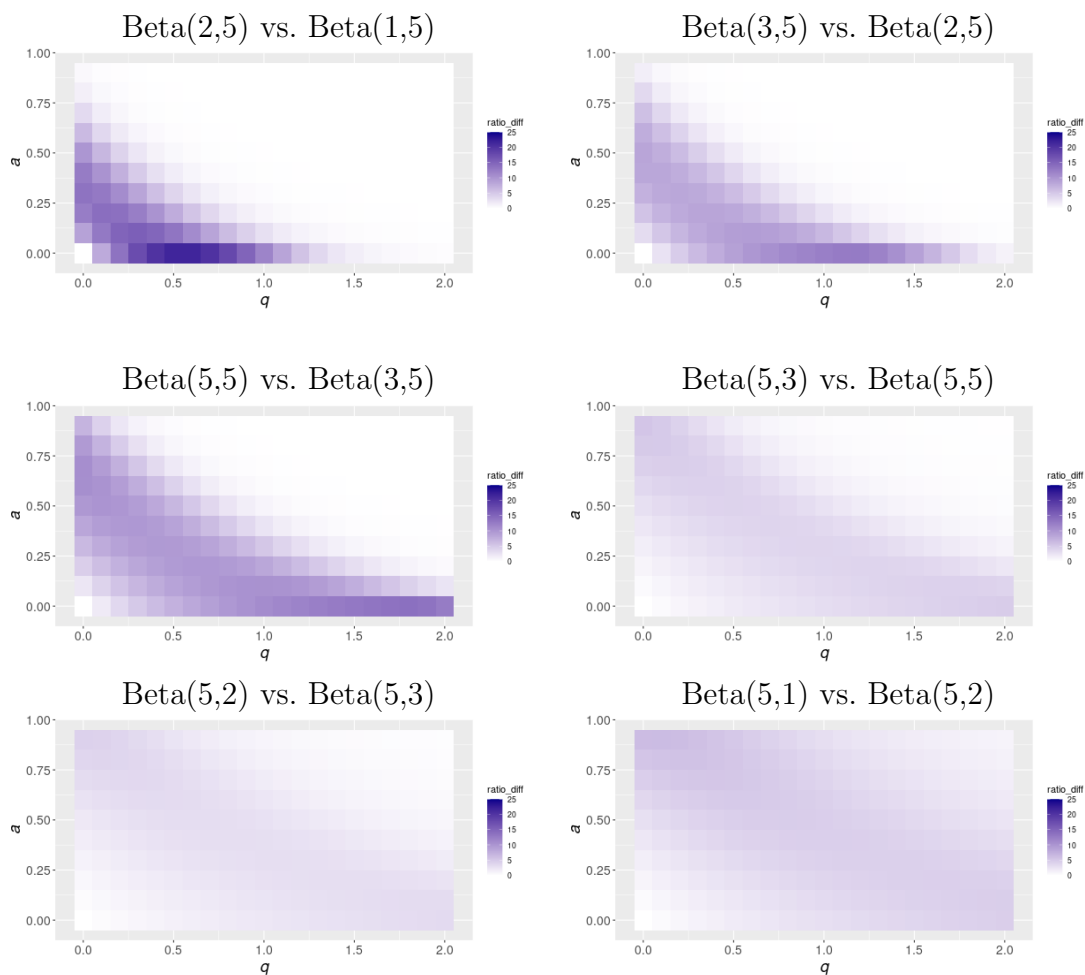

the ratio of the net surplus gains given a beta distribution denoted by β_i . Then, $R(\beta_1) - R(\beta_2)$ is the difference of ratios (ratio_diff) for two beta distributions β_1 and β_2 , where β_1 first-order stochastically dominates β_2 . The results show that the differences are positive across all (a, q) . This implies that the efficiency gains by the stochastically dominating distribution are *uniformly* larger than that by the dominated one.

We now consider a larger set of beta distributions with the stochastic dominance relationship. From the cdfs in Figure 5, we confirm that all beta distributions therein except beta(1,1) show the stochastic dominance relationship. In Figure 7, we conduct the same exercise above across all sequential pairs. We again find that all the differences are positive in each (a, q) cell. Therefore, this numerical evidence supports that the relative efficiency gains could be larger uniformly over (a, q) as one beta distribution stochastically dominates the other.

More efficient non-separating equilibria Suppose that the DM fixes the lower bound of feasible reactions such that $z_\ell = 0$ and hence $s_\ell(z_\ell) = 0$ (no sender stays out of the market). In this case, the belief function $\tilde{\mu}(s)$ allows for the closed-form expression of its inverse, which is the sender's equilibrium action function in the separating equilibrium:

$$\tilde{\sigma}(z) = \left(\frac{Ak}{2\beta} \frac{aq + a + 2}{q + 2} \right)^{\frac{1}{2-a}} z^{\frac{q+2}{2-a}} \text{ for } z < z_h.$$

Figure 7: Differences of Relative Surplus Gains

Notes. Each cell in the graph shows the difference of efficiency gains in the corresponding cell of beta distributions. Specifically, let $R(\beta_1) := 100 \times (\Pi_w(\beta_1) - \Pi_s(\beta_1))/\Pi_s(\beta_1)$ be the ratio of the net surplus gains given a beta distribution denoted by β_1 . Then, the difference of ratio (ratio_diff) is defined as $R(\beta_1) - R(\beta_2)$ for two beta distributions β_1 vs β_2 such that β_1 first-order stochastically dominates β_2 .

The aggregate net surplus in the well-behaved stronger monotone separating equilibrium is

$$\begin{aligned} \Pi_w(0, z_h, q, a, G) = & \left((Ak)^{\frac{2}{2-a}} \left(\frac{aq + a + 2}{2\beta(q+2)} \right)^{\frac{a}{2-a}} - \beta \left(\frac{Ak}{2\beta} \frac{aq + a + 2}{q+2} \right)^{\frac{2}{2-a}} \right) \int_0^{z_h} z^{\frac{2q+2+a}{2-a}} dG(z) \\ & + Ak s(z_h)^a \mathbb{E}[z|z \geq z_h] \int_{z_h}^{\bar{z}} z^q g(z) dz - \beta s_h(z_h)^2 \int_{z_h}^{\bar{z}} \frac{1}{z} g(z) dz. \end{aligned}$$

As z_h approaches the supremum of the support of G , $\Pi_w(0, z_h, q, a, G)$ becomes the aggregate net surplus $\Pi^*(a, q, G)$ without any restrictions on feasible reactions. We show that, when the relative heterogeneity of receiver types (q) and the productivity of the sender action (a) are not too large, there is a strictly well-behaved equilibrium only with the binding upper bound of feasible reactions that is more efficient than the separating equilibrium without any restrictions on the feasible reactions regardless of G .

Theorem 9 *There are $\hat{q}, \hat{a} > 0$ such that for any given $(q, a) \in [0, \hat{q}] \times [0, \hat{a}]$, the DM can set up the interval of feasible reactions $[0, \hat{t}]$ that induces a unique strictly well-behaved stronger monotone equilibrium, which is more efficient than the stronger monotone separating equilibrium with no restrictions on feasible reactions. Given $[0, \hat{t}]$, it is a unique stronger monotone equilibrium.*

Proof. First, we construct a (unique) strictly well-behaved stronger monotone equilibrium with $0 = z_\ell < z_h < \text{supremum of the support of } G$. Let $s_h(z_h, a, q)$ be the value of s_h that solves (26) at every a and q . Because functions in (26) are continuous in a and q , $s_h(z_h, a, q)$ is continuous in a and q . Given (26), we have

$$\begin{aligned} \lim_{q, a \rightarrow 0} \left(A s_h(z_h, q, a)^a k z_h^q \mathbb{E}[z|z \geq z_h] - \beta \frac{s_h(z_h, q, a)^2}{z_h} \right) \\ = \lim_{q, a \rightarrow 0} \left(Ak \tilde{\sigma}(z_h)^a z_h^{q+1} - \beta \frac{\tilde{\sigma}(z_h)^2}{z_h} \right). \end{aligned}$$

Therefore, we have that $\lim_{q, a \rightarrow 0} s_h(z_h, q, a) = \sqrt{z_h^2 Ak (\mathbb{E}[z|z \geq z_h] - 1) / \beta}$. This

implies that

$$\begin{aligned} \lim_{q,a \rightarrow 0} \Pi_w(0, z_h, q, a, G) &= \int_0^{z_h} \frac{Akz}{2} dG(z) + \int_{z_h}^{\bar{z}} Ak \mathbb{E}[z|z \geq z_h] dG(z) \\ &\quad - z_h^2 Ak (\mathbb{E}[z|z \geq z_h] - 1) \int_{z_h}^{\bar{z}} \frac{1}{z} dG(z). \end{aligned}$$

Taking the limit of $\lim_{q,a \rightarrow 0} \Pi_w(0, z_h, q, a, G)$ with respect to z_h yields

$$\lim_{z_h \rightarrow 0} \left[\lim_{q,a \rightarrow 0} \Pi_w(0, z_h, q, a, G) \right] = \int_0^{\bar{z}} Akz dG(z) = Ak\mu_z,$$

where μ_z is the unconditional mean of the sender type z .

On the other hand, the limit of the aggregate net surplus in the stronger monotone separating equilibrium is

$$\lim_{q,a \rightarrow 0} \Pi^*(q, a, G) = \int_0^{\bar{z}} Akz dG(z) - \int_0^{\bar{z}} \frac{Akz}{2} dG(z) = \frac{Ak\mu_z}{2}.$$

Therefore, we have that

$$\lim_{z_h \rightarrow 0} \left[\lim_{q,a \rightarrow 0} \Pi_w(0, z_h, q, a, G) \right] - \lim_{q,a \rightarrow 0} \Pi^*(q, a, G) = \frac{Ak\mu_z}{2} > 0. \quad (27)$$

Because $\Pi_w(0, z_h, q, a, G)$ and $\Pi^*(q, a, G)$ are continuous, there exists $\hat{q} > 0$, and $\hat{a} > 0$ and $\hat{z}_h(\hat{q}, \hat{a}) \in \text{Int } Z$ such that for every $(q, a) \in [0, \hat{q}] \times [0, \hat{a}]$ and every $z_h \in (0, \hat{z}_h(\hat{q}, \hat{a})]$, $\Pi_w(0, z_h, q, a, G) > \Pi^*(q, a, G)$. We can retrieve t_h given $z_h \in (0, \hat{z}_h(\hat{q}, \hat{a})]$. ■

In the well-behaved stronger monotone equilibrium constructed above, a small fraction of senders and receivers on the low end of the type distribution follow their equilibrium sender actions, reactions, and assortative matching that would have occurred in the stronger monotone separating equilibrium. The rest of senders and receivers are matched randomly because the rest of senders all choose the same action. We can also establish the same result for a stronger monotone pooling equilibrium as represented in Theorem 10 below.

Theorem 10 *There are $\tilde{q}, \tilde{a} > 0$ such that, for any given $(q, a) \in [0, \tilde{q}] \times [0, \tilde{a}]$, the DM can induce a unique stronger monotone pooling equilibrium that is more efficient*

than the stronger monotone separating equilibrium without restrictions on feasible reactions.

The intuition behind Theorem 10 is the same as that behind Theorem 9. A major difference is that a pooling equilibrium forces a small fraction of senders and receivers on the low end of type distribution to stay out of the market even though they can produce positive net surplus, whereas everyone is matched in the strictly well-behaved equilibrium identified in 9. Theorems 9 and 10 in fact show that a separating equilibrium is not optimal in the classical Spencian model (Spence 1973) of pure signaling with no heterogeneity of receivers (i.e., $a = q = 0$).

7 Concluding remarks

In this paper we generalize Spencian competitive signaling (Spence (1973)) with two-sided matching. A decision maker can choose a set of feasible reactions before senders and receivers move. We characterize a unique stronger monotone equilibrium (unique D1 equilibrium) given each set of feasible reactions. We propose a general method that the DM can use for the design of an optimal unique stronger monotone equilibrium and study the optimal equilibrium design in various settings. Our analysis sheds light on the effects of a trade-off between matching efficiency and signaling costs, the relative heterogeneity of receiver types to sender types and the productivity of the sender's action in the design of optimal stronger monotone signaling equilibrium.

A Lemma 10

Lemma 10 Consider an equilibrium $\{\sigma, \mu, \tau, m\}$. If Assumptions A is satisfied, the equilibrium satisfies the following properties: (i) σ is non-decreasing in z , (ii) μ is non-decreasing in the subset of domain, range σ , with respect to the stronger set order: for $s, s' \in \text{range } \sigma$, $s \geq s'$ implies $\text{supp } \mu(s') \leq_c \text{supp } \mu(s)$, (iii) τ is increasing.

Proof. For any s and s' in S^* such that $s > s'$, consider a sender who chooses s in equilibrium. Then, her utility must satisfy

$$u(\tau(s), s, z) \geq u(\tau(s'), s', z) \tag{S1}$$

Because $s > s'$ and u is decreasing in s and increasing in t , (S1) implies $\tau(s) > \tau(s')$ and hence τ is monotone increasing.

Now we prove the monotonicity of σ by contradiction. Suppose that for $z > z'$, type z chooses $s' \in S^*$ and type z' chooses $s \in S^*$ such that $s > s'$ in equilibrium. This implies $u(\tau(s), s, z') \geq u(\tau(s'), s', z')$. Because $(\tau(s), s) > (\tau(s'), s')$, the strict single crossing property of u in $((t, s); z)$ implies that $u(\tau(s), s, z) > u(\tau(s'), s', z)$ for any $z > z'$. This contradicts that z chooses s' . Therefore, σ is non-decreasing over types that choose actions in S^* .

For the non-decreasing property of σ , we only need to show that any z' with η is no higher than z with $s \in S^*$ in equilibrium. By contradiction, suppose that there exist z' with η and z with $s \in S^*$ such that $z' > z$. Then, we have that $0 \leq u(\tau(s), s, z) < u(\tau(s), s, z')$, where the weak inequality holds because s is the optimal choice for type z and the strict inequality holds due to the monotonicity of u in type. This contradicts that taking no action (i.e., null action η) is optimal for type z' . This completes the proof of the non-decreasing property of σ .

We prove the monotonicity of $\text{supp } \mu(s)$ in the subset of domain, range σ , in the stronger set order by contradiction. Suppose that for $s > s'$, there exist $z \in \text{supp } \mu(s)$ and $z' \in \text{supp } \mu(s')$ such that $z' > z$. Because $z \in \text{cl } \{\tilde{z} | \sigma(\tilde{z}) = s\}$ and

$z' \in \text{cl} \{\tilde{z} | \sigma(\tilde{z}) = s'\}$, it contradicts that σ is non-decreasing. Therefore, μ is non-decreasing in the subset of domain, range σ , with respect to the stronger set order.

■

B Lemma 11

Lemma 11 *Let σ and μ be a sender action function and a belief function in equilibrium respectively. If Assumption A is satisfied, the belief $\mu(s)$ conditional on $s \notin \text{range } \sigma$ that passes Criterion D1 is unique and it is characterized as follows:*

1. *If s belongs to the interval of off-path sender actions induced by the discontinuity of σ at z , then $\text{supp } \mu(s) = \{z\}$.*
2. *Let \bar{z} be the least upper bound of Z if it exists. If $s > \sigma(\bar{z})$, then $\text{supp } \mu(s) = \{\bar{z}\}$.*
3. *Let \underline{z} be the greatest lower bound of Z if it exists. If $s < \sigma(\underline{z})$, then $\text{supp } \mu(s) = \{\underline{z}\}$.*

Proof. According to the proof of Lemma 10, σ is non-decreasing if Assumption A is satisfied. If there are types who choose η and stay out of the market, those types are lower than the types who choose actions in S because of the non-decreasing property of σ . If this happens, let $z_\eta := \min \{z \in Z | \sigma(z) \in S^*\}$ (or $z_\eta := \inf \{z \in Z | \sigma(z) \in S^*\}$ if $\min \{z \in Z | \sigma(z) \in S^*\}$ does not exist).

At any discontinuity point z , let $\sigma(z_+) := \lim_{k \searrow z} \sigma(k)$ and $\sigma(z_-) := \lim_{k \nearrow z} \sigma(k)$. For the proof of item 1, we first consider the case where a discontinuity occurs at $z > z_\eta$ and σ is only right continuous at z , then, $\sigma(z_+) = \sigma(z)$. In this case, $[\sigma(z_-), \sigma(z))$ is the interval of off-path sender actions due to the discontinuity at z . We show that Criterion D1 places zero posterior weight on $z' \neq z$.

Case 1: We show that z' cannot be in the support of $\mu(s)$ for any $s \in [\sigma(z_-), \sigma(z))$ if $z' > z$. On the contrary, suppose that $z' \in \text{supp } \mu(s)$ for some $s \in [\sigma(z_-), \sigma(z))$ when $z < z'$. If $z < z'$, then we have z'' such that $z < z'' < z'$. For the proof, it is sufficient that if type z'' is weakly worse off by deviating to $s \in [\sigma(z_-), \sigma(z))$, then type z' is strictly worse off with the same deviation. For a reaction t chosen by the

receiver after observing such s , let

$$u(t, s, z'') \leq u(\tau(\sigma(z'')), \sigma(z''), z''). \quad (\text{S2})$$

Because $s \in [\sigma(z_-), \sigma(z)]$, we have that $s < \sigma(z)$. Because σ is non-decreasing, we have that $\sigma(z) \leq \sigma(z'')$. These two inequality relations yield $s < \sigma(z'')$. Because the first part of Assumption A says that u is decreasing in s and increasing in t , we must have that $t < \tau(\sigma(z''))$ in order to satisfy (S2). Because $s < \sigma(z'')$ and $t < \tau(\sigma(z''))$, we can use the strict single crossing property of u in Assumption A to show that (S2) implies that for $z' > z''$

$$u(t, s, z') < u(\tau(\sigma(z'')), \sigma(z''), z'). \quad (\text{S3})$$

On the other hand, we have that

$$u(\tau(\sigma(z'')), \sigma(z''), z') \leq u(\tau(\sigma(z')), \sigma(z'), z') \quad (\text{S4})$$

in equilibrium. Combining (S3) and (S4) yields that for $z' > z''$,

$$u(t, s, z') < u(\tau(\sigma(z')), \sigma(z'), z'),$$

which shows that type z' is strictly worse off with the same deviation. (8), the contrapositive of (7) in the definition of Criterion D1 implies that any $z' > z$ cannot be in the support of $\mu(s)$ for any $s \in [\sigma(z_-), \sigma(z)]$.

Case 2: We now show that z' cannot be in the support of $\mu(s)$ for any $s \in [\sigma(z_-), \sigma(z)]$ if $z' < z$. On the contrary, suppose that $z' \in \text{supp } \mu(s)$ for some $s \in [\sigma(z_-), \sigma(z)]$ when $z' < z$. We work with the original condition (7). If $z' < z$, then we have z'' such that $z' < z'' < z$. For a reaction t chosen by the receiver after observing such s , let

$$u(t, s, z') \geq u(\tau(\sigma(z')), \sigma(z'), z'), \quad (\text{S5})$$

that is, type z' is weakly better off by deviating to some $s \in [\sigma(z_-), \sigma(z)]$. On the other hand, we have that

$$u(\tau(\sigma(z')), \sigma(z'), z') \geq u(\tau(\sigma(z'')), \sigma(z''), z') \quad (\text{S6})$$

in equilibrium. Combining (S5) and (S6) yields

$$u(t; s; z^0) = u(\bar{z}^0; z^0; z^0) \quad (S7)$$

Because $s > \bar{z}^0$; the monotonicity of u in Assumption A implies that $t > \bar{z}^0$ in order to satisfy (S7). Then, applying the strict single crossing property of u in Assumption A to (S7), we have that for $z^0 > \bar{z}^0$,

$$u(t; s; z^0) > u(\bar{z}^0; z^0; z^0);$$

which shows that the sender of type \bar{z}^0 is strictly better off with the same deviation. Criterion D1 implies that any $z^0 < \bar{z}^0$ cannot be in the support of (s) for any $s \in [\bar{z}^0; \bar{z}]$. Therefore, the only (s) conditional on $s \in [\bar{z}^0; \bar{z}]$ that passes Criterion D1 puts all the posterior weights on \bar{z} and hence $\text{supp}(s) = \bar{z}$:

Item 1 can be proved similarly in the cases where u is only left continuous at z or $(z) < (z) < (z_+)$, or in the case where u is discontinuous at z . The only thing we need to be careful about is the case where u is discontinuous at z . If u is only right continuous at z_h ; the discontinuity at z_h creates θ -path actions $s \in S$ such that $s < \min S$ (or $s = \inf S$ if $\min S$ does not exist). We can show that any $z^0 > z_h$ cannot be in the support of (s) for any $s < \min S$ following the logic of Case 1 above. Consider $z^0 < z$: If $z^0 < z$; then we have \bar{z}^0 such that $z^0 < \bar{z}^0 < z_h$: Note that $(z^0) = (\bar{z}^0) = 0$ and hence, equilibrium utilities for both types are zero. For a reaction t chosen by the receiver after observing $s \in S$; let $u(t; s; z^0) = 0$: By the increasing property of u in type in Assumption A.(i), $u(t; s; z^0) = 0$ implies that $u(t; s; \bar{z}^0) > 0$: This shows that any $z^0 < z$ cannot be in the support of (s) given Criterion D1. Therefore, the only (s) conditional on any $s \in S$ that passes Criterion D1 puts all the posterior weights on z_h and hence $\text{supp}(s) = z_h$: Item 1 can be proved similarly if u is only left continuous at z_h or $(z_h) < (z_h) < (z_h)_+$:

For the proof of item 2, we can follow the proof of Case 2 to show that the only (s) conditional on $s > \bar{z}$ that passes Criterion D1 puts all the posterior weights on \bar{z} and hence $\text{supp}(s) = \bar{z}$ for $s > \bar{z}$. Similarly, for the proof of item 3, we can follow the proof of Case 1 above to show that only (s) conditional on $s < \underline{z}$ that passes Criterion D1 puts all the posterior weights on \underline{z} and hence $\text{supp}(s) = \underline{z}$ for $s < \underline{z}$: ■

C Corollary 1

According to the proof of Lemma 10, μ is non-decreasing in the subset of domain, range σ , with respect to the stronger set order if Assumption A is satisfied.

We first show that a non-decreasing μ in the stronger set order passes Criterion D1. Consider $s \notin \text{range } \sigma$. If $s > \sigma(\bar{z})$, a non-decreasing μ in the stronger set order must have $\{\bar{z}\}$ as $\text{supp } \mu(s)$. On the contrary, suppose that $z \in \text{supp } \mu(s)$ for $s > \sigma(\bar{z})$ and $z < \bar{z}$. This implies that $z < \bar{z}$ for $z \in \text{supp } \mu(s)$ and $\bar{z} \in \text{supp } \mu(\sigma(\bar{z}))$ but $s > \sigma(\bar{z})$: $\text{supp } \mu(s) \not\preceq_c \text{supp } \mu(\sigma(\bar{z}))$. This contradicts the monotonicity of μ in the stronger set order and hence $\text{supp } \mu(s) = \{\bar{z}\}$ for $s > \sigma(\bar{z})$. This passes Criterion D1, which requires it as in item 2 in Lemma 11. We can analogously show that if $s < \sigma(\underline{z})$, a monotone non-decreasing μ in the stronger set order must have $\{\underline{z}\}$ as $\text{supp } \mu(s)$ and that it passes Criterion D1, which requires it as in item 3 in Lemma 11.

Consider the case where s belongs to the interval of off-path sender actions induced by the discontinuity of σ at some z . Consider the case where σ is only right-continuous at z . Given the monotonicity of σ , we have that

$$\limsup_{k \nearrow z} \text{supp } \mu(\sigma(k)) = \min \text{supp } \mu(\sigma(z)) = z. \quad (\text{S8})$$

If μ is monotone non-decreasing in the stronger set order, $\text{supp } \mu(s')$ and $\text{supp } \mu(s'')$ for two different s' and s'' have at most one element in common. Therefore, (S8) implies that a non-decreasing μ in the stronger set order must have $\{z\}$ as $\text{supp } \mu(s)$ for any $s \in [\sigma(z_-), \sigma(z))$. This passes Criterion D1, which requires it as in item 1 in Lemma 11. We can analogously prove that a non-decreasing μ in the stronger set order satisfies item 1 in Lemma 11 in the cases where σ is only left continuous at z or $\sigma(z_-) < \sigma(z) < \sigma(z_+)$. It is straightforward to show that an equilibrium μ that passes Criterion D1 is non-decreasing in the stronger set order.

Corollary 2 *According to Lemma 11, the support of the belief $\mu(s)$ conditional on $s \notin \text{range } \sigma$ is a singleton if it passes Criterion D1. This implies that if the unique type in the support of the belief $\mu(s)$ is weakly worse off by deviating to $s \notin \text{range } \sigma$, any other type is strictly worse off with the same deviation.*

The proof of Corollary 2 is straightforward, so it is omitted.

D Proof of Lemma 1

If Assumption 2 is satisfied, then $g(t, s, z, x) = v(x, s, z) - t$ is supermodular in all arguments (t, s, z, x) . Because each of T, S, Z , and X is a lattice in \mathbb{R} , we can invoke Theorem 2.6.1 in Topkis (1998) to show that the supermodularity of $g(t, s, z, x)$ in all arguments implies non-decreasing differences in $((t, s, z), x)$, which in turn implies the single crossing property in $((t, s, z); x)$. Because Assumption 2.(i) implies that $g(t, s, z, x)$ has increasing differences in (z, x) . Therefore, Assumption B.(i) is satisfied. Assumption B.(ii) is satisfied by Assumption 2.(ii).

E Proof of Lemma 2

If $t_\ell \leq v(\underline{x}, \zeta(\underline{x}, \underline{z}), \underline{z})$, then $z_\ell = \underline{z}$ and $s_\ell = \zeta(\underline{x}, \underline{z})$. For the case with $t_\ell > v(\underline{x}, \zeta(\underline{x}, \underline{z}), \underline{z})$. Let $\Lambda(s, z) := v(n(z), s, z)$, so that (10) becomes $\Lambda(s, z) - t_\ell = 0$. Consider the receiver's indifference curve $\{(s, z) \in \mathbb{R}_+ \times [\underline{z}, \bar{z}] : \Lambda(s, z) - t_\ell = 0\}$. The slope of this indifference curve is

$$\frac{dz}{ds} = -\frac{\Lambda_s}{\Lambda_z} = -\frac{v_s}{v_x n' + v_z} \leq 0. \quad (\text{S9})$$

Given $v_s \geq 0$, $v_x > 0$, $v_z > 0$ (Assumptions 2.(ii), 3.(i), and 5), the sign above holds because of $n' > 0$. Note that $n' > 0$ holds because of Assumption 6 ($G'(z) > 0$ for all z and $H'(x) > 0$ for all x). On the other hand, $\{(s, z) \in \mathbb{R}_+ \times [\underline{z}, \bar{z}] : t_\ell - c(s, z) = 0\}$ is the sender's indifference curve based on (11) and its slope is

$$\frac{dz}{ds} = -\frac{c_s}{c_z} > 0 \quad (\text{S10})$$

where the sign holds due to Assumption 1.(i). (S9) and (S10) imply that the two indifference curves intersect at most once and the intersection becomes a unique solution for the system of equations, (10) and (11).

F Proof of Theorem 3

We first show that σ is continuous on $[z_\ell, \bar{z}]$. To prove that, we start by showing that $\sigma(z) \geq \zeta(x, z)$, the bilaterally efficient level of type z 's action, where x is the

type of the receiver who is matched with the sender of type z in equilibrium.

Lemma 12 *For all $z \in [z_\ell, \bar{z}]$, $\sigma(z) \geq \zeta(x, z)$ in any stronger monotone separating equilibrium, where x is the type of the receiver who matches with type z .*

Proof. We prove by contradiction. Suppose that there exists $z \in [z_\ell, \bar{z}]$ such that $\sigma(z) < \zeta(x, z)$. There are two possible cases. The first case is when $\sigma(z) < \zeta(x, z)$ and $\zeta(x, z) \notin S^*$. Then, it is a profitable sender deviation by type z to an off-path action $\zeta(x, z)$ if

$$\mathbb{E}_{\mu(\zeta(x, z))} [v(x, \zeta(x, z), z')] - c(\zeta(x, z), z) > v(x, \sigma(z), z) - c(\sigma(z), z). \quad (\text{S11})$$

Because of the constrained efficiency of $\zeta(x, z)$ given the strict concavity of $v - c$ in s (Assumption 3), we have that

$$v(x, \zeta(x, z), z) - c(\zeta(x, z), z) > v(x, \sigma(z), z) - c(\sigma(z), z). \quad (\text{S12})$$

Further, because $\sigma(z) < \zeta(x, z)$, we have $z' \geq z$ for all $z' \in \text{supp } \mu(\zeta(x, z))$ due to the stronger monotonicity of μ . Therefore, we have

$$\mathbb{E}_{\mu(\zeta(x, z))} [v(x, \zeta(x, z), z')] \geq v(x, \zeta(x, z), z). \quad (\text{S13})$$

Because of (S12) and (S13), (S11) holds.

Therefore, if there exists $z \in [z_\ell, \bar{z}]$ such that $\sigma(z) < \zeta(x, z)$, then it must be the second case where $\zeta(x, z) \in S^*$. This implies that there exists $z' > z$ such that $\sigma(z') = \zeta(x, z) < \zeta(x', z')$, where x' is the type of the receiver who matches with type z' , given the increasing property of σ in a stronger monotone separating equilibrium (implication of Lemma 10.(i)). Because we have $\sigma(z) < \zeta(x, z)$ and $\sigma(z') < \zeta(x', z')$, there exists an interval $(z_1, z_2) \subset (z, z')$ such that for all $z'' \in (z_1, z_2)$, $\sigma(z'') < \zeta(x'', z'')$, where x'' is the type of the receiver who matches with type z'' in equilibrium.

σ is increasing on (z_1, z_2) in any stronger monotone separating equilibrium. Further, σ is finite on (z_1, z_2) because $\sigma(z'') \leq \zeta(x_2, z_2)$, where x_2 is the type of the receiver who matches with type z_2 in equilibrium. One can invoke Theorem 7.21 in Wheeden and Zygmund (1977) to show that σ is differentiable with non-negative derivative σ' almost everywhere on (z_1, z_2) . Because σ is strictly increasing in $s \in S^*$

in a stronger monotone separating equilibrium, σ' must be in fact positive almost everywhere on (z_1, z_2) .

Because σ is differentiable with positive σ' almost everywhere on (z_1, z_2) , we can find an interval $(z'_1, z'_2) \subset (z_1, z_2)$ such that σ is differentiable with positive σ' everywhere on (z'_1, z'_2) . Because σ is differentiable with positive σ' everywhere on (z'_1, z'_2) , $\{\sigma(z'') : z'' \in (z'_1, z'_2)\}$ is an interval $(\sigma(z'_1), \sigma(z'_2))$ and μ is differentiable with positive $\mu' = 1/\sigma'$ everywhere on $(\sigma(z'_1), \sigma(z'_2))$. On the other hand, $\tau : S^* \rightarrow [t_\ell, t_h]$ is increasing according to Lemma 10.(iii). Invoking Theorem 7.21 in Wheeden and Zygmund (1977), we can show that τ is differentiable with non-negative τ' almost everywhere on $(\sigma(z'_1), \sigma(z'_2))$.

Finally, we can pick an interval $(z_1^\circ, z_2^\circ) \subset (z'_1, z'_2)$ such that (i) σ is differentiable with positive σ' everywhere on (z_1°, z_2°) , (ii) μ is differentiable with positive $\mu' = 1/\sigma'$ everywhere on $(\sigma(z_1^\circ), \sigma(z_2^\circ))$ and (iii) τ is differentiable with non-negative derivative everywhere on $(\sigma(z_1^\circ), \sigma(z_2^\circ))$. It implies that for all $z'' \in (z_1^\circ, z_2^\circ)$, the following first-order condition must be satisfied:

$$\tau'(\sigma(z'')) - c_s(\sigma(z''), z'') = 0. \quad (\text{S14})$$

Because (1) $\mu(s)$ is differentiable everywhere in $(\sigma(z_1^\circ), \sigma(z_2^\circ))$ and (2) τ is differentiable everywhere on $(\sigma(z_1^\circ), \sigma(z_2^\circ))$, π is differentiable everywhere on $(\sigma(z_1^\circ), \sigma(z_2^\circ))$. If type x'' chooses a sender with $s \in (\sigma(z_1^\circ), \sigma(z_2^\circ))$, the following first-order condition must be satisfied:

$$\pi_s(s, x'') = v_s(x'', s, \mu(s)) + v_z(x, s, \mu(s)) \mu'(s'') - \tau'(s'') = 0 \quad (\text{S15})$$

Let type z'' choose $s = \sigma(z'') \in (\sigma(z_1^\circ), \sigma(z_2^\circ))$, which type x'' chooses. Combining (S14) and (S15) yields that $v_s(x, s, \mu(s)) - c_s(\sigma(z''), z'') + v_z(x'', s, \mu(s)) \mu'(s) = 0$, which cannot hold. The reason is that (a) $v_s - c_s > 0$ because $v - c$ is strictly concave (Assumption 3) and $\sigma(z'') < \zeta(x'', z'')$, (b) $\mu' \geq 0$ and (c) $v_z > 0$ (Assumption 5). Therefore, we cannot have the case where $\sigma(z) < \zeta(x, z)$, and $\zeta(x, z) \in S^*$. This concludes the proof. ■

Lemma 13 σ is continuous on $[z_\ell, \bar{z}]$ and hence $S^* = [s_\ell, \sigma(\bar{z})]$ in any stronger monotone separating equilibrium

Proof. We prove by contradiction. Suppose that σ is discontinuous at some $z \in$

$[z_\ell, \bar{z}]$. We consider the case where σ is only right continuous at z , so that $\sigma(z_+) = \sigma(z) > \sigma(z_-)$. Because $\sigma(z) \geq \zeta(x, z)$ for all $z \in [z_\ell, \bar{z}]$ by Lemma 12, it implies that $\sigma(z) > \zeta(x, z)$, where x is the type of a receiver who matches with type z . This discontinuity creates an off-path action interval $[\sigma(z_-), \sigma(z))$. The stronger monotone belief μ implies that $\mu(s)$ puts all the weights on z conditional on $s \in [\sigma(z_-), \sigma(z))$ because of Lemma 11.1. Because $\sigma(z)$ is inefficiently high (i.e., $\sigma(z) > \zeta(x, z)$), there exists $s \in [\sigma(z_-), \sigma(z))$ such that

$$v(x, s, z) - c(s, z) > v(x, \sigma(z), z) - c(\sigma(z), z), \quad (\text{S16})$$

due to the strict concavity of $v - c$ in s (Assumption 3). (S16) shows the existence of a profitable sender deviation by type z to an off path action $s \in [\sigma_-(z), \sigma(z))$. One can analogously show the existence of a profitable sender deviation by type z in the case where σ is only left continuous at z or $\sigma(z_-) < \sigma(z) < \sigma(z_+)$. Therefore, σ is continuous at all $z \in [z_\ell, \bar{z}]$.

Because σ is increasing over $[z_\ell, \bar{z}]$ in any stronger monotone separating equilibrium, the continuity of σ at all $z \in [z_\ell, \bar{z}]$ implies a compact real interval $S^* = [s_\ell, \sigma(\bar{z})]$ ■

Lemma 14 $\tau : S^* \rightarrow T$ is increasing and continuous on S^* and has continuous derivative τ' on $\text{Int } S^*$ in any stronger monotone separating equilibrium.

Proof. The increasing property of τ is from Lemma 10.(iii). We prove the continuity of τ by contradiction. Suppose that τ is discontinuous at $s \in S^*$. Consider the case where τ is only right continuous at s . Let z be the type of a sender who chooses s in equilibrium, i.e., $\sigma(z) = s$. Because $\tau(\sigma(z_-)) < \tau(\sigma(z))$ and c and σ are continuous (Assumption 5.(i) and Lemma 13), there exists $z' < z$ such that $\tau(\sigma(z')) - c(\sigma(z'), z') < \tau(\sigma(z)) - c(\sigma(z), z')$, which contradicts the optimality of $\sigma(z')$ for type z' . We can analogously prove that the discontinuity of τ contradicts the optimality of the sender's action choice in the case where τ is left right continuous at s or $\tau(s_-) < \tau(s) < \tau(s_+)$. Therefore, $\tau : S^* \rightarrow T$ is continuous everywhere on S^* .

We prove the differentiability by contradiction as well. Suppose that τ is not differentiable at some $\hat{s} \in \text{Int } S^* = (s_\ell, \sigma(\bar{z}))$.

$\tau : S^* \rightarrow T$ is increasing and hence it is not differentiable only at finitely many points in $\text{Int } S^* = (s_\ell, \sigma(\bar{z}))$ due to Theorem 7.21 in Wheeden and Zygmund (1977). This implies that if τ is not differentiable at \hat{s} , there exists two intervals (s_1, \hat{s}) , $(\hat{s}, s_2) \subset \text{Int } S^*$ where τ is differentiable. Because τ is differentiable at any point in $(s_1, \hat{s}) \cup (\hat{s}, s_2)$ and c is differentiable everywhere (Assumption 4), the optimality of $s = \sigma(z)$ implies that the first-order condition $\tau'(s) = c_s(s, \mu(s))$ for all $s = \sigma(z) \in (s_1, \hat{s}) \cup (\hat{s}, s_2)$. Because c_s is continuous (Assumption 4) and $\mu = \sigma^{-1}$ is continuous on S^* , this implies that

$$\tau'(\hat{s}_-) = c_s(\hat{s}, \mu(\hat{s})) = \tau'(\hat{s}_+). \quad (\text{S17})$$

Because τ is continuous, (S17) implies that τ is differentiable at \hat{s} , which contradicts the non-differentiability of τ at \hat{s} . Therefore, τ must be differentiable everywhere on $\text{Int } S^*$.

Because τ is differentiable everywhere on $\text{Int } S^*$, the first-order condition $\tau'(s) = c_s(s, \mu(s))$ must be satisfied for all $s \in \text{Int } S^*$ in equilibrium. μ is continuous on S^* because it is the inverse of σ over S^* and σ is continuous (Lemma 13). Further c_s is continuous (Assumption 5.(i)). Therefore, $\tau'(s) = c_s(s, \mu(s))$ is continuous on $\text{Int } S^*$. ■

Lemma 15 $\mu : S \rightarrow \Delta(Z)$ is increasing and continuous on S^* and has continuous derivative μ' on $\text{Int } S^*$.

Proof. σ is continuous on Z and S^* is a compact real interval $[\sigma(z_\ell), \sigma(\bar{z})]$ (Lemma 13 in Online Appendix). Given Lemma 10.(i), σ is increasing over Z in a stronger monotone *separating* equilibrium. Therefore, Lemma 13 implies that $\mu(s)$ (the support of $\mu(s)$ to be precise) for all $s \in S^*$ is the inverse of $\sigma(z)$ so that μ is increasing and continuous on S^* .

Because μ is increasing on S^* and $\mu(s) \in Z$ for $s \in S^*$, we can apply Theorem 7.21 in Wheeden and Zygmund (1977) to show that μ is differentiable almost everywhere on $\text{Int } S^*$. Let us prove that μ is differentiable everywhere on $\text{Int } S^*$. Suppose that μ is not differentiable at $\check{s} \in \text{Int } S^*$. Because μ is not differentiable at only finitely many points, there exists $s_1, s_2 \in \text{Int } S^*$ such that μ is differentiable everywhere on (s_1, \check{s}) and (\check{s}, s_2) .

Because (1) v is differentiable with respect to s and z (Assumptions 3.(ii)), (2) μ is differentiable everywhere on (s_1, \check{s}) and (\check{s}, s_2) , and (3) τ is differentiable everywhere on $\text{Int } S^*$ (Lemma 14 in Online Appendix), $\pi(s, x) := v(x, s, \mu(s)) - \tau(s)$, x is differentiable everywhere on $(s_1, \check{s}) \cup (\check{s}, s_2)$.

Let x be the type of a receiver who matches with a sender with $s = \xi(x)$. For the receiver's matching problem, the following first-order condition is satisfied: for all $s = \xi(x) \in (s_1, \check{s}) \cup (\check{s}, s_2)$:

$$\pi_s(s, x) = v_s(x, s, \mu(s)) + v_z(x, s, \mu(s)) \mu'(s) - \tau'(s) = 0 \quad (\text{S18})$$

Suppose that $\xi(x) = \xi(x') = s$ for some $s \in S^*$ with $x > x'$. It implies that $\xi(x'') = s$ for all $x'' \in [x, x']$ because ξ is non-decreasing in a stronger monotone equilibrium (Theorem 2) given Assumptions 1 and 2. Then, the market clearing condition is not satisfied because $H([x, x']) > G(\{s\}) = 0$. Therefore, ξ is increasing on X .

Then, the *market-clearing condition* implies that $\xi = \sigma \circ n^{-1}$. Because σ is continuous on Z (Lemma 13) and n^{-1} is continuous on X (implication of Assumption 6), ξ is continuous on $[z_\ell, \bar{z}]$. Because ξ is increasing and continuous on Z , $\xi^{-1} = n \circ \mu$ is increasing and continuous on S^* .

Given $v_z > 0$ (Assumption 3.(i)), replacing x with $\xi^{-1}(s)$ in (S18) yields that

$$\mu'(s) = \frac{-[v_s(\xi^{-1}(s), s, \mu(s)) - \tau'(s)]}{v_z(\xi^{-1}(s), s, \mu(s))}, \quad \forall s \in (s_1, \check{s}) \cup (\check{s}, s_2). \quad (\text{S19})$$

In addition to the continuity of ξ^{-1} on S^* , v_s , v_z , τ' , and μ are continuous (Assumption 3.(ii) and Lemmas 13 and 14 in Online Appendix). Therefore, from (S19), we have that

$$\mu'(\check{s}_-) = \frac{-[v_s(\xi^{-1}(\check{s}), \check{s}, \mu(\check{s})) - \tau'(\check{s})]}{v_z(\xi^{-1}(\check{s}), \check{s}, \mu(\check{s}))} = \mu'(\check{s}_+) \quad (\text{S20})$$

Because μ is continuous on S^* , (S20) implies that μ is differentiable at \check{s} , which contradicts the non-differentiability of μ at \check{s} . Therefore, μ must be differentiable everywhere on $\text{Int } S^*$ in any stronger monotone separating equilibrium. Further, the continuity of v_s , v_z , τ' , ξ^{-1} , and μ implies that μ' is continuous on $\text{Int } S^*$. ■

G Stronger monotone separating equilibrium

Here we present the stronger monotone separating equilibrium $\{\tilde{\sigma}, \tilde{\mu}, \tilde{\tau}, \tilde{m}\}$ given z_ℓ induced by t_ℓ and $t_\ell < t_h = \infty$. Once we establish the stronger monotone equilibrium, it is convenient to establish the (strictly) well-behaved equilibrium with the same z_ℓ but $t_h < \tilde{\tau}(\tilde{\sigma}(\bar{z}))$.

Theorem 11 *The necessary and sufficient conditions for a stronger monotone separating equilibrium $\{\tilde{\sigma}, \tilde{\mu}, \tilde{\tau}, \tilde{m}\}$ are*

1. $\tilde{\sigma}(\underline{z}) = \zeta(\underline{x}, \underline{z})$, and $\tilde{\sigma}(z)$ satisfies that $\tilde{\tau}'(\tilde{\sigma}(z)) - c_s(\tilde{\sigma}(z), z) = 0$ for all $z \in \text{Int } Z$.
2. For $s \in [0, \tilde{\sigma}(\underline{z})]$, $\tilde{\mu}(s) = \underline{z}$; for all $s \in S^*$, $\tilde{\mu}(s) = \tilde{\sigma}^{-1}(s)$, where $\tilde{\sigma}^{-1}(s)$ satisfies $\tilde{\sigma}(\tilde{\sigma}^{-1}(s)) = s$ for all $s \in S^*$; for all $s > \tilde{\sigma}(\bar{z})$, $\tilde{\mu}(s) = \bar{z}$.
3. $\xi(x)$ satisfies

$$v_s(x, s, \tilde{\mu}(s)) + v_z(x, s, \tilde{\mu}(s)) \tilde{\mu}'(s) - \tilde{\tau}'(s) = 0 \quad (\text{S21})$$

at $s = \xi(x)$ for all $x \in \text{Int } X$.

4. $\tilde{\tau}$ with $\tilde{\tau}(\tilde{\sigma}(\underline{z})) = t_\ell$ clears the market given \tilde{m} such that $\tilde{m}(s) = \xi^{-1}(s) = n(\tilde{\mu}(s))$ for all $s \in S^*$.

The proof is below.

Proof of Condition 1 If there are types who stay out of the market, they must be below z_ℓ given that c is decreasing in z (Assumption 1.(i)). Note that type z_ℓ is indifferent between staying out of the market and taking action s_ℓ because they satisfy 11. Since c is decreasing in z (Assumption 1.(i)), it means that any type in $[\underline{z}, z_\ell)$ is strictly better off by staying out of the market instead of taking action s_ℓ .

Given that τ is continuous on S^* and differentiable on $\text{Int } S^*$ (Theorem 3.(ii)) and c is differentiable (Assumption 5.(i)), it is clear that $\tilde{\tau}'(\tilde{\sigma}(z)) - c_s(\tilde{\sigma}(z), z) = 0$ for all $z \in (z_\ell, \bar{z})$ is a necessary condition for $\tilde{\sigma}(z)$ to be an optimal action for type $z \in [z_\ell, \bar{z}]$ among all actions in $S^* = [\tilde{\sigma}(z_\ell), \tilde{\sigma}(\bar{z})]$. We show that it is also a sufficient condition for $\tilde{\sigma}(z)$ to be an optimal action for type $z \in [z_\ell, \bar{z}]$ among all actions in

$S^* = [\tilde{\sigma}(z_\ell), \tilde{\sigma}(\bar{z})]$. We need to be careful about the boundary condition. A part of Condition 1 in Theorem 1 is that $\tilde{\sigma}(z)$ satisfies that

$$\tilde{\tau}'(\tilde{\sigma}(z)) - c_s(\tilde{\sigma}(z), z) = 0 \text{ for all } z \in (z_\ell, \bar{z}). \quad (\text{S22})$$

Applying the strict supermodularity of $-c$ (Assumption 1.(ii)) to (S22) yields that

$$\tilde{\tau}'(\tilde{\sigma}(z')) - c_s(\tilde{\sigma}(z'), z) \geq 0 \text{ if } z' \leq z, \forall z, z' \in (z_\ell, \bar{z}) \quad (\text{S23})$$

$$\tilde{\tau}(\tilde{\sigma}(z)) - c(\tilde{\sigma}(z), z) > \tilde{\tau}(\tilde{\sigma}(z')) - c(\tilde{\sigma}(z'), z) \quad \forall z, z' \in (z_\ell, \bar{z}) \text{ s.t. } z \neq z' \quad (\text{S24})$$

(S23) implies that $\tilde{\sigma}$ is increasing in $z \in (z_\ell, \bar{z})$. Because $\tilde{\sigma}$ is continuous on S^* (Lemmas 13), it implies that $\tilde{\sigma}$ is increasing over $[z_\ell, \bar{z}]$. Because $\tilde{\sigma}$ is increasing over $[z_\ell, \bar{z}]$ and $\tilde{\tau}$ and c are continuous (Theorem 3.(ii) and Assumption 5.(i)), (S24) implies that

$$\tilde{\tau}(\tilde{\sigma}(z)) - c(\tilde{\sigma}(z), z) > \tilde{\tau}(\tilde{\sigma}(z')) - c(\tilde{\sigma}(z'), z) \quad \forall z, z' \in [z_\ell, \bar{z}] \text{ s.t. } z \neq z'. \quad (\text{S25})$$

(S25) shows that $\tilde{\sigma}(z)$ is be an optimal action for type $z \in [z_\ell, \bar{z}]$ among all actions in $S^* = [\tilde{\sigma}(z_\ell), \tilde{\sigma}(\bar{z})]$, ignoring the individual rationality.

To show the individual rationality, let $\tilde{U}(z) := \tilde{\tau}(\tilde{\sigma}(z)) - c(\tilde{\sigma}(z), z)$. Because of 11, we have that $\tilde{U}(z_\ell) = \tilde{\tau}(\tilde{\sigma}(z_\ell)) - c(\tilde{\sigma}(z_\ell), z_\ell) = 0$. It is clear that $\tilde{U}(z) > \tilde{\tau}(\tilde{\sigma}(z_\ell)) - c(\tilde{\sigma}(z_\ell), z) > \tilde{U}(z_\ell) = 0$ for all $z \in (z_\ell, \bar{z}]$, where the first inequality holds because of (S25) and the second inequality holds because c is decreasing in z (Assumption 1.(i)).

We need to show that type z has no incentive to deviate to $s \notin$ range σ to complete the proof that $\tilde{\sigma}(z)$ is an optimal action for type z among all actions in S . We defer it to the end. First we start with the stronger monotone belief $\tilde{\mu}$

Proof of Condition 2 Note that range $\sigma = \{0\} \cup [s_\ell, \tilde{\sigma}(\bar{z})]$. Therefore, we can derive the belief on the equilibrium path as follows: (i) for $s = 0$, $\tilde{\mu}(s) = G(z|z < z_\ell)$ and (ii) for all $s \in [s_\ell, \tilde{\sigma}(\bar{z})]$, $\tilde{\mu}(s) = \tilde{\sigma}^{-1}(s)$, where $\tilde{\sigma}^{-1}(s)$ satisfies $\tilde{\sigma}(\tilde{\sigma}^{-1}(s)) = s$. This is part of Condition 2 in Theorem 11 so that consistency is satisfied. There are two intervals of off path sender actions: $(0, s_\ell)$ and $(\tilde{\sigma}(\bar{z}), \infty)$. The monotonicity of the belief in the stronger set order uniquely determines the belief conditional on $s \notin$ range σ : (iii) for $s \in (0, s_\ell)$, $\tilde{\mu}(s) = z_\ell$ and (iv) for $s \in (\tilde{\sigma}(\bar{z}), \infty)$, $\tilde{\mu}(s) = \bar{z}$.

The belief function $\tilde{\mu}$ satisfying (i) -(iv), which is Condition 2 in Theorem 11, is the unique equilibrium monotone in the stronger set order given σ in Condition 1

Proof of Conditions 3 If there are types who stay out of the market, they must be below x_ℓ given that v is increasing in x (Assumption 2.(ii)). Note that type x_ℓ is indifferent between staying out of the market and matching with the sender of type z_ℓ because they satisfy (10). Since v is increasing in x (Assumption 2.(ii)), it means that any type in $[\underline{x}, x_\ell)$ is strictly better off by staying out of the market.

Consider the matching problem for type $x \in [x_\ell, \bar{x}]$. Note that $v, c, \gamma, \tilde{\tau}$ and $\tilde{\mu}$ are continuous and differentiable (Assumptions 4.(ii) and 5.(i) and Theorem 3). Therefore, it is clear that for all $x \in (x_\ell, \bar{x})$,

$$\pi_s(\xi(x), x) = v_s(x, \xi(x), \tilde{\mu}(\xi(x))) + v_z(x, \xi(x), \tilde{\mu}(\xi(x))) \tilde{\mu}'(\xi(x)) - \tilde{\tau}'(\xi(x)) = 0 \quad (\text{S26})$$

is a necessary condition for $\xi(x)$ to be an optimal choice of a matching partner (in terms of her action) for type $x \in [x_\ell, \bar{x}]$ among all actions in S^* .

We show that (S26) is also a sufficient condition for $\xi(x)$ to be an optimal action of a matching partner for type $x \in [x_\ell, \bar{x}]$ among all actions in S^* . Applying the supermodularity of v (Assumptions 2.(i)) to (S26) yields that

$$\pi_s(\xi(x'), x) \geq 0 \text{ if } x' \leq x \forall x, x' \in (x_\ell, \bar{x}), \quad (\text{S27})$$

$$\pi(\xi(x), x) > \pi(\xi(x'), x) \forall x, x' \in (x_\ell, \bar{x}) \text{ s.t. } x \neq x' \quad (\text{S28})$$

(S27) implies that $\xi(x)$ is increasing on (x_ℓ, \bar{x}) . Given the increasing property of ξ on (x_ℓ, \bar{x}) , ξ must be continuous on $[x_\ell, \bar{x}]$. Otherwise, senders in the interval created by a discontinuity of ξ are not matched in equilibrium and it violates the market clearing condition.

The continuity of ξ on $[x_\ell, \bar{x}]$ makes it increasing on $[x_\ell, \bar{x}]$ because ξ is increasing on $x \in (x_\ell, \bar{x})$. Together with the continuity of ξ over $[x_\ell, \bar{x}]$, the continuity of v and $\tilde{\tau}$ (Assumptions 3.(ii) and 14) makes $\pi(\xi(x'), x)$ continuous in $x' \in [x_\ell, \bar{x}]$ and $x \in [x_\ell, \bar{x}]$. Therefore, (S28) implies that

$$\pi(\xi(x), x) > \pi(\xi(x'), x) \forall x, x' \in [x_\ell, \bar{x}] \text{ s.t. } x \neq x'. \quad (\text{S29})$$

(S29) shows that $\xi(x)$ is be an optimal choice of a matching partner for type $x \in [z_\ell, \bar{z}]$ among all actions in $S^* = [\tilde{\sigma}(z_\ell), \tilde{\sigma}(\bar{z})]$, ignoring the individual rationality.

To show the individual rationality, let $\tilde{\pi}(x) := \pi(\xi(x), x)$. Because of (10), we have that $\pi(\xi(x_\ell), x_\ell) = 0$. It is clear that $\pi(\xi(x), x) > \pi(\xi(x_\ell), x) > \pi(\xi(x_\ell), x_\ell) = 0$ for all $x \in (x_\ell, \bar{x}]$, where the first inequality holds because of (S29) and the second inequality holds because v is increasing in x (Assumption 2.(ii)).

Proof of Condition 4 It is straightforward that \tilde{m} in in Condition 4 is a unique measure-preserving matching function given that ξ and $\tilde{\sigma}$ are both increasing.

Proof of no profitable sender deviation to an off-path action Applying Lemma 11 and Corollary 1, the monotone belief in the stronger set order is the unique belief that pass Criterion D1. Because $\tilde{\mu}(s)$ for $s \notin \text{range } \sigma$ is a degenerate probability distribution with a singleton as its support, as suggested in Corollary 2, we only need to check if the type of the sender in that support has an incentive to deviate in order to check if any sender has an incentive to deviate to such s .

Now let us prove no profitable sender deviation to an off-path action. Conditional on $s \in (0, s_\ell)$, it is believed that the sender who chose s is $\tilde{\mu}(s) = z_\ell$. According to Corollary 1, if the sender of type z_ℓ has no profitable deviation to $s \in (0, s_\ell)$, then no one else does. Therefore, we only need to check if the sender of type z_ℓ has an profitable deviation to $s \in (0, s_\ell)$. If she reduces her action down to $s \in (0, s_\ell)$, no receiver wants her because he has to transfer at least t_ℓ but he can be matched with a sender with s_ℓ at t_ℓ . Therefore, there is no sender profitable deviation to s .

Now, let us examine if there is a profitable sender deviation to $s \in (\tilde{\sigma}(\bar{z}), \infty)$. First, agents at the action choice stage expect \tilde{m} is increasing and the equilibrium transfer $\tilde{\tau} : S^* \rightarrow T$ satisfies

$$\tilde{\tau}'(s) = v_s(\tilde{m}(s), s, \tilde{\mu}(s)) + v_z(\tilde{m}(s), s, \tilde{\mu}(s))\tilde{\mu}'(s). \quad (\text{S30})$$

Because the support of $\tilde{\mu}(s)$ for $s > \tilde{\sigma}(\bar{z})$ is a singleton, \bar{z} , we only need to check if the sender of type \bar{z} has an incentive to choose $s > \tilde{\sigma}(\bar{z})$. Because there is a continuum of receivers with different actions and types, we need to check which receiver is willing to transfer the largest amount to the sender with $s > \tilde{\sigma}(\bar{z})$. The

type x receiver's maximum willingness to transfer is

$$t(s, x) = v(x, s, \bar{z}) - [v(x, \tilde{\sigma}(n^{-1}(x))), n^{-1}(x)] - \tilde{\tau}(\tilde{\sigma}(n^{-1}(x))).$$

Because $s > \tilde{\sigma}(\bar{z})$ and $\bar{z} \geq n^{-1}(x)$, we have that $t(s, x) > \tilde{\tau}(\tilde{\sigma}(n^{-1}(x)))$.

Given $\tilde{\tau}'$ in (S30), taking the derivative of $t(s, x)$ with respect to x yields

$$t_x(s, x) = v_x(x, s, \bar{z}) - v_x(x, \tilde{\sigma}(n^{-1}(x))), n^{-1}(x) > 0. \quad (\text{S31})$$

Note that $v_x(x, s, z)$ is non-decreasing in s and increasing in z , given Assumption 2.(i) - $v(b, x, s, z)$ is supermodular in (b, x, s, z) and strictly supermodular in (z, x) . Because $s > \tilde{\sigma}(n^{-1}(x))$ and $\bar{z} \geq n^{-1}(x)$ for all $x \geq x_\ell$, this implies that $t_x(s, x)$ is positive for any $s > \tilde{\sigma}(\bar{z})$, as in (S31). It in turn implies that the maximum amount of transfer that the receiver of type \bar{x} is willing to make is the largest. Then, given Criterion D1, we only need to check if the sender of type \bar{z} has a profitable deviation to $s > \tilde{\sigma}(\bar{z})$ while keeping her current match partner, the receiver of type \bar{x} .

There is a profitable sender deviation to $s > \tilde{\sigma}(\bar{z})$ for \bar{z} if and only if for some $s > \tilde{\sigma}(\bar{z})$

$$v(\bar{x}, s, \bar{z}) - c(s, \bar{z}) > v(\bar{x}, \tilde{\sigma}(\bar{z})) - c(\tilde{\sigma}(\bar{z}), \bar{z}). \quad (\text{S32})$$

However, the inequality above is not satisfied for any $s > \tilde{\sigma}(\bar{z})$. The reason is that the information rent, the last term in (S30), makes $\tilde{\sigma}(\bar{z})$ larger than the constrained efficient action level for the sender of type \bar{z} . Therefore, if $s > \tilde{\sigma}(\bar{z})$, then $v - c$ is even smaller given the strict concavity of $v - c$ in s (Assumption 3).

H Proof of Lemma 4

Let $Z(s)$ be the set of the types of senders who choose the same action s and it has a positive measure. We start with the case where there exists $\max Z(s)$. Let $z^\circ := \max Z(s)$. We first show that $z^\circ = \bar{z}$. Let $x^\circ := \max X(s)$, where $X(s)$ be the set of types of receivers who are matched with a sender with s in equilibrium. We prove by contradiction. Suppose that bunching does not happen on the top, i.e.,

$z^\circ < \bar{z}$. Then we have that

$$s = \sigma(z^\circ) \leq \lim_{z \searrow z^\circ} \sigma(z) \quad (\text{S33})$$

This is due to the monotonicity of σ in Lemma 10.(i). We like to show that (S33) holds with strict inequality, i.e., $s < \lim_{z \searrow z^\circ} \sigma(z)$. In equilibrium, we have that for any $z > z^\circ$,

$$\tau(s) - c(s, z^\circ) \geq \lim_{z \searrow z^\circ} [\tau(\sigma(z)) - c(\sigma(z), z^\circ)] \quad (\text{S34})$$

$$\mathbb{E}[v(x^\circ, s, z' | z' \in Z(s))] - \tau(s) \geq \lim_{z \searrow z^\circ} (\mathbb{E}[v(x^\circ, \sigma(z), z'' | z'' \in Z(\sigma(z)))] - \tau(\sigma(z))) \quad (\text{S35})$$

For any $\sigma(z) \geq s$, we have that $z'' \geq z^\circ = \max Z(s)$ for any $z'' \in Z(\sigma(z))$ because of the monotonicity of σ (Lemma 10.(i)). Further $Z(s)$ has a positive measure. Therefore, the monotonicity of v in Assumption 3.(i) implies that, for any $z > z^\circ$

$$\mathbb{E}[v(x^\circ, s, z' | z' \in Z(s))] < \mathbb{E}[v(x^\circ, \sigma(z), z'' | z'' \in Z(\sigma(z)))] \quad (\text{S36})$$

(S35) and (S36) imply that

$$\tau(s) < \lim_{z \searrow z^\circ} \tau(\sigma(z)) \quad (\text{S37})$$

Because c is decreasing in s (Assumption 1.(i)), (S34) and (S37) induces that

$$s = \sigma(z^\circ) < \lim_{z \searrow z^\circ} \sigma(z). \quad (\text{S38})$$

Therefore, any $s' \in (s, \lim_{z \searrow z^\circ} \sigma(z))$ is not chosen in equilibrium given that the monotonicity of σ .

The support of $\mu(s)$ is $Z(s)$. On the other hand, we have that $\lim_{z \searrow z^\circ} \inf \text{supp}(\mu(\sigma(z))) = z^\circ$. This implies that there is the unique stronger monotone belief on the sender's type conditional on any $s' \in (s, \lim_{z \searrow z^\circ} \sigma(z))$ and it is equal to $\mu(s') = z^\circ$.

Suppose that the sender of type z° deviates to action $s + \epsilon \in (s, \lim_{z \searrow z^\circ} \sigma(z))$. A receiver of type x who is currently matched with a sender with s receives the matching utility of $\mathbb{E}[v(x, s, z | z \in Z(s))] - \tau(s)$. Note that $\tau(s) < t_h$ given (S37).

Therefore, there is a profitable deviation for the sender of type z° if

$$v(x, s + \epsilon, z^\circ) - c(s + \epsilon, z^\circ) > \mathbb{E}[v(x, s, z | z \in Z(s)) - c(s, z^\circ)]. \quad (\text{S39})$$

Because v and c are continuous in the sender's action, v is increasing in z , and $Z(s)$ has a positive measure, we have that

$$\lim_{\epsilon \searrow 0} (v(x, s + \epsilon, z^\circ) - c(s + \epsilon, z^\circ)) > \mathbb{E}[v(x, s, z | z \in Z(s)) - c(s, z^\circ)] \quad (\text{S40})$$

Because v and c are continuous in the sender's action, (S40) implies that there exists ϵ such that (S39) is satisfied. This contradicts that s is an equilibrium chosen by all senders whose types are in $Z(s)$.

We can analogously prove that there exists a profitable sender deviation if $z^\circ < \bar{z}$ when z° is defined as $\sup Z(s)$ rather than $\max Z(s)$.

Assumption 6 implies that there is no atom in the sender type distribution. Therefore, $Z(s)$ is an interval with $\max Z(s) = \bar{z}$ due to the monotonicity of σ (Lemma 10.(i)).

I Proof of Lemma 5

Let z^* be the minimum of $Z(s)$ (We can analogously prove the lemma for the case where z^* is infimum of $Z(s)$). If $Z(s)$ has a positive measure, we have that $z^* < \bar{z}$ given Assumption 6 on G . Let t^* be the reaction to action s chosen by the positive measure of senders. We prove by contradiction.

On the contrary, suppose that $t^* < t_h$ in a stronger monotone equilibrium. Because type \bar{z} is one of senders who choose s and \bar{z} is the maximum of sender types, the stronger monotonicity of μ implies that $\mu(s') = \bar{z}$ for any $s' > s$. Suppose that the sender of type \bar{z} deviates to $s + \epsilon$ for small $\epsilon > 0$. The type of this sender is believed to be \bar{z} . Suppose that the receiver of type \bar{x} is matched with the sender with $s + \epsilon$. A profitable upward deviation for a sender is equivalent to the existence of $t \in [t_\ell, t_h]$ and $\epsilon > 0$ such that

$$v(\bar{x}, s + \epsilon, \bar{z}) - t > \mathbb{E}[v(\bar{x}, s, z') | z^* \leq z' < \bar{z}] - t^*, \quad (\text{S41})$$

$$t - c(s + \epsilon, \bar{z}) > \bar{\tau}(s) - t^*, \quad (\text{S42})$$

which yield

$$v(\bar{x}, s + \epsilon, \bar{z}) - c(s + \epsilon, \bar{z}) > \mathbb{E}[v(\bar{x}, s, z') | z^* \leq z' < \bar{z}] - c(s, \bar{z}). \quad (\text{S43})$$

Given $G'(z) > 0$ for all $z \in Z$ (Assumption 6), the monotonicity of v in z (Assumption 3.(i)) implies that

$$v(\bar{x}, s, \bar{z}) - c(s, \bar{z}) > \mathbb{E}[v(\bar{x}, s, z') | z^* \leq z' < \bar{z}] - c(s, \bar{z}). \quad (\text{S44})$$

Because v and c are continuous in the sender action, (S44) ensures the existence of $\epsilon > 0$ that satisfies (S43). Because $t^* < t_h$, (S43) implies that there exists t such that $t^* < t < t_h$ and it satisfies (S41) and (S42). Therefore, the only way to prevent such an upward deviation by the sender is $t^* = t_h$.

J Proof of Lemma 8

When all senders of type z_h or above choose the same action s_h in equilibrium, we have that for all $z > z_h$

$$t_h - c(s_h, z) \geq \tilde{\tau}(\tilde{\sigma}(z_h)) - c(\tilde{\sigma}(z_h), z). \quad (\text{S45})$$

Since (18) holds at (s_h, z_h) , (18) and (S45) imply that for all $z > z_h$,

$$-c(s_h, z) + c(\tilde{\sigma}(z_h), z) \geq -c(s_h, z_h) + c(\tilde{\sigma}(z_h), z_h),$$

which implies that $s_h \geq \tilde{\sigma}(z_h)$ by the strict supermodularity of $-c$ (Assumption 1.(ii)). Because $s_h \geq \tilde{\sigma}(z_h)$, both (18) and (S45) imply that $t_h \geq \tilde{\tau}(\tilde{\sigma}(z_h))$.

Because $s_h \geq \tilde{\sigma}(z_h)$, we have that $\mathbb{E}[v(n(z_h), s_h, z') | z' \geq z_h] > v(n(z_h), \tilde{\sigma}(z_h), z_h)$. (19) at $(s, z) = (s_h, z_h)$ is written as $\mathbb{E}[v(n(z_h), s_h, z') | z' \geq z_h] - t_h = v(n(z_h), \tilde{\sigma}(z_h), z_h) - \tilde{\tau}(\tilde{\sigma}(z_h))$, which implies $t_h > \tilde{\tau}(\tilde{\sigma}(z_h))$ given $\mathbb{E}[v(n(z_h), s_h, z') | z' \geq z_h] > v(n(z_h), \tilde{\sigma}(z_h), z_h)$. If $t_h > \tilde{\tau}(\tilde{\sigma}(z_h))$, (18) at (s_h, z_h) implies that $s_h > \tilde{\sigma}(z_h)$.

For all z , let $s_h^s(z)$ be the value of s that satisfies $t_h - c(s_h^s(z), z) = \tilde{\tau}(\tilde{\sigma}(z)) - c(\tilde{\sigma}(z), z)$. Because $t_h < \tilde{\tau}(\tilde{\sigma}(\bar{z}))$, $s_h^s(\bar{z}) < \tilde{\sigma}(\bar{z})$. On the other hand, $s_h = s_h^s(z_h) < s_h^s(\bar{z})$ because $z_h < \bar{z}$ and s_h^s is increasing in z . Therefore, we have that $s_h < \tilde{\sigma}(\bar{z})$.

K Proof of Lemma 7

Consider the following set for senders:

$$\{(s, z) \in \mathbb{R}_{++} \times Z : t_h - c(s, z) = \tilde{\tau}(\tilde{\sigma}(z)) - c(\tilde{\sigma}(z), z), s > \tilde{\sigma}(z)\} \quad (\text{S46})$$

Because (s_h, z_h) must satisfy (18) and $s_h > \tilde{\sigma}(z_h)$ (Lemma 8), (s_h, z_h) must belong to the set in (S46). Applying the envelope theorem for $\tilde{\sigma}$, to the total differential of $t_h - c(s, z) = \tilde{\tau}(\tilde{\sigma}(z)) - c(\tilde{\sigma}(z), z)$ yields the slope of the equation as

$$\frac{dz}{ds} = -\frac{c_s(s, z)}{c_z(s, z) - c_z(\tilde{\sigma}(z), z)} > 0 \text{ for all } s > \tilde{\sigma}(z), \quad (\text{S47})$$

where the sign holds because $c_s > 0$ and $c_z(s, z) - c_z(\tilde{\sigma}(z), z) < 0$ due to Assumption 1.(ii).

Consider the following set for receivers:

$$\left\{ (s, z) \in \mathbb{R}_{++} \times Z : \begin{array}{l} \mathbb{E}[v(n(z), s, z') | z' \geq z] - t_h = v(n(z), \tilde{\sigma}(z), z) - \tilde{\tau}(\tilde{\sigma}(z)), \\ s > \tilde{\sigma}(z) \end{array} \right\}. \quad (\text{S48})$$

Because (s_h, z_h) must satisfy (19) and $s_h > \tilde{\sigma}(z_h)$ (Lemma 8), (s_h, z_h) must belong to the set in (S48).

Applying the envelope theorem for $\tilde{\sigma}$, and $\tilde{\tau}$ to the total differential of $\mathbb{E}[v(n(z), s, z') | z' \geq z] - t_h = v(n(z), \tilde{\sigma}(z), z) - \tilde{\tau}(\tilde{\sigma}(z))$, we can express the slope of the equation as

$$\frac{dz}{ds} = -\frac{\mathbb{E}v_s}{\mathbb{E}v_x n' + \frac{\partial \mathbb{E}[v | z' > z]}{\partial z} - (v_x n' + v_z)} \leq 0 \text{ for all } s > \tilde{\sigma}(z), \quad (\text{S49})$$

where the sign holds because $-\mathbb{E}v_s \leq 0$ ($v_s \geq 0$ according to Assumption 3.(i)) and the denominator is positive due to Assumptions 2, 3.(i), and 3.(iv) given $n' > 0$.

(S47) and (S49) imply that the two sets in (S46) and (S48) have at most one element in common. This implies that if there is a solution (s_h, z_h) that solves (S47) and (S49), it must be unique.

L Proof of Theorem 6

Note that when $t_h < \tilde{\tau}(\bar{z})$, $\{\hat{\sigma}, \hat{\mu}, \hat{\tau}, \hat{m}\}$ follows the separating equilibrium $\{\tilde{\sigma}, \tilde{\mu}, \tilde{\tau}, \tilde{m}\}$ with the same z_ℓ before z hits z_h . Therefore, we will use some of the proof of Theorem 11. Because there is a jump to s_h and every sender of type z_h or higher chooses the same action s_h , $\lim_{z \nearrow z_h} \hat{\sigma}(z) = \tilde{\sigma}(z_h)$. Therefore, we will use $\tilde{\sigma}(z_h)$ instead of $\lim_{z \nearrow z_h} \hat{\sigma}(z)$ for simplicity of notation.

It is straightforward to show that the beliefs in Condition 2 of Theorem 6 satisfies the consistency and the stronger monotonicity. There are three off-path sender action intervals, $(0, s_\ell)$, $[\tilde{\sigma}(z_h), s_h)$ and (s_h, ∞) . The *stronger monotonicity* of beliefs (Lemma 11 and Corollary 1) uniquely pins down the singleton support of a belief $\hat{\mu}(s)$ conditional on s in each off-path sender action interval. Further, we only need to check the type- $\hat{\mu}(s)$ sender's incentive to deviate to s in any off-path action interval, thanks to Corollary 2.

L.1 Sender's optimal action choice

In subsection (a) below, we first show that there is no profitable deviation to an off-path action for every sender if they choose actions according to $\hat{\sigma}$.

In the remaining subsections, we show that $\hat{\sigma}(z)$ solves Problem 1 if Problem 1 admits a solution; $\hat{\sigma}(z) = 0$ otherwise. Note that $\hat{\sigma}(z)$ solves Problem 1 for $z \in S^*[s_\ell, \tilde{\sigma}(z_h)) \cup s_h$. When it does, the sender's equilibrium utility $\hat{U}(z)$ is increasing and positive for $z > z_\ell$ starting from $\hat{U}(z_\ell) = 0$ due to the envelope theorem. Therefore, the constraint in Problem 1 is satisfied.

(a) No profitable sender deviation to an off-path action There are three intervals of actions that are not observed in equilibrium: $(0, s_\ell)$, $[\tilde{\sigma}(z_h), s_h)$, and (s_h, ∞) . First, consider a deviation to $s > s_h$. Since the belief $\hat{\mu}(s) = \bar{z}$ for $s > s_h$ passes Criterion D1, we only need to check if the sender of type \bar{z} has an incentive to deviate to such s in order to establish that there is no profitable sender deviation to such s . Suppose that the sender of type \bar{z} increases her action above s_h . The maximum transfer she can receive is $t = t_h$. Because $\hat{\sigma}(\bar{z}) < s$ and $\hat{\tau}(\hat{\sigma}(\bar{z})) = t_h$, we have that $\hat{\tau}(\hat{\sigma}(\bar{z})) - c(\hat{\sigma}(\bar{z}), \bar{z}) > t_h - c(s, \bar{z})$. Therefore, the sender of type \bar{z} cannot gain by changing her action to $s > s_h$.

Second, consider a deviation to $s \in (0, s_\ell)$. In this case, the belief is $\hat{\mu}(s) = z_\ell$. Note that $\hat{\mu}(s_\ell) = z_\ell$. Since a receiver can be matched with a sender with z_ℓ whose type is believed to be z_ℓ , transferring the lower bound of transfers, t_ℓ to her, no receiver wants a sender with $s < s_\ell$ whose type is believed to be z_ℓ , transferring t_ℓ to her. Therefore, there is no profitable deviation to $s \in (0, s_\ell)$.

Third, consider a deviation to $s \in [\tilde{\sigma}(z_h), s_h)$. In this case, the belief is $\hat{\mu}(s) = z_h$. Suppose that the sender of type z_h decreases her action from s_h to $s \in (\tilde{\sigma}(z_h), s_h)$. She can be matched with a receiver of type $x \in [x_\ell, x_h)$ or a receiver of type $x \in [x_h, \bar{x}]$.

We first show that there is no profitable sender deviation to $s \in [\tilde{\sigma}(z_h), s_h)$, being matched with any receiver of type $x \in [x_\ell, x_h)$. Let $t(s, x)$ be the maximum amount of transfer that a receiver of type $x \in [x_\ell, x_h)$ is willing to make to a sender with $s \in (\tilde{\sigma}(z_h), s_h)$. Following the proof of no profitable sender deviation in the stronger monotone separating equilibrium, we can show that the receiver's maximum willingness increases as x approaches x_h from the left. Therefore, the supremum of the amount of transfers to the sender with s is

$$t(s, x_h) = v(x_h, s, z_h) - (v(x_h, \tilde{\sigma}(z_h), z_h) - \tilde{\tau}(\tilde{\sigma}(z_h))). \quad (\text{S50})$$

Because $s > \tilde{\sigma}(z_h)$, we have that $t(s, x_h) > \tilde{\tau}(\tilde{\sigma}(z_h))$. Given the upper bound of transfers t_h , the receiver of type x_h cannot transfer $t(s, x_h)$ if $t(s, x_h) > t_h$. Suppose that the receiver can always transfer $t(s, x_h)$ as if there is no upper bound of transfers. If a sender of type z_h has no incentive to deviate to s when there is no upper bound of transfers, then she also has no incentive to deviate to s when there is the upper bound of transfers.

Therefore, the sender of type z_h has an incentive to deviate to $s \in (\tilde{\sigma}(z_h), s_h)$ if and only if

$$t(s, x_h) - c(s, z_h) > t_h - c(s_h, z_h) = \tilde{\tau}(\tilde{\sigma}(z_h)) - c(\tilde{\sigma}(z_h), z_h), \quad (\text{S51})$$

where the equality comes from (18). (S50) and (S51) together implies that the sender of type z_h has an incentive to deviate to $s \in (\tilde{\sigma}(z_h), s_h)$ if and only if

$$v(x_h, s, z_h) - c(s, z_h) > v(x_h, \tilde{\sigma}(z_h), z_h) - c(\tilde{\sigma}(z_h), z_h). \quad (\text{S52})$$

$\tilde{\sigma}(z_h)$ is the action chosen by type z_h in the stronger monotone separating equilibrium. The first-order conditions for action choices by type z_h and type x_h in Conditions 1 and 4 in Theorem 11 imply that

$$v_s(x_h, \tilde{\sigma}(z_h), z_h) + v_z(x_h, \tilde{\sigma}(z_h), z_h) \tilde{\mu}'(\tilde{\sigma}(z_h)) - c_s(\tilde{\sigma}(z_h), z_h) = 0.$$

Because $\tilde{\mu}' > 0$ for all $s \in \text{Int } S^*$ (implication of Theorem 3.(iii)), the equality above means that

$$v_s(x_h, \tilde{\sigma}(z_h), z_h) - c_s(\tilde{\sigma}(z_h), z_h) < 0 \quad (\text{S53})$$

Because $s > \tilde{\sigma}(z_h)$ and $v - c$ is strictly concave in s (Assumption 3), (S53) implies that (S52) is not satisfied. Therefore, there is no profitable sender deviation to $s \in [\tilde{\sigma}(z_h), s_h)$, being matched with any receiver of type $x \in [x_\ell, x_h)$.

Finally, we show that there is no profitable sender deviation to any off-path action s in $[\tilde{\sigma}(z_h), s_h)$, followed by matching with a receiver in $[x_h, \bar{x}]$. $[x_h, \bar{x}]$ is the interval of receiver types who are matched with senders on the top. The maximum amount of the reaction that the receiver of type $x \in [x_h, \bar{x}]$ is willing to choose is

$$T(s, x) = v(x, s, z_h) - (\mathbb{E}[v(x, s_h, z') | z' \geq z_h] - t_h) \quad (\text{S54})$$

Because $z_h \leq z'$ and $s < s_h$, we have that $T(s, x) < t_h$ and we can also apply Assumption 2.(i) to show that $T(s, x)$ decreases in x . Therefore, if and only if

$$v(x_h, s, z_h) - c(s, z_h) \leq \mathbb{E}[v(x_h, s_h, z') | z' \geq z_h] - c(s_h, z_h) \text{ for all } s \in [\tilde{\sigma}(z_h), s_h) \quad (\text{S55})$$

is satisfied, the sender of type z_h has no profitable deviation to any $s \in [\tilde{\sigma}(z_h), s_h)$, followed by matching with a receiver in $[x_h, \bar{x}]$. Consequently, Corollary 2 implies that no sender has an incentive to deviate to any off-path action s in $[\tilde{\sigma}(z_h), s_h)$ if and only if (S55) is satisfied for all $s \in [\tilde{\sigma}(z_h), s_h)$. Because (18) and (19) are satisfied in equilibrium, we have that

$$\mathbb{E}[v(x_h, s_h, z') | z' \geq z_h] - c(s_h, z_h) = v(x_h, \tilde{\sigma}(z_h), z_h) - c(\tilde{\sigma}(z_h), z_h). \quad (\text{S56})$$

Applying (S56) to (S55) yields that for $s \in [\tilde{\sigma}(z_h), s_h)$,

$$v(x_h, s, z_h) - c(s, z_h) \leq v(x_h, \tilde{\sigma}(z_h), z_h) - c(\tilde{\sigma}(z_h), z_h), \quad (\text{S57})$$

which is always satisfied given Assumption 5 (strict concavity of $v - c$ in s) because $\tilde{\sigma}(z_h)$ is greater than the bilaterally efficient action $\zeta(x_h, z_h)$. Therefore, there is no profitable sender deviation to any off-path action s in $[\tilde{\sigma}(z_h), s_h)$, followed by matching with a receiver in $[x_h, \bar{x}]$.

(a) Action choice in S^* by the sender of type z_h The sender's equilibrium action is s_h . Note that $S^* = [s_\ell, \tilde{\sigma}(z_h)) \cup s_h$. Because of (18), her utility is the same as $\tilde{\tau}(\tilde{\sigma}(z_h)) - c(\tilde{\sigma}(z_h), z_h)$, which is her utility in the stronger monotone separating equilibrium. Suppose that she chooses $s \in [s_\ell, \tilde{\sigma}(z_h))$. Because the transfer schedule $\hat{\tau}$ is the same as $\tilde{\tau}$ in the stronger monotone separating equilibrium, we can apply Theorem 11 to show that the sender of type z_h has no incentive to decrease her action to $s \in [s_\ell, \tilde{\sigma}(z_h))$. Therefore, s_h solves Problem 1.

(b) Action choice in S^* by the sender of type $z \in (z_h, \bar{z}]$ The sender's equilibrium action is s_h . From (a) above, we know that for all $s \in [s_\ell, \tilde{\sigma}(z_h))$,

$$t_h - c(s_h, z_h) \geq \hat{\tau}(s) - c(s, z_h). \quad (\text{S58})$$

Applying Assumption 1.(ii) to (S58) yields that $t_h - c(s_h, z_h) > \hat{\tau}(s) - c(s, z_h)$ for all $z > z_h$ and all $s \in [s_\ell, \tilde{\sigma}(z_h))$, which shows that the sender of type $z > z_h$ has no incentive to change her action to any other action in S^* . Therefore, s_h solves Problem 1.

(c) Action choice in S^* by the sender of type $z \in [z_\ell, z_h)$ Because $z < z_h$, the sender's action is lower than $\tilde{\sigma}(z_h)$. Because (i) the transfer schedule $\hat{\tau}$ for the action in $[s_\ell, \tilde{\sigma}(z_h))$ is the same as the one in the equilibrium with only the lower bound of transfers and (ii) the sender's action $\hat{\sigma}(z)$ is the same $\tilde{\sigma}(z)$ that she would have chosen in the stronger monotone separating equilibrium, we apply the proof of Condition 1 in Theorem 11 to show that for any $s \in [s_\ell, \tilde{\sigma}(z_h))$ and $s \neq \hat{\sigma}(z)$

$$\hat{\tau}(\hat{\sigma}(z)) - c(\hat{\sigma}(z), z) > \hat{\tau}(s) - c(s, z). \quad (\text{S59})$$

Therefore, the sender has no incentive to change her action to another action in $[s_\ell, \tilde{\sigma}(z_h))$.

Now suppose that the sender changes her action to s_h . We know that for the sender of type z_h ,

$$t_h - c(s_h, z_h) = \hat{\tau}(\tilde{\sigma}(z_h)) - c(\tilde{\sigma}(z_h), z_h).$$

Because $s_h > \tilde{\sigma}(z_h)$ by Lemma 8 and $z_h > z$, applying Assumption 1.(ii) to the equation above yields that

$$t_h - c(s_h, z) < \hat{\tau}(\tilde{\sigma}(z_h)) - c(\tilde{\sigma}(z_h), z). \quad (\text{S60})$$

Combining (S59) at $s = \tilde{\sigma}(z_h)$ and (S60) yields that $\hat{\tau}(s) - c(s, z) > t_h - c(s_h, z)$, which shows that the sender of type $z \in [z_\ell, z_h)$ has no incentive to increase her action to s_h . Therefore, s_h solves Problem 1.

(d) No action choice by the sender of type $z \in [z, z_\ell)$ The sender chooses no action in the equilibrium: $\hat{\sigma}(z) = 0$. Consider a change to s_ℓ . We know that for the sender of type z_ℓ , $t_\ell - c(s_\ell, z_\ell) = 0$. Because $z < z_\ell$, applying Assumption 1.(ii) yields that

$$t_\ell - c(s_\ell, z) < 0, \quad (\text{S61})$$

which implies that the sender's utility is lower than zero, so the sender cannot gain by increasing her action to s_ℓ .

Consider a change to $s \in S^*$ with $s > s_\ell$. From the previous section, we know that for all $s \in S^*$ with $s > s_\ell$

$$t_\ell - c(s_\ell, z_\ell) > \hat{\tau}(s) - c(s, z_\ell).$$

Because $z < z_\ell$, applying Assumption 1.(ii) to the inequality relation above yields that for all $s \in S^*$ with $s > s_\ell$

$$t_\ell - c(s_\ell, z) > \hat{\tau}(s) - c(s, z). \quad (\text{S62})$$

Combining (S61) and (S62) yields that $0 > \hat{\tau}(s) - c(s, z)$ for $s \in S^*$ with $s > s_\ell$, which shows that a change to any $s \in S^*$ with $s > s_\ell$ lowers the sender's utility. Therefore, for the sender of type $z \in [z, z_\ell)$, there is no solution for Problem 1.

L.2 Receiver's optimal matching choice

Applying the envelope theorem to the receiver's equilibrium utility $\hat{\Pi}(x)$, we can show that $\hat{\Pi}(x)$ is increasing and positive for $x > x_\ell$ starting from $\hat{\Pi}(x_\ell) = 0$. The receiver's matching problem can be seen as: which sender with an action in S^* does he want to match with as formulated in (4)?

(a) Optimal matching choice by the receiver of type x_h The equilibrium partner is a sender with s_h as his partner. Suppose that the receiver wants to choose a sender with $s \in [s_\ell, \tilde{\sigma}(z_h))$ as his partner. According to (19), the receiver's equilibrium utility with a sender with s_h satisfies

$$\mathbb{E}[v(x_h, s_h, z)|z \geq z_h] - t_h = v(x_h, \tilde{\sigma}(z_h), z_h) - \tilde{\tau}(\tilde{\sigma}(z_h)). \quad (\text{S63})$$

The proof of Condition 3 of Theorem 11 shows that in the stronger monotone separating equilibrium, we have that for any $s \in [s_\ell, \tilde{\sigma}(z_h))$,

$$v(x_h, \tilde{\sigma}(z_h), z_h) - \tilde{\tau}(\tilde{\sigma}(z_h)) > v(x_h, s, \tilde{\mu}(s)) - \tilde{\tau}(s). \quad (\text{S64})$$

Because $\hat{\mu}(s) = \tilde{\mu}(s)$ and $\hat{\tau}(s) = \tilde{\tau}(s)$ for any $s \in [s_\ell, \tilde{\sigma}(z_h))$, (S63) and (S64) together show that for any $s \in [s_\ell, \tilde{\sigma}(z_h))$

$$\mathbb{E}[v(x_h, s_h, z)|z \geq z_h] - t_h > v(x_h, s, \hat{\mu}(s)) - \hat{\tau}(s), \quad (\text{S65})$$

which shows that the receiver has no incentive to change his action to be matched with a sender with $s \in [s_\ell, \tilde{\sigma}(z_h))$.

(b) Optimal matching choice by the receiver of type $x > x_h$ The equilibrium utility for the receiver of type x with a sender with s_h as his partner is $\mathbb{E}[v(x, s_h, z)|z \geq z_h] - t_h$. Suppose that the receiver changes his partner to a sender with $s \in [s_\ell, \tilde{\sigma}(z_h))$. Given $s \in [s_\ell, \tilde{\sigma}(z_h))$, the belief on the sender's type is $\hat{\mu}(s) < z_h$ and his utility is $v(x, s, \hat{\mu}(s)) - \hat{\tau}(s)$. Therefore, we need to examine the sign of the utility difference:

$$\mathbb{E}[v(x, s_h, z)|z \geq z_h] - t_h - [v(x, s, \hat{\mu}(s)) - \hat{\tau}(s)] \quad (\text{S66})$$

Applying the envelope theorem for $b_e(x, s_h)$ and $\gamma(x, s, \hat{\mu}(s))$, we can express the partial derivative of (S66) with respect to x

$$\mathbb{E}[v_x(x, s_h, z) | z \geq z_h] - v_x(x, s, \hat{\mu}(s)) > 0. \quad (\text{S67})$$

To show the positive sign in (S67), note that $s_h > s$. Therefore, Assumption 2.(i) implies that $v_x(x, s_h, z) > v_x(x, s, \hat{\mu}(s))$ for any $z \geq z_h > \hat{\mu}(s)$, which leads to $\mathbb{E}[v_x(x, s_h, z) | z \geq z_h] > v_x(x, s, \hat{\mu}(s))$.

Because the utility difference in (S66) is zero at $x = x_h$ and $s = \tilde{\sigma}(z_h)$, (S67) implies that (S66) is positive for $x > x_h$, which means that the receiver of type $x > x_h$ has no incentive to change his partner to a sender with $s \in [s_\ell, \tilde{\sigma}(z_h))$.

(c) Optimal matching choice by the receiver of type $x \in [x_\ell, x_h)$ The equilibrium outcomes for receivers of type $x \in [x_\ell, x_h)$ and senders of types in $[z_\ell, z_h)$ are the same as the outcomes in the stronger monotone separating equilibrium, including actions, transfers and matching. Therefore, from the proof of Conditions 3 in Theorem 11, we know that the utility for the receiver will be lower by changing his partner to any sender with $s \in [s_\ell, \tilde{\sigma}(z_h))$.

Suppose that the receiver changes his partner to a sender with s_h . To see if the receiver prefers such a change, first note that

$$\mathbb{E}[v(x_h, s_h, z) | z \geq z_h] - t_h = v(x_h, \tilde{\sigma}(z_h), z_h) - \tilde{\tau}(\tilde{\sigma}(z_h)) \quad (\text{S68})$$

Given $s_h > \tilde{\sigma}(z_h)$ and $z \geq z_h$, we can apply Assumption 2.(i) to show that for $x < x_h$

$$\mathbb{E}[v(x, s_h, z) | z \geq z_h] - t_h < v(x, \tilde{\sigma}(z_h), z_h) - \tilde{\tau}(\tilde{\sigma}(z_h)). \quad (\text{S69})$$

From the proof of Conditions 3 in Theorem 11, we also know that for $x < x_h$

$$v(x, \tilde{\sigma}(z_h), z_h) - \tilde{\tau}(\tilde{\sigma}(z_h)) < v(x, \tilde{\sigma}(n^{-1}(x)), n^{-1}(x)) - \tilde{\tau}(\tilde{\sigma}(n^{-1}(x))) \quad (\text{S70})$$

Combining (S69) and (S70) yields

$$\mathbb{E}[v(x, s_h, z) | z \geq z_h] - t_h < v(n^{-1}(x), x, \tilde{\sigma}(n^{-1}(x)), n^{-1}(x)) - \tilde{\tau}(\tilde{\sigma}(n^{-1}(x))) \quad (\text{S71})$$

The expression on the right-hand side of (S71) is indeed the same as the equi-

librium utility for the receiver of type $x < x_h$ in the well-behaved equilibrium. Therefore, a receiver of type $x \in [x_\ell, x_h)$ strictly prefers a sender with $\hat{\sigma}(n^{-1}(x)) = \tilde{\sigma}(n^{-1}(x))$ as his partner.

(d) Optimal action choice by the receiver of type $x \in [\underline{x}, x_\ell)$ The receiver of type $x \in [\underline{x}, x_\ell)$ is unmatched in equilibrium. Suppose that the receiver decides to choose a sender with s_ℓ as his partner. We know that $v(x_\ell, s_\ell, \hat{\mu}(s_\ell)) - t_\ell = 0$. This implies that for $x \in [\underline{x}, x_\ell)$,

$$v(x, s_\ell, \hat{\mu}(s_\ell)) - t_\ell < 0. \quad (\text{S72})$$

Therefore, the receiver of type $x \in [\underline{x}, x_\ell)$ has no incentive to choose a sender with s_ℓ as his partner.

Suppose that the receiver of type $x \in [\underline{x}, x_\ell)$ chooses a sender with $s \in (s_\ell, \tilde{\sigma}(z_h))$ as his partner. According to Subsection (c) above, we know that for any $s \in (s_\ell, \tilde{\sigma}(z_h))$,

$$v(x_\ell, s, \hat{\mu}(s)) - \tau(s) < v(x_\ell, s_\ell, \hat{\mu}(s_\ell)) - t_\ell \quad (\text{S73})$$

Applying Assumption 2.(i) to (S52) yields that for any $s \in (s_\ell, \tilde{\sigma}(z_h))$ and any $x \in [\underline{x}, x_\ell)$

$$v(x, s, \hat{\mu}(s)) - \tau(s) < v(x, s_\ell, \hat{\mu}(s_\ell)) - t_\ell. \quad (\text{S74})$$

Because the expression on the right hand side of (S53) is the same as the expression on the left hand side of (S51), we can conclude that $v(x, s, \hat{\mu}(s)) - \tau(s) < 0$ for $x < x_\ell$ and $s \in (s_\ell, \tilde{\sigma}(z_h))$, which show that the receiver's utility becomes negative to choose a sender with $s \in (s_\ell, \tilde{\sigma}(z_h))$ as his partner.

Finally, suppose that the receiver of type $x \in [\underline{x}, x_\ell)$ chooses a sender with s_h as his partner. According to Subsection (c) above, we know that

$$\mathbb{E}[v(x_\ell, s_h, z) | z \geq z_h] - t_h < v(x_\ell, s_\ell, \hat{\mu}(s_\ell)) - t_\ell \quad (\text{S75})$$

Given $s_h > s_\ell$, $z_h > \hat{\mu}(s_\ell)$, applying Assumption 2.(i) implies that for $x < x_\ell$

$$\mathbb{E}[v(x, s_h, z) | z \geq z_h] - t_h < v(x, s_\ell, \hat{\mu}(s_\ell)) - t_\ell \quad (\text{S76})$$

Because the expression on the right hand side of (S55) is the same as the expression

on the left hand side of (S51), we can conclude that $\mathbb{E}[v(x, s_h, z) | z \geq z_h] - t_h < 0$ for $x < x_\ell$. This shows that the receiver's utility is negative with a sender a sender with s_h as his partner. This concludes that no receiver of type $x \in [\underline{x}, x_\ell)$ wants to choose any sender in the market as his partner.

M Proof of Proposition 1

When $z_\ell = \underline{z}$, $s_\ell = \zeta(\underline{x}, \underline{z}) = 0$ and $t_\ell = c(\zeta(\underline{x}, \underline{z}), \underline{z}) = 0$. When $t_\ell = 0$, $z_\ell = \underline{z}$ and $s_\ell = \zeta(\underline{x}, \underline{z}) = 0$.

Now consider the case with $z_\ell \in (\underline{z}, \bar{z})$. First consider case (i) in Assumption 7. For any given $z_\ell \in (\underline{z}, \bar{z}]$, (10) and (11) induce the equation:

$$v(n(z_\ell), s, z_\ell) - c(s, z_\ell) = 0. \quad (\text{S77})$$

If $s = 0$, then the left-hand side of (S77) is positive. As $s \rightarrow \infty$, the left-hand side approaches $-\infty$ because of Assumption 4. Given Assumption 7.(i), $v(n(z_\ell), s, z_\ell)$ is positive and it is independent of s . Because c is continuous in s (Assumption 4), it means that there exists a unique s_ℓ satisfying ((S77)). Then, a unique t_ℓ is determined by either (10) or (11) given s_ℓ and z_ℓ .

Now consider case (ii) in Assumption 7. For any given $z_\ell \in (\underline{z}, \bar{z})$, the left hand side of (S77) is zero at $s = 0$. However, we cannot have $s_\ell = 0$. If $s_\ell = 0$, then t_ℓ must be zero. Then every seller's utility is zero by entering the market. This implies that every sender will enter the market so z_ℓ cannot be greater than \underline{z} given our assumption that everyone enters the market if she is indifferent between entering the market and staying out of it.

Because of Assumptions 4 and 5, $v - c$ is strictly concave and the left hand side of (S77) approaches $-\infty$ as $s \rightarrow \infty$. Since the left hand side of (S77) is zero at $s = 0$, this implies that there exists a unique positive s_ℓ satisfying (S77). Then, a unique t_ℓ is determined by either (10) or (11) given s_ℓ and z_ℓ .

Suppose that the DM chooses t_ℓ , a part of the unique solution (t_ℓ, s_ℓ) that solves (10) and (11) given z_ℓ . Then, (z_ℓ, s_ℓ) is a unique solution that solves (10) and (11) because of Lemma 2.

N Proof of Proposition 2

First consider case (i) in Assumption 7. For any given $z_h \in (z_\ell, \bar{z})$, (18) and (19) induces the equation:

$$c(s, z_h) - c(\tilde{\sigma}(z_h), z_h) = \mathbb{E}[v(n(z_h), s, z') | z' \geq z_h] - v(n(z_h), \tilde{\sigma}(z_h), z_h). \quad (\text{S78})$$

The right hand side of (S78) is positive because it is independent of s and $\tilde{\sigma}(z_h)$ and $z' \geq z_h$ for $z_h < \bar{z}$. The left-hand side is continuous and increasing in s . Because of Assumptions 1.(i) and 4, the left hand side is increasing in s with $\lim_{s \searrow 0} [c(s, z_h) - c(\tilde{\sigma}(z_h), z_h)] < 0$ and $\lim_{s \nearrow \infty} [c(s, z_h) - c(\tilde{\sigma}(z_h), z_h)] = \infty$. Therefore, we have a unique solution for s_h that solves (S78). Then, t_h can be uniquely derived from either (18) and (19). Therefore, for any given $z_h \in (z_\ell, \bar{z})$, there exists a unique (t_h, s_h) that satisfies (18) and (19).

Now consider case (ii) in Assumption 7. For any given $z_h \in (z_\ell, \bar{z})$, (18) and (19) induce the equation:

$$\mathbb{E}[v(n(z_h), s, z') | z' \geq z_h] - c(s, z_h) = v(n(z_h), \tilde{\sigma}(z_h), z_h) - c(\tilde{\sigma}(z_h), z_h). \quad (\text{S79})$$

The right hand side of (S79) is positive because it is the sum of the equilibrium utilities for the sender type z_h and the receiver type $n(z_h)$ for $z_h \in (z_\ell, \bar{z})$ in the stronger monotone separating equilibrium and both equilibrium utilities for senders and receivers are increasing in types in the separating equilibrium. Because of Assumption 4 ($c(0, z) = 0$ for all z) and case (ii) in Assumption 7 ($v(x, 0, z) = 0$ for all x and z), we have that

$$0 = \mathbb{E}[v(n(z_h), 0, z') | z' \geq z_h] - c(0, z_h) < v(n(z_h), \tilde{\sigma}(z_h), z_h) - c(\tilde{\sigma}(z_h), z_h) \quad (\text{S80})$$

Because of Assumption 5 ($\lim_{s \rightarrow \infty} v_s(x, s, z) = 0$ given any x and z and $\lim_{s \rightarrow \infty} c_s(s, z) = \infty$ given any z), we have that

$$-\infty = \lim_{s \rightarrow \infty} [\mathbb{E}[v(n(z_h), s, z') | z' \geq z_h] - c(s, z_h)] < v(n(z_h), \tilde{\sigma}(z_h), z_h) - c(\tilde{\sigma}(z_h), z_h) \quad (\text{S81})$$

When $s = \tilde{\sigma}(z_h)$, we have that

$$\mathbb{E}[v(n(z_h), \tilde{\sigma}(z_h), z') | z' \geq z_h] - c(\tilde{\sigma}(z_h), z_h) > v(n(z_h), \tilde{\sigma}(z_h), z_h) - c(\tilde{\sigma}(z_h), z_h). \quad (\text{S82})$$

because $\mathbb{E}[v(n(z_h), \tilde{\sigma}(z_h), z') | z' \geq z_h] > v(n(z_h), \tilde{\sigma}(z_h), z_h)$.

Because $\mathbb{E}[v(n(z_h), s, z') | z' \geq z_h] - c(s, z_h)$ is strictly concave in s due to Assumption 5, (S80), (S81), and (S82) imply that there are two values, s^0 and s^1 that satisfy (S79) with $s^0 < \tilde{\sigma}(z_h) < s^1$. Because $\tilde{\sigma}(z_h) < s_h$ from Lemma 8, s_h is equal to s^1 . Because t_h can be uniquely derived from either (18) and (19), there exists a unique (t_h, s_h) that satisfies (18) and (19) for any given $z_h \in (z_\ell, \bar{z})$. Therefore, in both cases in Assumption 7, there exists a unique t_h and a unique s_h that satisfies (18) and (19) for any given $z_h \in (z_\ell, \bar{z})$. Suppose that the DM chooses t_h , a part of the unique solution (t_h, s_h) that solves (18) and (19) given $z_h \in (z_\ell, \bar{z})$. Then, (z_h, s_h) is a unique solution that solves (18) and (19) because of Lemma 7.

Because all functions in (18) and (19) are continuous (Assumptions 3.(ii), 4.(i), 6.(ii) and Theorem 3), it is clear that the solution (t_h, s_h) is continuous in z_h and that z_h , the part of the solution (z_h, s_h) is also continuous in t_h . Finally, $\lim_{z_h \rightarrow z_\ell} t_h = t_\ell$ and $\lim_{z_h \rightarrow z_\ell} s_h = \tilde{\sigma}(z_\ell)$ because (18) and (19) are satisfied only when $(t_h, s) = (t_\ell, \tilde{\sigma}(z_\ell))$ as $z_h \rightarrow \underline{z}$.

O Proof of Lemma 9

It is clear that if $z_h \rightarrow \bar{z}$, $\{\hat{\sigma}, \hat{\mu}, \hat{\tau}, \hat{m}\}$ converges to the stronger monotone separating equilibrium with the same lower threshold sender type z_ℓ as the pooling part vanishes. Note that as $z_h \rightarrow z_\ell$, $\lim_{z_h \rightarrow z_\ell} t_h = t_\ell$ and $\lim_{z_h \rightarrow z_\ell} s_h = \tilde{\sigma}(z_\ell) = s_\ell$ because (18) and (19) are satisfied only when $(t_h, s_h) = (t_\ell, \tilde{\sigma}(z_\ell))$. Therefore, combining (10) and (11) with (18) and (19) yields that

$$\begin{aligned} \lim_{z_h \rightarrow z_\ell} [t_h - c(s_h, z_h)] &= t_\ell - c(s_\ell, z_\ell) = 0, \\ \lim_{z_h \rightarrow z_\ell} [\mathbb{E}[v(n(z_h), s_h, z') | z' \geq z_h] - t_h] &= \mathbb{E}[v(n(z_\ell), s_\ell, z') | z' \geq z_\ell] - t_\ell \geq 0, \end{aligned}$$

where the inequality holds with equality if $z_\ell > \underline{z}$. The second equality of the first line and the inequality of the second line are a consequence of Theorem 5. These

imply that $\{\hat{\sigma}, \hat{\mu}, \hat{\tau}, \hat{m}\}$ converges the stronger monotone pooling equilibrium where t_ℓ is the single feasible reaction, z_ℓ is the threshold sender type for market entry and s_ℓ is the pooled action for senders in the market. Note that when $z_\ell = \underline{z}$, we have $s_\ell = 0$ and $t_\ell = 0$ in $\{\hat{\sigma}, \hat{\mu}, \hat{\tau}, \hat{m}\}$ due to Theorem 5.

P Proof of Proposition 3

Consider the initial value problem:

$$\begin{cases} v_s(n(\mu(s)), s, \mu(s)) + v_z(n(\mu(s)), s, \mu(s))\mu'(s) - c_s(s, \mu(s)) = 0 \\ \mu(s_\ell) = z_\ell \end{cases} .$$

Given $v(x, s, z) = As^axz$, $c(s, z) = \beta\frac{s^2}{z}$, and $n(z) = kz^q$, we have that $v_z(x, s, z) = As^ax$, $v_s(x, s, z) = aAs^{a-1}xz$, and $c_s(s, z) = 2\beta\frac{s}{z}$. Therefore, the above IVP becomes

$$aAs^{a-1}k\mu(s)^q\mu(s) + As^ak\mu(s)^q\mu'(s) - \frac{2\beta s}{\mu(s)} = 0. \quad (\text{S83})$$

Rewriting (S83) gives

$$\frac{Ak}{2\beta}\mu(s)^{1+q}\mu'(s) + \frac{aAk}{2\beta s}\mu(s)^{2+q} = s^{1-a}. \quad (\text{S84})$$

Let $D =: \frac{Ak}{2\beta}$. Thus, (S84) becomes

$$D\mu^{1+q}\mu' + \frac{aD}{s}\mu^{2+q} = s^{1-a} \quad (\text{S85})$$

where we denote $\mu =: \mu(s)$ for simplicity.

Let $v = \mu^{2+q}$. Then $v' = (2+q)\mu^{1+q}\mu'$ and (S85) becomes

$$v' + \frac{a(2+q)}{s}v = \left(\frac{2+q}{D}\right)s^{1-a} \quad (\text{S86})$$

which is a first order linear differential equation with integrating factor $\mathcal{I}(s) =$

$s^{a(2+q)}$. Therefore, (S86) is equivalent to

$$\frac{d}{ds} \{v s^{a(2+q)}\} = \left(\frac{2+q}{D}\right) s^{1+a+aq},$$

which implies

$$v s^{a(2+q)} = \left(\frac{2+q}{D}\right) \int s^{1+a+aq} ds + \kappa, \quad (\text{S87})$$

where κ is some integration constant. Equation (S87) implies

$$v = \left(\frac{2+q}{D}\right) \left(\frac{s^{2-a}}{2+a+aq}\right) + \frac{\kappa}{s^{a(2+q)}}. \quad (\text{S88})$$

Recall that $v = \mu^{2+q}$. Therefore, (S88) becomes

$$\mu(s)^{2+q} = \left(\frac{2+q}{D}\right) \left(\frac{s^{2-a}}{2+a+aq}\right) + \frac{\kappa}{s^{a(2+q)}}. \quad (\text{S89})$$

By using the initial condition $\mu(s_\ell) = z_\ell$, we compute κ as follows:

$$z_\ell^{2+q} = \left(\frac{2+q}{D}\right) \left(\frac{s_\ell^{2-a}}{2+a+aq}\right) + \frac{\kappa}{s_\ell^{a(2+q)}} \quad (\text{S90})$$

which gives

$$\kappa = \frac{D[2+a+aq]s_\ell^{a(2+q)}z_\ell^{2+q} - (2+q)s_\ell^{a(2+q)}s_\ell^{(2-a)}}{D(2+a+aq)} \quad (\text{S91})$$

or

$$\kappa = \frac{s_\ell^{a(2+q)} \left[D(2+a+aq)z_\ell^{2+q} - (2+q)s_\ell^{(2-a)} \right]}{D(2+a+aq)}. \quad (\text{S92})$$

Plugging (S92) into (S89) gives

$$\tilde{\mu}(s)^{2+q} = \left(\frac{2+q}{D}\right) \left(\frac{s^{2-a}}{2+a+aq}\right) + \left(\frac{s_\ell}{s}\right)^{a(2+q)} \frac{s_\ell^{a(2+q)} \left[D(2+a+aq)z_\ell^{2+q} - (2+q)s_\ell^{(2-a)} \right]}{D(2+a+aq)}. \quad (\text{S93})$$

with $D = \frac{Ak}{2\beta}$ gives

$$\tilde{\mu}(s) = \left[\left(\frac{2\beta(2+q)}{Ak} \right) \frac{s^{2-a}}{2+a+aq} + \left(\frac{s_\ell}{s} \right)^{a(2+q)} \frac{[Ak(2+a+aq)z_\ell^{2+q} - 2\beta(2+q)s_\ell^{(2-a)}]}{Ak(2+a+aq)} \right]^{\frac{1}{2+q}}, \quad (\text{S94})$$

where s_ℓ is determined by (23) and it is $s_\ell(z_\ell) = \left(\frac{Ak}{\beta} z_\ell^{q+2} \right)^{\frac{1}{2-a}}$.

Q Proof of Theorem 10

First, we construct a (unique) stronger monotone pooling equilibrium with a positive single feasible reaction $t^* > 0$. Because (16) and (17) must hold with equality by Theorem 5 with $z^* > \underline{z}$, the pooled action $s^*(z^*, q, a)$ solves

$$As^{*a}kz^{*q}\mathbb{E}[z|z \geq z^*] - \beta \frac{s^{*2}}{z^*} = 0$$

and hence we have that

$$s^*(z^*, q, a) = \left(\frac{z^{*q+1}Ak\mathbb{E}[z|z \geq z^*]}{\beta} \right)^{\frac{1}{2-a}}$$

Therefore, we have that $\lim_{q,a \rightarrow 0} s^*(t, q, a) = \sqrt{z^*Ak\mathbb{E}[z|z \geq z^*]}/\beta$.

The aggregate net surplus in the stronger monotone pooling equilibrium is

$$\Pi_p(z^*, q, a, G) := \int_{z^*}^{\bar{z}} As^*(z^*, q, a)^a kz^{*q}\mathbb{E}[z|z \geq z^*] dG(z) - \beta s^*(z^*, q, a)^2 \int_{z^*}^{\bar{z}} \frac{1}{z} dG(z).$$

This implies that

$$\begin{aligned} \lim_{q,a \rightarrow 0} \Pi_p(z^*, q, a, G) &= \int_{z^*}^{\bar{z}} Ak\mathbb{E}[z|z \geq z^*] dG(z) - z^* Ak\mathbb{E}[z|z \geq z^*] \int_{z^*}^{\bar{z}} \frac{1}{z} dG(z), \\ \lim_{z^* \rightarrow 0} \left[\lim_{q,a \rightarrow 0} \Pi_p(z^*, q, a, G) \right] &= \int_0^{\bar{z}} Ak\mu_z dG(z) = Ak\mu_z \end{aligned}$$

where μ_z is the unconditional mean of the sender type z .

Because $\lim_{q,a \rightarrow 0} \Pi^*(q, a, G) = \frac{Ak\mu_z}{2}$, we have that

$$\lim_{z^* \rightarrow 0} \left[\lim_{q,a \rightarrow 0} \Pi_p(z^*, q, a, G) \right] - \lim_{q,a \rightarrow 0} \Pi^*(q, a, G) = \frac{Ak\mu_z}{2} > 0. \quad (\text{S95})$$

Because $\Pi_p(z^*, q, a, G)$ and $\Pi^*(q, a, G)$ are continuous, there exists $\tilde{q} > 0$, and $\tilde{a} > 0$ and $z^*(\tilde{q}, \tilde{a}) \in \text{Int } Z$ such that for every $(q, a) \in [0, \tilde{q}] \times [0, \tilde{a}]$ and every $z^* \in (0, z^*(\tilde{q}, \tilde{a})]$, $\Pi_p(z^*, q, a, G) > \Pi^*(q, a, G)$. We can retrieve t^* given $z^* \in (0, z^*(\tilde{q}, \tilde{a})]$.
