Abstract. We consider the use of Gaussian process (GP) priors for solving inverse problems in a Bayesian framework. As is well known, the computational complexity of GPs scales cubically in the number of datapoints. We here show that in the context of inverse problems involving integral operators, one faces additional difficulties that hinder inversion on large grids. Furthermore, in that context, covariance matrices can become too large to be stored. By leveraging results about sequential disintegrations of Gaussian measures, we are able to introduce an implicit representation of posterior covariance matrices that reduces the memory footprint by only storing low rank intermediate matrices, while allowing individual elements to be accessed on-the-fly without needing to build full posterior covariance matrices. Moreover, it allows for fast sequential inclusion of new observations. These features are crucial when considering sequential experimental design tasks. We demonstrate our approach by computing sequential data collection plans for excursion set recovery for a gravimetric inverse problem, where the goal is to provide fine resolution estimates of high density regions inside the Stromboli volcano, Italy. Sequential data collection plans are computed by extending the weighted integrated variance reduction (wIVR) criterion to inverse problems. Our results show that this criterion is able to significantly reduce the uncertainty on the excursion volume, reaching close to minimal levels of residual uncertainty. Overall, our techniques allow the advantages of probabilistic models to be brought to bear on large-scale inverse problems arising in the natural sciences. Particularly, applying the latest developments in Bayesian sequential experimental design on realistic large-scale problems opens new venues of research at a crossroads between mathematical modelling of natural phenomena, statistical data science and active learning.

1. Introduction. Gaussian processes (GP) provide a powerful Bayesian approach to regression (Rasmussen and Williams, 2006). While traditional regression considers pointwise evaluations of an unknown function, GPs can also include data in the form of linear operators (Solak et al., 2003; Särkkä, 2011a; Jidling et al., 2017; Mandelbaum, 1984; Tarieladze and Vakhania, 2007; Hairer et al., 2005; Owhadi and Scovel, 2015; Klebanov et al., 2020). This allows GPs to provide a Bayesian framework to address inverse problems (Tarantola and Valette, 1982; Stuart, 2010; Dashti and Stuart, 2016). Even tough GP priors have been shown to perform well on toy inverse problems, difficulties arise when one tries to apply them to large inverse problems (be it high dimensional or high resolution) and these get worse when one considers sequential data assimilation settings such as in Chevalier et al. (2014a). The main goal of this work is to overcome these difficulties and to provide solutions for scaling GP priors to large-scale Bayesian inverse problems.
Methods for extending Gaussian processes to large datasets (Wang et al., 2019) or to a large number of prediction points (Wilson et al., 2020) gained a lot of attention over the last years, however these methods do not address the case of linear operator data, nor do they consider sequential data assimilation problems. At the same time, the topic of large-scale sequential assimilation of linear operator data has been of central interest in the Kalman filter community. To the best of our knowledge, techniques employed in this framework usually rely on a low rank representation of the covariance matrix, obtained either via factorization (Kitanidis, 2015) or from an ensemble estimate (Mandel, 2006). Our goal in this work is to elaborate similar methods for Gaussian processes without relying on a particular factorization of the covariance matrix. We focus on the case where: 1. the number of prediction points is large, 2. the data has to be assimilated sequentially, and 3. it comes in the form of integral operators observations. Integral operators are harder to handle than pointwise observations since, when discretized on a grid (which is the usual inversion approach), they turn into a matrix with entries that are not predominantly null, in our case non-zero for most grid points. For the rest of this work, we will only consider settings that enjoy these three properties. This situation is typical of Bayesian large-scale inverse problems because those are often solved on a discrete grid, forcing one to consider a large number of prediction points when inverting at high resolution; besides, the linear operators found in inverse problems are often of integral form (e.g. gravity, magnetics).

**Example 1.1.** For the rest of this work, we will use as red thread a real-world inverse problem that enjoys the above properties. This problem is that of reconstructing the underground mass density inside the Stromboli volcano, Italy, from observations of the (vertical component of) gravity field at different locations of the surface of the volcano (with respect to a reference station).

![Example inverse problem](image1.png)

**Figure 1:** Example inverse problem: (a) Simulated underground mass density inside the Stromboli volcano (realisation from GP prior). (b) vertical intensity of the generated gravity field at locations where data has been gathered (Linde et al., 2014). Colorscales were chosen arbitrarily.

We will use a real dataset of gravimetric observations that was collected during a field campaign in 2012 (courtesy of Linde et al. (2014)). In Linde et al. (2014) the inversion domain...
is discretized at 50 $[m]$ resolution, which, as we explain in section 4 results in larger-than-memory covariance matrices, calling for the methods developed in this work.

Our main contribution to overcome the above difficulties is the introduction of an implicit representation of the posterior covariance matrix that only requires storage of low rank intermediate matrices and allows individual elements to be accessed on-the-fly, without ever storing the full matrix. Our method relies on an extension of the kriging update formulae (Chevalier et al., 2014c; Emery, 2009; Gao et al., 1996; Barnes and Watson, 1992) to linear operator observations. As a minor contribution, we also provide a technique for computing posterior means on fine discretizations using a chunking technique and explain how to perform posterior simulations in the considered setting. The developed implicit representation allows for fast updates of posterior covariances under linear operator observations on very large grids. This is particularly useful when computing sequential data acquisition plans for inverse problems, which we demonstrate by computing sequential experimental designs for excursion set learning in gravimetric inversion. We find that our method provides significant computational time savings over brute-force conditioning and scales to problem sizes that are too large to handle using state-of-the-art techniques.

In order to give sound theoretical foundations to our implicit update framework, we formulate it using the language of disintegrations of Gaussian measures. This approach to Bayesian inverse problems is less known than the usual one involving Gaussian processes but both are equivalent, as we recall in Appendix A.1. The Gaussian measure approach offers several advantages. First, it is more natural for discretization-independent formulations; second, it provides a clear description (in terms of dual spaces) of the observation operators for which a posterior can be defined and third in integrates well with excursion set estimation.

In this context, we extend results from Tarieladze and Vakhania (2007) to formulate the posterior in Bayesian inverse problems as a disintegration of a Gaussian measure. Then, in subsection 2.3, we provide update formulae for sequential disintegrations. As a byproduct, we also explicit the link between the Gaussian measure formulation of Bayesian inverse problems and the traditional Gaussian process one by extending results from Rajput and Cambanis (1972).

To demonstrate our method, we apply it to the Stromboli inverse problem described above. In this context, we show how it allows computing the posterior at high resolution, how hyperparameters of the prior can be trained and how we can sample from the posterior on a large grid. Finally, we illustrate how our method may be applied to a state-of-the-art sequential experimental design task for excursion set recovery. Sequential design criterion for excursion sets have gained a lot of attention recently (Azzimonti et al., 2019), but, to the best of our knowledge, this is the first time that sequential experimental design for set estimation is considered in the setting of Bayesian inverse problems.

2. Infinite Dimensional Inversion: Conditioning Gaussian Random Elements in Banach Spaces. When treating inverse problems with a Bayesian framework, one needs to define pri-
ors over spaces of functions. We will restrict ourselves to continuous functions defined over a compact subset $D \subset \mathbb{R}^d$ of Euclidean space. Hence, let $C(D)$ denote the Banach space of continuous functions over $D$ endowed with the sup-norm / the topology of uniform convergence. Solving an inverse problem then resorts to the task of inverting the relation $G : C(D) \rightarrow \mathbb{R}^p$, where $G$ is a bounded linear operator. To achieve this, we define a prior over $C(D)$ and then compute the posterior distribution given data observed under noise.

As a simple example of an inverse problem falling in this setting, we consider the task of learning a continuous function defined on the interval $[-1, 1]$ via different types of data: pointwise function values, integrals of the function, Fourier coefficients, etc. Figure 2 provides an illustration of solutions obtained under a Gaussian process prior. Note that the Five different combinations of observations in Figure 2 can be described as a linear operator $G : C([-1, 1]) \rightarrow \mathbb{R}^p$.

Gaussian processes provide a convenient class of priors on function spaces and are particularly useful as priors in Bayesian inverse problems. Nevertheless, for theoretical inquiries, the equivalent language of Gaussian measures and disintegrations is often preferred. This frameworks provides several advantages, such as enabling one to formulate discretization-independent algorithms (Cotter et al., 2013) and it also makes clear which types of observations are allowed (namely only elements of the dual space). In subsection 2.1, we provide theoretical background and show the equivalence between the Gaussian Process and the Gaussian measure formulation of Bayesian inverse problems. In subsection 2.2, we derive the posterior in the Gaussian measure formulation by extending results from Tarieladze and Vakhania (2007) and make the link to the usual conditioning formulae as found four example in Tarantola and Valette (1982). Finally, we will consider sequential data assimilation problems and prove our main sequential conditioning theorem in subsection 2.3. For the necessary mathematical background, as well as the proof of the theorems, we refer the reader to Appendix A.

2.1. Gaussian Processes and Gaussian Measure: Background and Equivalence. When working with Gaussian priors over function spaces, two complementary approaches are often used:

- One can work with a Gaussian process, which is defined as a stochastic process $Z$ over $D$ with continuous sample paths, such that for any number of points $x_1, ..., x_n \in D$, the distribution of $(Z_{x_1}, ..., Z_{x_n})$ is Gaussian, e.g., (Tarantola and Valette, 1982; Särkkä, 2011b).
- One can work with a Gaussian measure which is defined as a Borel measure on $C(D)$ such that for any continuous linear functional $\ell \in C(D)^*$, the measure $\mu \circ \ell^{-1}$ on $\mathbb{R}$ is Gaussian, e.g., (Stuart, 2010; Dashti and Stuart, 2016; Sullivan, 2015; Ernst et al., 2014).

For a Gaussian process $Z$ on some set $D$, its mean and covariance function are defined as

$$m_x := \mathbb{E}[Z_x]$$

$$k(x, y) := \mathbb{E}[Z_x Z_y] = \mathbb{E}[Z_x] \mathbb{E}[Z_y],$$

This manuscript is for review purposes only.
for any $x, y \in D$. When working with a Gaussian measure $\mu$ over a separable Banach space $X$, these notions are replaced by the **mean element** and **covariance operator**.

**Definition 2.1.** Given a Gaussian measure $\mu$ on a Banach space $X$, the **mean** of $\mu$ is the unique element $m_\mu \in X$ such that:

\[
\int_X \langle f, g^* \rangle d\mu(f) = \langle m_\mu g^* \rangle, \quad \forall g^* \in X^*.
\]
The covariance operator of $\mu$ is the linear operator $C_\mu : X^* \rightarrow X$ defined by

$$(2.2) \quad C_\mu g^* = \int_X \langle f, g^* \rangle f d\mu(f) - \langle m_\mu, g^* \rangle m_\mu,$$

where the integrals are to be seen as Bochner integrals. We refer the reader to Vakhania et al. (1987) for more details.

When one works over the Banach space of continuous functions $C(D)$ over some compact Euclidean domain $D \subset \mathbb{R}^d$, the Gaussian process and Gaussian measure point of view are equivalent. Indeed, for any Gaussian measure on $C(D)$ there is a corresponding Gaussian process on $D$ with continuous trajectories, and vice-versa (we refer the reader to Appendix A.1 for more details about this correspondence). Under this correspondence, the mean and covariance functions of the process may be obtained as special cases of the mean element and covariance operator of the corresponding measure by acting on them with Dirac delta functionals, as shown in the following lemma.

**Lemma 2.2.** Let $Z$ be a Gaussian process on a compact Euclidean domain $D$ with continuous trajectories, and let $\mu$ be the corresponding induced measure on $C(D)$. Then the covariance operator $C_\mu$ and mean element $m_\mu$ of the measure are related to the mean $m_x$ and covariance function $k(x,y)$ of the process via

$$(2.3) \quad m_x = \mathbb{E}[Z_x] = \langle m_\mu, \delta_x \rangle,$$

$$(2.4) \quad k(x,y) = \mathbb{E}[Z_x Z_y] - \mathbb{E}[Z_x] \mathbb{E}[Z_y] = \langle C_\mu \delta_y, \delta_x \rangle,$$

for all $x, y \in D$.

These considerations allow us to work interchangeably with the two points of views. In the following, we will use the Gaussian measure theory to provide a framework for computing the posterior in linear Bayesian inverse problems under linear form observations.

**Remark 2.3.** The correspondence between Gaussian processes and Gaussian measures is not limited to the Banach space $C(D)$ of continuous functions over a compact Euclidean domain. Indeed Rajput and Cambanis (1972) also prove correspondence for $L^p$ spaces and spaces of absolutely continuous functions. However, the proofs are done on a case by case basis, so we choose to restrict ourselves to one single type of Banach spaces.

**2.2. Disintegration of Gaussian Measures under Operator Observations.** Now that we have introduced the equivalence of the process and the measure approaches, we consider the posterior in the Gaussian measure formulation of Bayesian inverse problems. In this setting, conditional laws are defined using the language of disintegrations of measures. The treatment presented here will follow that in Tarieladze and Vakhania (2007) and extend some of the theorems therein.

As in subsection 2.1, we work on the separable Banach space $C(D)$ of continuous functions.
over a compact Euclidean domain and use $\mu$ to denote a Gaussian measure on $C(D)$ and $Z$ for the corresponding associated Gaussian process on $D$. Again $G : C(D) \to \mathbb{R}^p$ will denote a bounded linear operator. One way to address the conditional law of the measure under observation of $G$ is the concept of disintegration.

**Definition 2.4.** Given measurable spaces $(X, \mathcal{A})$ and $(Y, \mathcal{F})$, a probability measure $\mu$ on $X$ and a measurable mapping $G : X \to Y$, a disintegration of $\mu$ with respect to $G$ is a mapping $\tilde{\mu} : \mathcal{A} \times Y \to [0, 1]$ satisfying the properties:

1. For each $y \in Y$ the set function $\tilde{\mu}(\cdot, y)$ is a probability measure on $X$ and for each $A \in \mathcal{A}$ the function $\tilde{\mu}(A, \cdot)$ is $\mathcal{F}$-measurable.

2. There exists $Y_0 \in \mathcal{F}$ with $\mu \circ G^{-1} (Y_0) = 1$ such that for all $y \in Y_0$ we have $\{y\} \in \mathcal{F}$ and for each $y \in Y_0$, the probability measure $\tilde{\mu}(\cdot, y)$ is concentrated on the fiber $G^{-1} (\{y\})$

   $$\tilde{\mu} (G^{-1} (\{y\}), y) = 1.$$

3. The measure $\mu$ may be written as a mixture:

   $$\mu (A) = \int_Y \tilde{\mu} (A, y) \, d(\mu \circ G^{-1}) (y), \ \forall A \in \mathcal{A}.$$

We will use the notation $\mu_{|G=y} (\cdot) := \tilde{\mu} (\cdot, y)$ for the disintegrating measure.

In a Bayesian inverse problem, the computation of the posterior then amounts to computing a disintegration of the prior with respect to the observation operator. The existence of the disintegration is guaranteed by Theorem 3.11 in Tarieladze and Vakhania (2007), which we reproduce here in a slightly adapted formulation generalized to non-centered measures.

**Theorem 2.5.** Let $X, Y$ be real separable Banach spaces and $\mu$ be a Gaussian measure on the Borel $\sigma$-algebra $\mathcal{B}(X)$ with mean element $m_\mu \in X$ and covariance operator $C_\mu : X^* \to X$. Let also $G : X \to Y$ be a bounded linear operator. Then, provided that the operator $C_\nu := GC_\mu G^* : Y^* \to Y$ has finite rank $p$, there exists a continuous linear map $\tilde{m}_\mu : Y \to X$, a symmetric positive operator $\tilde{C}_\mu : X^* \to X$ and a disintegration $(\mu_{|G=y})_{y \in Y}$ of $\mu$ with respect to $G$ such that for each $y \in Y$ the measure $\mu_{|G=y}$ is Gaussian with mean element $\tilde{m}_\mu (y)$ and covariance operator $\tilde{C}_\mu$. Furthermore, for any $C_\nu$-representing sequence $y_i^*$, $i = 1, \ldots, n$, the mean and covariance are equal to

\begin{align}
\tilde{m}_\mu (y) &= m_\mu + \sum_{i=1}^p (y - Gm_\mu, y_i^*) C_\mu G^* y_i^*
\tag{2.5}
\end{align}

\begin{align}
\tilde{C}_\mu &= C_\mu - \sum_{i=1}^p (C_\mu G^* y_i^*, \cdot) C_\mu G^* y_i^*
\tag{2.6}
\end{align}

The mean element also satisfies $G \tilde{m}_\mu (y) = y$ for all $y \in Y$.

This manuscript is for review purposes only.
The explicit formulae for the posterior mean and covariance provided by the above theorem require the use of representing sequences.

**Definition 2.6.** Tarieladze and Vakhania (2007) Given a Banach space $X$ and a non-zero, symmetric positive operator $R : X^* \to X$, a family $(x_i^*)_{i \in I}$ of elements of $X^*$ is called $R$-representing if the following two conditions hold:

$$
\langle Rx_i^*, x_j^* \rangle = \delta_{ij},
$$

$$
\sum_{i \in I} \langle Rx_i^*, x^* \rangle^2 = \langle Rx^*, x^* \rangle, \quad \forall x^* \in X^*.
$$

**Remark 2.7.** When the operator $R$ has finite rank $p$ and $X$ is an Hilbert space, one can explicitly compute an $R$-representing sequence by defining $x_i^* := R^{-1/2}e_i$, $i = 1, ..., p$ where $e_i$, $i = 1, ..., p$ is an orthonormal basis of the range of $R$ (see Appendix A for a proof). This fact will be used to link the posterior provided by Theorem 2.5 to the usual formulae for Gaussian processes.

Using Lemma 2.2 we can translate the disintegration provided by Theorem 2.5 to the language of Gaussian processes in the case where $X$ is the Banach space $C(D)$ of continuous functions over a compact Euclidean domain $D$:

**Corollary 2.8.** Let $Z$ be a Gaussian process on a compact Euclidean domain $D$ with continuous trajectories and let $G : C(D) \to Y$ be a linear bounded operator into a real separable Banach space $Y$. Denote by $C_\mu$ the covariance operator of the measure associated to the process. Provided the operator $C_\nu := GC_\mu G^*$ has finite rank $p$, then, for all $y \in Y$ the conditional law of $Z$ given $G = y$ is Gaussian with mean and covariance function given by, for all $x, x_1, x_2 \in D$:

$$
\bar{m}_x(y) = \langle \bar{m}_\mu(y), \delta_x \rangle = m_x + \sum_{i=1}^p \langle y - Gm_\nu, y_i^* \rangle (C_\mu G^* y_i^*)|_x,
$$

$$
\bar{k}(x_1, x_2) = \langle \bar{C}_\mu \delta_{x_2}, \delta_{x_1} \rangle = k(x_1, x_2) - \sum_{i=1}^p (C_\mu G^* y_i^*)|_{x_2} (C_\mu G^* y_i^*)|_{x_1},
$$

where $m_x$ denotes the mean function of $Z$ and $Gm_\nu$ denotes application of the operator $G$ to the mean function seen as an element of $C(D)$ and $(y_i^*)_{i=1,...,p}$ is any $C_\nu$-representing sequence.

When $G$ maps into a finite-dimensional Euclidean space, then one can explicitly compute representing sequences and duality pairings, allowing the conditional mean and covariance in Corollary 2.8 to be entirely written in terms of the prior mean and covariance function of the process, making the link to the Gaussian process conditioning formulae as found for example in Tarantola and Valette (1982). Indeed, since the dual of $C(D)$ is the space of Radon measures on $D$, any bounded linear operator $G : C(D) \to \mathbb{R}^p$ may be written as a collection.
of integral operators $GZ = \left( \int_D Z(x) d\lambda_i(x) \right)_{i=1,...,p}$ where the $\lambda_i$’s are Radon measures on $D$. This special form allows us to compute closed-from expressions for the conditional mean and covariance.

**Corollary 2.9.** Consider the situation of Corollary 2.8 and let $G : C(D) \to \mathbb{R}^p$ have the form $GZ = \left( \int_D Z(x) d\lambda_i(x) \right)_{i=1,...,p}$, with the $\lambda_i$’s being Radon measures on $D$. Then, the conditional law of $Z$ given $G = y$ is Gaussian with mean and covariance function given by, for all $x, x_1, x_2 \in D$:

\[
\begin{align*}
\hat{m}_x(y) &= m_x - KxGk^{-1}_{GG}(x - Gm), \\
\hat{k}(x_1, x_2) &= k(x_1, x_2) - Kx_1Gk^{-1}_{GG}K_{x_2G}T
\end{align*}
\]

where we have used the compact notation $Gm.$ to denote the application of $G$ to the mean function of the GP seen as an element of $C(D)$ and we have defined the following vectors and matrices:

\[
\begin{align*}
KxG : &= \left( \int_D k(x, y) d\lambda_i(y) \right)_{i=1,...,p} \in \mathbb{R}^p, \\
K_{GG} : &= \left( \int_D \int_D k(y, z) d\lambda_i(y) d\lambda_j(z) \right)_{i,j=1,...,p} \in \mathbb{R}^{p \times p},
\end{align*}
\]

where $k(\cdot, \cdot)$ denotes the covariance function of $Z$.

**2.3. Sequential Disintegrations.** We now turn to the situation where several stages of conditioning are performed sequentially. Let again $X$ be a real separable Banach space and consider two bounded linear operators $G_1 : X \to Y_1$ and $G_2 : X \to Y_2$, where $Y_1$ and $Y_2$ are also real separable Banach spaces. Then, if one views these operators as defining two stages of observations, there is two ways in which one can compute the posterior.

- On the one hand, one can compute it in two steps by first computing the disintegration of $\mu$ under $G_1$ and then, for each $y_1 \in Y_1$, compute the disintegration of $\mu|_{G_1^{-1}y_1}$. Under $G_2$.
- On the other hand, one can compute it in one go by considering the disintegration of $\mu$ with respect to the bundled operator $G : X \to Y_1 \bigoplus Y_2$, $x \mapsto G_1(x) \bigoplus G_2(x)$. From now one, we will denote this operator by $(G_1, G_2)$.

We show that these two approaches yield the same disintegration, as guaranteed by the following theorem.

**Theorem 2.10.** Let $X, Y_1, Y_2$ be real separable Banach spaces, $\mu$ be a Gaussian measure on $\mathcal{B}(X)$ with mean element $m_\mu$ and covariance operator $C_\mu : X^* \to X$. Also let $G_1 : X \to Y_1$ and $G_2 : X \to Y_2$ be bounded linear operators. Suppose that both $C_{\nu_1} := G_1C_\mu G_1^*$ and $C_{\nu_2} := G_2C_\mu G_2^*$ have finite rank $p_1$ and $p_2$, respectively. Then

\[
\mu|_{(G_1, G_2)^{-1}(y_1, y_2)} = \left( \mu|_{G_1^{-1}y_1} \right)_{G_2^{-1}y_2},
\]

This manuscript is for review purposes only.
where the equality holds for almost all \((y_1, y_2) \in Y_1 \bigoplus Y_2\) with respect to the pushforward measure \(\mu \circ (G_1, G_2)^{-1}\) on \(Y_1 \bigoplus Y_2\).

Now, since both disintegrating measures are equal, it also follows that all their moments are equal. In the case of finite dimensional data, this yields, using Corollary 2.9:

**Corollary 2.11.** Let \(Z\) be a Gaussian process on a compact Euclidean domain \(D\) with continuous trajectories. Consider two observation operators \(G_1 : C(D) \to \mathbb{R}^{p_1}\), \((G_1 Z)\| = \int_D Z_x d\lambda_1^{(1)}\) and \(G_2 : C(D) \to \mathbb{R}^{p_2}\), \((G_2 Z)\| = \int_D Z_x d\lambda_2^{(2)}\). Denote by \(m^*\) and \(k(\cdot, \cdot)\) the mean and covariance function of \(Z\). Then, for any \(y = (y_1, y_2) \in \mathbb{R}^{p_1+p_2}\) and any \(x, x_1, x_2 \in D\), we have:

\[
\begin{align*}
    m_x + K_{xG} K_{GG}^{-1} (y - Gm_x) &= m_x + K_{xG_1} K_{G_1G_1}^{-1} (y_1 - G_1 m_x) + K_{xG_2} \left( \tilde{K}_{G_2G_2}^{(1)} \right)^{-1} \left( y_2 - G_2 \tilde{m}_1^{(1)} \right), \\
    k(x_1, x_2) - K_{xG} K_{GG}^{-1} K_{yG}^T &= k(x_1, x_2) - K_{xG_1} K_{G_1G_1}^{-1} K_{yG_1}^T - \tilde{K}_{xG_2} \left( \tilde{K}_{G_2G_2}^{(1)} \right)^{-1} \left( \tilde{K}_{yG_2}^{(1)} \right)^T,
\end{align*}
\]

where \(G := (G_1, G_2)\) and \(\tilde{m}_1^{(1)}\) denotes the conditional mean \(Z\) given \(G_1 = y_1\) as given by Corollary 2.9. Also \(\tilde{K}_{G_2G_2}^{(1)}\) and \(\tilde{K}_{xG_2}^{(1)}\) denote the same matrices as in (2.9) and (2.10) with the prior covariance \(k(\cdot, \cdot)\) replaced by the conditional covariance of \(Z\) given \(G_1 = y_1\).

Now that we have a well-developed theoretical framework for conditioning and updating Gaussian processes under linear operator observations, we turn to the practical application of this framework to Bayesian inverse problems, study the challenges that arise and propose solutions to overcome these.

Here an inverse problem is the task of recovering some unknown function \(\rho \in C(D)\) from observation of a bounded linear operator \(G : C(D) \to \mathbb{R}^p\) applied to \(\rho\). To solve the problem within a Bayesian framework, one puts a Gaussian process prior on \(D\) and uses the conditional law of the process, conditional on the data, to approximate the unknown \(\rho\).

Even if one can formulate the problem in an infinite dimensional setting (section 2) and discretization should take place as late as possible (Stuart, 2010), when solving inverse problems in practice there is always some form of discretization involved, be it through quadrature methods (Hansen, 2010) or through basis expansion (Wagner et al., 2021). It turns out that, regardless of the type of discretization used, one quickly encounters computational bottlenecks arising from memory limitations when trying to scale inversion to real-world problems. We here focus on inverse problems discretized on a grid, but stress that the computational difficulties described next also plague spectral approaches.

Let \(W = (w_1, \ldots, w_r) \in D^r\) be a given set of discretization points, we consider observation operators that (after discretization) may be written as linear combinations of Dirac delta functions.
functionals

\[ G : C(D) \to \mathbb{R}^p, \quad G = \left( \sum_{j=1}^{r} g_{ij} \delta w_j \right)_i, \quad i = 1, \ldots, p, \]

with arbitrary coefficients \( g_{ij} \in \mathbb{R} \). Using Corollary 2.9 we can compute the conditional law of a GP \( Z \sim G_{p}(m,k) \) on \( D \) conditionally on the data \( Y = G_{Z} W + \epsilon \), where \( \epsilon \sim \mathcal{N}(0, \tau^2 I_p) \) is some observational noise. The conditional mean and covariance are then given by:

\[ \tilde{m}_{X} = m_{X} + K_{XW} G^{T} (G K_{WW} G^{T} + \tau^2 I_p)^{-1} (y - G m_{W}), \]

\[ \tilde{K}_{XX'} = K_{XX'} - K_{XW} G^{T} (G K_{WW} G^{T} + \tau^2 I_p)^{-1} K_{WX'}. \]

**Notation:** When working with discrete operators as in (3.1) it is more convenient to use matrices. Hence we will use \( G \) to denote the \( p \times r \) matrix with elements \( g_{ij} \). Relation (3.1) will then be written compactly as \( \rho \mapsto G_{\rho} W \). Similarly, given a Gaussian process \( Z \sim G P(m,k) \) on \( D \subset \mathbb{R}^d \) and another set of points \( X = (x_1, \ldots, x_m)^T \in D^m \), we will use \( K_{XW} \) to denote the \( m \times r \) matrix obtained by evaluating the covariance function at all couples of points \( K_{ij} = k(x_i, w_j) \). In a similar fashion, let \( Z_{X} \in \mathbb{R}^{m} \) denote the vector obtained by concatenating the values of the field at the different points. From now on, boldface letters will be used to denote concatenated quantities (usually datasets). The identity matrix will be denoted by \( I \), the dimension being inferred from the context.

Even if (3.2) and (3.3) only involve basic matrix operations, their computational cost depends heavily on the number of prediction points \( X = (x_1, \ldots, x_m)^T \) and on the number of discretization points \( W = (w_1, \ldots, w_r) \), making their application to real-world inverse problems a non-trivial task. Indeed, when both \( m \) and \( r \) are big, there are two main difficulties that hamper the computation of the conditional distribution:

- the \( r \times r \) matrix \( K_{WW} \) may never be built in memory due to its size, and
- the \( m \times m \) posterior covariance \( K_{XX} \) may be too large to store.

The first of these difficulties can be solved by performing the product \( K_{WW} G^{T} \) in chunks, as described in Subsection 3.3. The second one only becomes of particular interest in sequential data assimilation settings as considered in Subsection 3.1. In Subsection 3.2 we will introduce an (almost) matrix-free implicit representation of the posterior covariance matrix enabling us to overcome both these memory bottlenecks.

### 3.1. Sequential Data Assimilation in Bayesian Inverse Problems and Update Formulae.

We now consider a sequential data assimilation problem where data is made available in discrete stages. At each stage, a set of observations described by a (discretized) operator \( G_i \) is made and one observes a realization \( y_i \) of

\[ Y_i = G_i Z_{W_i} + \epsilon_i, \]
where \( W_i \) is some set of points in \( D \). Then, the posterior mean and covariance after each stage of observation may be obtained by performing a low rank update of their counterparts at the previous stage. Indeed, Corollary 2.11 provides an extension of Chevalier et al. (2014c); Emery (2009); Gao et al. (1996); Barnes and Watson (1992) to linear operator observations, and gives:

**Theorem 3.1.** Let \( Z \sim Gp(m,k) \) and let \( m^{(n)} \) and \( K^{(n)} \) denote the conditional mean and covariance function conditional on the data \( \{ Y_i = y_i : i = 1, ..., n \} \) with \( Y_i \) defined as in (3.4), where \( n \geq 1 \) and \( m^{(0)} \) and \( K^{(0)} \) are used to denote the prior mean and covariance. Then:

\[
\begin{align*}
m^{(n)}(X) &= m^{(n-1)}(X) + \lambda_n(X)^T (y_n - G_i m^{(n-1)}_W), \\
K^{(n)}(XX^T) &= K^{(n-1)}(XX^T) - \lambda_n(X)^T S_n \lambda_n(X^T),
\end{align*}
\]

with \( \lambda_n(X) \), \( S_n \) defined as:

\[
\begin{align*}
\lambda_n(X) &= S_n^{-1} G_i K^{(n-1)}_{W_i W_i}, \\
S_n &= G_i K^{(n-1)}_{W_i W_i} G_i^T + \tau^2 I.
\end{align*}
\]

At each stage \( i \), these formulae require computation of the \( p_i \times m \) matrix \( \lambda_i(X) \), which involves a \( p_i \times p_i \) matrix inversion, where \( p_i \) is the dimension of the operator \( G_i \) describing the current dataset to be included. This allows computational savings by reusing already computed quantities, avoiding inverting the full dataset at each stage, which would require a \( p_{tot}^2 \) matrix inversion, where \( p_{tot} = \sum_{i=1}^n p_i \).

In order for these update equations to bring computational savings, one has to be able to store the past covariances \( K^{(n-1)}_{W_i W_i} \) (Chevalier et al., 2015). This makes their application to large-scale sequential Bayesian inverse problems difficult, since the covariance matrix on the full discretization may become too large for storage above a certain number of discretization points.

The next section presents our main contributions to overcome this limitation. They rely on an implicit representation of the posterior covariance that allows the computational savings offered by the kriging update formulae to be brought to bear on large scale inverse problems.

### 3.2. Implicit Representation of Posterior Covariances for Sequential Data Assimilation in Large-Scale Bayesian Inverse Problems

We consider the same sequential data assimilation setup as in the previous section, and for the sake of simplicity we assume that \( W_1, ..., W_n = X \) and use the lighter notation \( m^{(i)} := m^{(i)}_X \) and \( K^{(i)} := K^{(i)}_{XX} \). The setting we are interested in here is the one where \( X \) is so large that the covariance matrix gets bigger than the available computer memory.

Our key insight is that instead of building the full posterior covariance \( K^{(n)} \) at each stage \( n \), one can just maintain a routine that computes the product of the current posterior covariance with any other low rank matrix. More precisely, at each stage \( n \), we provide a
routine CovMul_n, that allows to compute the product of the current covariance matrix with any thin matrix $A \in \mathbb{R}^{m \times q}$, $q \ll m$:

$$ CovMul_n : A \mapsto K^{(i)} A, $$

where thin is to be understood as small enough so that the result of the multiplication can fit in memory.

This representation of the posterior covariance was inspired by the covariance operator of Gaussian measures. Indeed, if we denote by $C_{\mu(n)}$ the covariance operator of the Gaussian measure associated to the posterior distribution of the GP at stage $n$, then

$$(K^{(n)} A)_{ij} = \sum_{k=1}^{m} \langle C_{\mu(n)} \delta_{x_i}, \delta_{x_k} \rangle A_{kj}. $$

Hence, the procedure CovMul_n may be thought of as computing the action of the covariance operator of the Gaussian measure associated to the posterior on the Dirac delta functionals at the discretization points.

This motivates us to think in terms of an updatable covariance object, where the inclusion of new observations (the updating) amounts to redefining a right-multiplication routine. It turns out that by grouping terms appropriately in Corollary 2.11 such a routine may be defined by only storing low rank matrices at each data acquisition stage.

**Lemma 3.2.** For any $n \in \mathbb{N}$ and any $m \times q$ matrix $A$:

$$ K^{(n)} A = K^{(0)} A - \sum_{i=1}^{n} \bar{K}_i R_i^{-1} \bar{K}_i^T A, $$

with intermediate matrices $\bar{K}_i$ and $R_i^{-1}$ defined as:

$$ \bar{K}_i = K^{(i-1)} G_i^T, $$

$$ R_i^{-1} = \left( G_i K^{(i-1)} G_i^T + \tau^2 I \right)^{-1}. $$

Hence, in order to compute products with the posterior covariance at stage $n$, one only has to store $n$ matrices $\bar{K}_i$, each of size $m \times p_i$, and $n$ matrices $R_i^{-1}$ of size $p_i \times p_i$, where $p_i$ is the number of observations made at stage $i$ (i.e. the number of lines in $G_i$). In turn, each of these objects is defined by multiplications with the covariance matrix at previous stages, so that one may recursively update the multiplication procedure CovMul_n. Algorithms 3.1, 3.2, and 3.3 may be used for multiplication with the current covariance matrix, update of the representation and update of the posterior mean.

**3.3. Prior Covariance Multiplication Routine and Chunking.** To use Algorithm 3.1, one should be able to compute products with the prior covariance matrix $K^{(0)}$. This may be achieved by chunking the set of grid points into $n_c$ subsets $\mathbf{X} = (\mathbf{X}_1, ..., \mathbf{X}_{n_c})$, where each $\mathbf{X}_i$
Algorithm 3.1 Covariance Right Multiplication Procedure after n conditioning

Require:
- Precomputed matrices $\bar{K}_i$, $R_i^{-1}$, $i = 1, \ldots, n$.
- Prior multiplication routine CovMul0.
- Input matrix $A$.

Ensure: $K^{(n)}A$.

procedure CovMul\(_n\)(A)
- Compute $K^{(0)}A = \text{CovMul}_0(A)$.
- Return $K^{(0)}A - \sum_{i=1}^{n} \bar{K}_i R_i^{-1} \bar{K}_i^T A$.

Algorithm 3.2 Updating intermediate quantities at conditioning stage n

Require:
- Last multiplication routine CovMul\(_{n-1}\).
- Measurement matrix $G_i$, noise variance $\tau^2$.

Ensure: Step n intermediate matrices $\bar{K}_n$ and $R_n$.

procedure Update\(_n\)
- Compute $\bar{K}_n = \text{CovMul}_{n-1} G_i^T$.
- Compute $R_n^{-1} = (\bar{G}_i \bar{K}_n + \tau^2 I)^{-1}$.

Algorithm 3.3 Computation of conditional mean at step n

Require:
- Previous conditional mean $m^{(n-1)}$.
- Current data $y_n$ and forward $G_i$.
- Intermediate matrices $\bar{K}_n$ and $R_n^{-1}$.

Ensure: Step n conditional mean $m^{(n)}$.

procedure MeanUpdate\(_n\)
- Return $m^{(n-1)} + \bar{K}_n R_n^{-1} (y_n - \bar{G}_i m^{(n-1)})$.

contains a subset of the points. Without loss of generality, we assume all subsets to have the same size $m_c$. We may then write the product as

$$K^{(0)}_{XX} A = \left(K^{(0)}_{X_1 X} A, \ldots, K^{(0)}_{X_n X} A\right)^T.$$

Each of the subproducts may then be performed separately and the results gathered together at the end. The individual products then involve matrices of size $m_c \times m$ and $m \times q$. One can then choose the number of chunks so that these matrices can fit in memory. Each block $K^{(0)}_{X_i X}$ may be built on-demand provided $K_{XX}$ is defined through a given covariance function.

This ability of the prior covariance to be built quickly on-demand is key to our method. The fact that the prior covariance matrix does not need to be stored allows us to handle larger-than-memory posterior covariances by expressing products with it as a multiplication with the prior and a sum of multiplications with lower rank matrices.
Remark 3.3 (Choice of Chunk Size). Thanks to chunking, the product may be computed in parallel, allowing for significant performance improvements in the presence of multiple computing devices (CPUs, GPUs, ...). In that case, the chunk size should be chosen as large as possible to limit data transfers, but small enough so that the subproducts may fit on the devices.

3.4. Computational Cost and Comparison to Non-Sequential Inversion. For the sake of comparison, assume that all \( n \) datasets have the same size \( p_c \) and let \( p = np_c \) denote the total data size. The cost of computing products with the current posterior covariance matrix at some intermediate stage is given by:

**Lemma 3.4 (Multiplication Cost).** Let \( A \) be an \( m \times q \) matrix. Then, the cost of computing \( K_n A \) at some stage \( n \) using Algorithms 3.1 and 3.2 is \( \mathcal{O}(m^2 q + n(mp_c q + p_c^2 q)) \).

Using this recursively, we can then compute the cost of creating the implicit representation of the posterior covariance matrix at stage \( n \):

**Lemma 3.5 (Implicit Representation Cost).** To leading order in \( m \) and \( p \), the cost of defining \( \text{CovMul}_n \) is \( \mathcal{O}(m^2 p + mp^2 + p^3 p_c^2) \). This is also the cost of computing \( m^{(n)} \).

This can then be compared with a non-sequential approach where all datasets would be concatenated into a single dataset of dimension \( p \). More precisely, define the \( p \times m \) matrix \( G \) and the \( p \)-dimensional vector \( y \) as the concatenations of all the measurements and data vectors into a single operator, respectively vector. Then computing the posterior mean using (3.2) with those new observation operators and data vector the cost is, to leading order in \( p \) and \( m \):

\[
\mathcal{O}(m^2 p + mp^2 + p^3).
\]

In this light, we can now sum up the two main advantages of the proposed sequential approach:

- the cubic cost \( \mathcal{O}(p^3) \) arising from the inversion of the data covariances is decreased to \( \mathcal{O}(p^2 p_c) \) in the sequential approach
- if a new set of observations has to be included, then the direct approach will require the \( \mathcal{O}(m^2 p) \) computation of the product \( K G^T \), which can become prohibitively expensive when the number of prediction points is large, whereas the sequential approach will only require a marginal computation of \( \mathcal{O}(m^2 p_c) \).

Aside from the computational cost, our implicit representation also provides significant memory savings compared to an explicit approach where the full posterior covariance matrix would be stored. The storage requirement for the implicit representation as a function of the number of discretization points \( m \) is shown in Figure 3.

3.5. Toy Example: 2D Fourier Transform. To illustrate the various methods presented in subsection 3.2, we here apply them to a toy two-dimensional example: we consider a GP discretized on a large square grid \( \{0, ..., M\} \times \{0, ..., M\} \) and try to learn it through various types of linear operator data.

More precisely, we will here allow two types of observations: pointwise field values and Fourier

*This manuscript is for review purposes only.*
Figure 3: Memory footprint of the posterior covariance matrix as a function of discretization size for explicit and implicit representation.

coefficient data. Indeed, the field values at the nodes $Z_{kl}$, $k, l \in \{1, \ldots, M\}$ are entirely determined by its discrete Fourier transform (DFT):

$$F_{uv} = \sum_{k=1}^{M} \sum_{l=1}^{M} Z_{kl} e^{-2\pi i (\frac{uk}{M} + \frac{vl}{M})}, \: u, v \in \{1, \ldots, M\}.$$ (3.5)

Note that the above may be viewed as the discretized version of some operator and thus fits our framework for sequential conditioning. One may then answer questions such as how much uncertainty is left after the first 10 Fourier coefficient $F_{kl}$, $k, l = 1, \ldots, 10$ have been observed? Or which Fourier coefficient provide the most information about the GP?

For example, Figure 4 compares the posterior mean after observation of various Fourier coefficients, compared to observing pointwise values along a space-filling sequence. The GP model is a constant mean Matérn 5/2 random field on a square domain $[-1, 1]^2$. The domain is discretized onto a 400 $\times$ 400 grid. Note that, by nature, each Fourier coefficient involves the field values at all points of the discretization grid and thus direct computation of the posterior mean requires the full $400^2 \times 400^2$ covariance matrix (which would translate to roughly 100 GB of storage). This makes this situation suitable to demonstrate the techniques presented in this section.

In this example, the Fourier coefficients are ordered by growing $l_\infty$ norm. One observes

This manuscript is for review purposes only.
that Fourier coefficients provide very different information than pointwise observations and decrease uncertainty in a more spatially uniform way, as shown in Figure 5.

The extent to which Fourier coefficients provide more or less information than pointwise observations (depending on ordering) depends on the correlation length of the field’s covariance function. Indeed, for long correlation lengths, the low frequency Fourier coefficients contain most of the information about the field’s global behaviour, whereas for small correlation length, high frequency coefficients are needed to learn the small-scale structure.

4. Application: Scaling Gaussian Processes to Large-Scale Inverse Problems. In this section, we demonstrate how the implicit representation of the posterior covariance introduced in subsection 3.2 allows scaling Gaussian processes to situations that are too large to handle using more traditional techniques. Such situations are frequently encountered in large-scale inverse problems and we will thus focus our exposition on such a problem arising in geophysics. In this setting, we demonstrate how our implicit representation allows to train prior hyper-parameters in subsection 4.1, in subsection 4.2 we demonstrate posterior sampling on large grids and finally in subsection 4.3 address a state-of-the-art sequential experimental design problem for excursion set recovery.

Example Gravimetric Inverse Problem: We focus on the problem of reconstructing the mass density distribution \( \rho : D \to \mathbb{R} \) in some given underground domain \( D \) from observations of the vertical component of the gravitational field at points \( s_1, \ldots, s_p \) on the surface of the domain. As an example dataset we use gravimetric data gathered on the surface of the
Figure 5: Posterior standard deviation after observation of \( n = 10, 50, 100 \) Fourier coefficients (top) and after observation of \( n = 10, 50, 100 \) field values along a space-filling design (bottom). Ground truth is shown on the left. Correlation parameter (Matérn 5/2) \( \lambda = 0.5 \).

Strombli volcano during a field campaign in 2012 (Linde et al., 2014). In subsection 4.3 we will also consider the problem of recovering high (or low) density regions inside the volcano. Figure 6 displays the main components of the problem.

The observation operator describing gravity measurements is an integral one (see Appendix C), which fits the Bayesian inversion framework of section 2. This kind of problems is usually discretized on a finite grid of points \( X = (x_1, \ldots, x_m) \), hence the available data is of the form

\[
Y = G\rho X + \epsilon,
\]

where the \( n \times m \) matrix \( G \) represents the discretized version of the observation operator for the gravity field at \( s_1, \ldots, s_p \) and we assume i.i.d Gaussian noise \( \epsilon \sim \mathcal{N}(0, \tau^2 I_p) \). The posterior may then be computed using (3.2) and (3.3). Note that the three-dimensional nature of the problem quickly makes it intractable for traditional inversion methods as the resolution of the inversion grid is refined. For example, when discretizing the Stromboli inversion domain as Linde et al. (2014) into cubic cells of 50m side length, one is left with roughly \( 2 \cdot 10^3 \) cells, which translates to posterior covariance matrices of size 160 GB (using 32 bits floating point numbers). This characteristic of gravimetric inverse problems make them well-suited to demonstrate the implicit representation framework which we introduced in subsection 3.2. In subsection 4.3 we will show how our technique allows state-of-the-art adaptive design techniques to be applied to large real-world problems.
4.1. Hyperparameter Optimization. When using Gaussian process priors to solve inverse problems, one has to select the hyperparameters of the prior. There exists different approaches for optimizing hyperparameters. We here only consider maximum likelihood estimation (MLE).

We restrict ourselves to GP priors that have a constant prior mean $m_0 \in \mathbb{R}$ and a covariance kernel $k$ that depends on a prior variance parameter $\sigma_0^2$ and other correlation parameters $\theta_0 \in \mathbb{R}^t$:

$$ k(x, y) = \sigma_0^2 r(x, y; \theta_0), \quad \text{(4.2)} $$

where $r(.,.; \theta_0)$ is a correlation function, such that $r(x, x; \theta_0) = 1, \forall x \in D$. The maximum likelihood estimator for the hyperparameters may then be obtained by minimizing the negative marginal log likelihood (nmll) of the data, which in the discretized setting of section 3 may be written as (Rasmussen and Williams, 2006):

$$ L(m_0, \sigma_0, \theta_0; y) = \log \det R + \left( y - \Omega m_0 \right)^T R^{-1} \left( y - \Omega m_0 \right) + n \log 2\pi, \quad \text{(4.3)} $$

$$ R := \left( \Omega K_{XX} \Omega^T + \tau^2 I_n \right). \quad \text{(4.4)} $$
Since only the quadratic term depends on \( m_0 \), we can adapt concentration identities (Park and Baek, 2001) to write the optimal \( m_0 \) as a function of the other hyperparameters:

\[
\hat{m}_0^{MLE}(\sigma_0, \theta_0) = \left( 1_m^T \Omega^T R^{-1} G 1_m \right)^{-1} y^T R^{-1} G 1_m,
\]

where \( 1_m \) denotes the \( m \)-dimensional column vector containing only 1’s. Here we always assume \( R \) to be invertible. The remaining task is then to minimize the concentrated nml:

\[
(\sigma_0, \theta_0) \rightarrow -\mathcal{L}(\hat{m}_0^{MLE}(\sigma_0, \theta_0), \sigma_0, \theta_0).
\]

Note that the main computational challenge in the minimization of (4.3) comes from the presence of the \( m \times m \) matrix \( K_{XX} \). In the following, we will only consider the case of kernels that depend on a single lengthscale parameter: \( \theta_0 = \lambda_0 \in \mathbb{R} \), tough the procedure described below can in principle be adapted for multidimensional \( \theta_0 \).

In practice, for kernels of the form (4.2) the prior variance \( \sigma_0^2 \) may be factored out of the covariance matrix (for known noise variance), so that only the prior lengthscale \( \lambda_0 \) appears in this large matrix. One then optimizes these parameters separately, using chunking (subsection 3.3) to compute matrix products. Since \( \sigma_0 \) only appears in an \( n \times n \) matrix which does not need to be chunked (the data size \( n \) being moderate in real applications), one can use automatic differentiation libraries such as Paszke et al. (2019) to optimize it by gradient descent. On the other hand, there is no way to factor out \( \lambda_0 \) out of the large matrix \( K_{XX} \), so we resort to a brute force approach by specifying a finite search space for it. To summarize, we proceed here in the following way:

(i) (brute force search) Discretize the search space for the lengthscale by only allowing \( \lambda_0 \in \Lambda_0 \), where \( \Lambda_0 \) is a discrete set (usually equally spaced values on a reasonable search interval);

(ii) (gradient descent) For each possible value of \( \lambda_0 \), minimize the (concentrated) \( \mathcal{L} \) over the remaining free parameter \( \sigma_0 \) by gradient descent.

We ran the above approach on the Stromboli dataset with standard stationary kernels (Matérn 3/2, Matérn 5/2, exponential). In agreement with Linde et al. (2014), the observational noise has standard deviation 0.1 $mGal$. The optimization results for different values of the lengthscale parameter are shown in Figure 7. The best estimates of the parameter values for each kernels are shown in Table 1. The table also shows the practical range \( \bar{\lambda} \) which is defined as the distance at which the covariance falls to 5% of its original value.

In order to asses the robustness of each kernel, we predict a set of held out (test) observations by conditioning on the remaining (training) observations. Figure 8 shows the root mean squared error (RMSE) on the test set for different proportion of train/test splits. For each given proportion, members of the train/test sets are chosen at random among the available datapoints.

Note the the above procedure is more of a quality assurance than a rigorous statistical evaluation of the model, since all datapoints were already used in the fitting of the hyperparameters. Since the exponential kernel tends to exhibit pathological phenomenon, like the
Figure 7: (a) concentrated negative marginal log-likelihood and (b) optimal hyperparameter values for different lengthscale parameters $\lambda_0$.

Figure 8: Root mean squared error on test set for the different models (with optimal hyperparameters). The full dataset contains 541 observations.
MLE for lengthscale parameter going to infinity, we choose to use the Matérn 3/2 model for the experiments of subsection 4.2 and subsection 4.3. The maximum likelihood estimator of the prior hyperparameters for this model are $\hat{\lambda}_0^{MLE} = 549.2$ [kg/m$^3$], $\sigma_0^{MLE} = 527.8$ [kg/m$^3$] and $\hat{\lambda}_0^{MLE} = 891.7$ [m].

4.2. Posterior Sampling. Our implicit representation also allows for efficient sampling from the posterior by using the residual kriging algorithm (Chilès and Delfiner, 2012; de Fouquet, 1994), which we here adapt to linear operator observations. Note that in order to sample a Gaussian process at $m$ sampling points, one needs to generate $m$ correlated Gaussian random variables, which involves covariance matrices of size $m^2$, leading to the same computational bottlenecks as described in section 3. On the other hand, the residual kriging algorithm generates realizations from the posterior by updating realizations of the prior, as we explain next.

As before, suppose we have a GP $Z$ defined on some compact Euclidean domain $D$ and assume $Z$ has continuous sample paths almost surely. Furthermore, say we have $p$ observations described by linear operators $\ell_1, ..., \ell_p \in \mathcal{C}(D)^*$. Then the conditional expectation of $Z$ conditional on the $\sigma$-algebra $\Sigma := \sigma(\ell_1(Z), ..., \ell_p(Z))$ is an orthogonal projection (in the $L^2$-sense (Williams, 1991)) of $Z$ onto $\Sigma$. This orthogonality can be used to decompose the conditional law of $Z$ conditional on $\Sigma$ into a conditional mean plus a residual. Indeed, if we let $Z'$ be another GP with the same distribution as $Z$ and let $\Sigma' := \sigma(\ell_1(Z'), ..., \ell_p(Z'))$, then we have the following equality in distribution:

$$Z_x | \Sigma = \mathbb{E}[Z_x | \Sigma] + \left(Z'_x - \mathbb{E}[Z'_x | \Sigma'] \right), \text{ all } x \in D.$$  \hspace{1cm} (4.6)

Compared to direct sampling of the posterior, the above approach involves two main operations: sampling from the prior and conditioning under operator data. When the covariance kernel is stationary and belongs to one of the usual families (Gaussian, Matérn), methods exist to sample from the prior on large grids (Mantoglou and Wilson, 1982); whereas the conditioning part may be performed using our implicit representation.

Remark 4.1. Note that in a sequential setting as in subsection 3.1, the residual kriging algorithm may be used to maintain an ensemble of realizations from the posterior distribution by updating a fixed set of prior realizations at every step in the spirit of Chevalier et al. (2015).

4.3. Sequential Experimental Design for Excursion Set Recovery. As a last example of application where our implicit update method provides substantial savings, we consider
a sequential data collection task involving an inverse problem. Though sequential design criterion for inverse problems have already been considered in the literature (Attia et al., 2018), most of them only focus on selecting observations to improve the reconstruction of the unknown parameter field, or some linear functional thereof.

We here consider a different setting. In light of recent progress in excursion set estimation (Azzimonti et al., 2016; Chevalier et al., 2013), we instead focus on the task of recovering an excursion set of the unknown parameter field $\rho$, that is we want to learn the unknown set $\Gamma^* := \{x \in D : \rho(x) \geq T\}$, where $T$ is some threshold. In the present context of Stromboli, high density areas are related to dykes (previous feeding conduits of the volcano), while low density values are related to deposits formed by paroxysmal explosive phreato-magmatic events (Linde et al., 2014). To the best of our knowledge such sequential experimental design problems for excursion set learning in inverse problems have not been considered elsewhere in the literature.

**Remark 4.2.** For the sake of simplicity, we focus only on excursion sets above some threshold, but all the techniques presented here may be readily generalized to generalized excursion sets of the form $\Gamma^* := \{x \in D : \rho(x) \in I\}$ where $I$ is any finite union of intervals on the extended real line.

We here consider a sequential setting, where observations are made one at a time and at each stage we have to select which observation to make next in order to optimally reduce the uncertainty on our estimate of $\Gamma^*$.

Building upon Picheny et al. (2010); Bect et al. (2012a); Azzimonti et al. (2019); Chevalier et al. (2014a), there exists several families of criteria to select the next observations. Here, we restrict ourselves to a variant of the weighted IMSE criterion (Picheny et al., 2010). The investigation of other state-of-the-art criteria is left for future work. We note in passing that most Bayesian sequential design criteria involve posterior covariances and hence tend to become intractable for large-scale problems. Moreover in a sequential setting, fast updates of the posterior covariance are crucial. Those characteristics make the problem considered here particularly suited for the implicit update framework introduced in subsection 3.2.

The weighted IMSE criterion selects next observations by maximizing the variance reduction they will provide at each location, weighted by the probability for that location to belong to the excursion set $\Gamma^*$. Assuming that $n$ data collection stages have already been performed and using the notation of subsection 3.1, the variant that we are considering here selects the next observation location by maximizing the weighted integrated variance reduction (wIVR):

$$
(4.7) \quad \text{wIVR}^n(s) = \int_D \left( K_{xx}^{(n)} - K_{xx}^{(n+1)} [G_s] \right) p_n(x) dx,
$$

where $s$ is some potential observation location, $K^{(n+1)}$ denotes the conditional covariance after including a gravimetric observation made at $s$ (this quantity is independent of the observed data) and $G_s$ is the forward operator corresponding to this observation. Also, here $p_n$ denotes the coverage function at stage $n$ (we refer the reader to Appendix B for more details on Bayesian set estimation). After discretization, applying Theorem 3.1 turns this criterion into a sequential optimization problem.

This manuscript is for review purposes only.
Figure 9: Realizations from Matérn 3/2 GP prior (hyperparameters taken from Table 1) with corresponding excursion sets: (left to right) Underground mass density field (arbitrary colorscale), high density regions and low density regions (thresholds are 2600 [kg/m$^3$] and 1700 [kg/m$^3$]).

\[
\sum_{\mathbf{x} \in \mathbf{X}} K^{(n)}_{xX} G^T_s \left( G_s K^{(n)}_{XX} G^T_s + \tau^2 I \right)^{-1} G_s K^{(n)}_{Xx} p_n(x),
\]

where we have assumed that all measurements are affected by $\mathcal{N}(0, \tau^2)$ distributed noise.

Note that for large-scale problems, the wIVR criterion in the form given in (4.8) becomes intractable for traditional methods because of the presence of the full posterior covariance matrix $K^{(n)}_{XX}$ in the parenthesis. The implicit representation presented in subsection 3.2 can be used to overcome this difficulty, allowing new observations to be seamlessly integrated along the way by updating the representation using Algorithm 3.2.

**Experiments and Results:** We now study how the wIVR criterion can help to reduce the uncertainty on excursion sets within the Stromboli volcano. We here focus on recovering the volume of the excursion set instead of its precise location. To the best of our knowledge,
in the existing literature such sequential design criteria for excursion set recovery have only been applied to small-scale inverse problems and have not been scaled to larger, more realistic problems where the dimensions at play prevent direct access to the posterior covariance matrix.

In the following experiments, we use the Stromboli volcano inverse problem and work with a discretization into cubic cells of 50 \(m\) side length. We use a Matérn 3/2 GP prior with hyperparameters trained on real data (Table 1) to generate semi-realistic ground truths for the experiments. We then simulate numerically the data collection process by computing the response that results from the considered ground truth. When computing sequential designs for excursion set estimation, the threshold that defines the excursion set can have a large impact on the accuracy of the estimate. Indeed, different thresholds will produce excursion sets of different sizes, which may be easier or harder to estimate depending on the set estimator used. For the present problem, Figure 10 shows the distribution of the excursion volume under the considered prior for different excursion thresholds.

![Figure 10: Distribution of excursion set volume under the prior for different thresholds. Size is expressed as a percentage of the volume of the inversion domain.](image)

It turns out that the estimator used in our experiments (Vorob’ev expectation) behaves differently depending on the size of the excursion set to estimate. Indeed, the Vorob’ev expectation tends to produce a smoothed version of the true excursion set, which in our situation results in a higher fraction of false positives for larger sets. Thus, we consider two scenarios: a large scenario where the generated excursion sets have a mean size of 10\% of the total inversion volume and a small scenario where the excursion sets have a mean size of 5\%
of the total inversion volume. One should note that those percentages are in broad accordance
with the usual size of excursion sets that are of interest in geology. The chosen thresholds are
2500 \([\text{kg/m}^3]\) for the large excursions and 2600 \([\text{kg/m}^3]\) for the small ones.

\[(a) \text{ (large scenario) threshold: } 2500 \text{[kg/m}^3]\]

\[(b) \text{ (small scenario) threshold: } 2600\text{[kg/m}^3]\]

Figure 11: Distribution of excursion volume (with kernel density estimate) under the prior
for the two considered thresholds, together with excursion volumes for each ground truths.

The experiments are run on five different ground truths, which are samples from a Matérn
3/2 GP prior (see previous paragraphs). The samples were chosen such that their excursion
set for the large scenario have volumes that correspond to the 5%, 27.5%, 50%, 72.5% and
95% quantiles of the prior excursion volume distribution for the corresponding threshold.

Figure 11 shows the prior excursion volume distribution together with the volumes of the
five different samples used for the experiments. Figure 12 shows a profile of the excursion
set (small and large scenario) for one of the five samples used in the experiments. The data
collection location from the 2012 field campaign (Linde et al., 2014) are denoted by black
dots. The island boundary is denoted by blue dots. Note that, for the sake of realism, in the
experiments we only allow data collection at locations that are situated on the island (data
acquired on a boat would have larger errors); meaning that parts of the excursion set that are
outside of the island will be harder to recover.

Experiments are run by starting at a fixed starting point on the volcano surface, and
then sequentially choosing the next observation locations on the volcano surface according to
the wIVR criterion. Datapoints are collected one at a time. We here only consider myopic
optimization, that is, at each stage, we select the next observation site \(s_{n+1}\) according to:

\[s_{n+1} = \arg \min_{s \in S_c} \text{wIVR}^n(s),\]

where ties are broken arbitrarily. Here \(S_c\) is a set of candidates among which to pick the
next observation location. In our experiments, we fix \(S_c\) to consist of all surface points within

This manuscript is for review purposes only.
Figure 12: Projection of the underground density for the first ground truth. Island boundary denoted in blue, observation location from previous field campaign denoted by black dots.

We see that in the large scenario Figure 13 the wIVR criterion is able to correctly detect 70 to 80% of the excursion set (in volume) for each ground truth after 450 observations. For the small scenario Figure 14 the amount of true positives reached after 450 observations is
similar, though two ground truths are harder to detect. Note that in Figures 13 and 14 the fraction of false negatives is expressed as a percentage of the volume of the complementary of the true excursion set $D \setminus \Gamma^*$. We see that the average percentage of false positives after 450 observations tends to lie between 5 and 15%, with smaller excursion sets yielding fewer false positives. While the Vorob’ev expectation is not designed to minimize the amount of false positives, there exists conservative set estimators (Azzimonti et al., 2019) that specialize on this task. We identify the extension of such estimators to inverse problems as a promising venue for new research.

In both figures we also plotted the fraction of true positives and false positives that result from the data collection plan that was used in Linde et al. (2014). Here only the situation at the end of the data collection process is shown. We see that for some of the ground truths the wIVR criterion is able to outperform static designs by around 10%. Note tough that there are ground truths where it performs similarly to a static design. We believe this is due to the fact that for certain ground truths most of the information about the excursion set can be gathered by spreading the observations across the volcano, which is the case for the static design that also considers where it is practical and safe to measure (see Figure 12 for a depiction of the observation location).

**Limiting Distribution:** The dashed horizontal lines in Figures 13 and 14 show the detection percentage that can be achieved using the limiting distribution. We define the limiting distribution as the posterior distribution one were to obtain if one had gathered data at all allowed locations (everywhere on the volcano surface). This distribution may be approximated by gathering data at all points of a given (fine grained) discretization of the surface. In general, this is hard to compute since it requires ingestion of a very large amount of data,
Figure 14: Evolution of true and false positives for the small scenario as a function of the number of observations.

but thanks to our implicit representation (subsection 3.2) we can get access to this object, thereby, allowing new forms of uncertainty quantification.

In a sense, the limiting distribution represents the best we can hope for when covering the volcano this type of measurements (gravimetric). It gives a measure of the residual uncertainty inherent to the type of observations used (gravimetric). Indeed, it is known that a given density field is not identifiable from gravimetric data alone (see Blakely (1995) for example). Even if gravity data will never allow for a perfect reconstruction of the excursion set, we can use the limiting distribution to compare the performance of different sequential design criteria and strategies. It also provides a mean of quantifying the remaining uncertainty under the chosen class of models. A sensible performance metric is then the number of observations that a given criterion needs to approach the minimal level of residual uncertainty which is given by the limiting distributions.

As a last remark, we stress that the above results and the corresponding reconstruction qualities are tied to an estimator, in our case the Vorob’ev expectation. If one were to use another estimator for the excursion set, those results could change significantly.

Posterior Volume Distribution: Thanks to our extension of the residual kriging algorithm to inverse problems (see subsection 4.2), we are able to sample from the posterior at the end of the data collection process. This opens new venues for uncertainty quantification in inverse problems. For example, we can use sampling to estimate the posterior distribution of the excursion volume and estimate the residual uncertainty on the size of the excursion set.
Figure 15: True excursion set and visited locations (wIVR strategy). Island boundary is shown in blue.

Figure 16 shows the empirical posterior distribution of the excursion volume for each of the ground truths considered in the preceding experiments. When compared to the prior distribution, Figure 11, one sees that the wIVR criterion is capable of significantly reducing the uncertainty on the excursion volume. This shows that tough the location of the excursion
set can only be recovered with limited accuracy, as shown in Figures 13 and 14, the excursion volume can be estimated quite well. This is surprising given that the criterion used (wIVR) is a very crude one and was not designed for that task. On the other hand, there exist more refined criterion, like the so called SUR strategies (sequential uncertainty reduction) (Chevalier et al., 2014b; Bect et al., 2019), among which some were specifically engineered to reduce the uncertainty on the excursion volume (Bect et al., 2012b). Tough those criterion are more computationally challenging than the wIVR one, especially in the considered framework, we identify their application to large Bayesian inverse problem as a promising avenue for future research.

5. Conclusion and Perspectives. Leveraging new results about sequential disintegrations of Gaussian measures, we have introduced an implicit almost matrix free representation of the posterior covariance of a GP and have demonstrated fast update of the posterior covariance on large grids under general linear functional observations. Our method allows streamline updating and fast extraction of posterior covariance information even when the matrices are larger than the available computing memory. Using our novel implicit representation, we have shown how targeted design criteria for excursion set recovery may be extended to inverse problems discretized on large grids. We also demonstrated UQ on such problems using posterior sampling via residual kriging. Our results suggest that using considered design criteria allows reaching close-to-minimal levels of residual uncertainty using a moderate number of observations and also exhibit significant reduction of uncertainty on the excursion volume. The GP priors used in this work are meant as a proof of concept and future work should address the pitfalls of such priors, such as lack of positiveness of the realisations and lack of expressivity. Other promising research avenues include extension to multivariate excursions Fossum et al. (2021) and inclusion of more sophisticated estimators such as conservative es-

Figure 16: Empirical posterior distribution (after 450 observations) of the excursion volume for each ground truth. True volumes are denoted by vertical lines.
estimates Azzimonti et al. (2019). On the dynamic programming side, extending the myopic optimization of the criterion to finite horizon optimization in order to provide optimized data collection trajectories is an obvious next step which could have significant impact on the geophysics community. Also, including location dependent observation costs such as accessibility or dangerosity in the design criterion could help provide more realistic observation plans.

Appendix A. Mathematical Background for Infinite Dimensional Formulation of Bayesian Inversion and Proofs of the Theorems. This chapter recalls the concepts and definitions needed for the infinite dimensional formulation of Bayesian inverse problem introduced in section 2 and contains the proof of the theorems presented therein. For the functional analysis background, we refer the reader to Folland (2013) and to Tarieladze and Vakhania (2007); Vakhania et al. (1987) for the background about Gaussian measures. The theorems for equivalence between Gaussian processes and Gaussian measures are adopted from Rajput and Cambanis (1972), while the one for conditioning / disintegration of Gaussian measures are adapted from Tarieladze and Vakhania (2007).

Most of this chapter will be concerned with random variables taking values in the space of continuous function $C(D)$, where $D$ is a compact subset of Euclidean space. When endowed with the sup-norm, $C(D)$ turns into a Banach space. This space enjoys two useful properties:

1. $C(D)$ is separable, and as a consequence, the Borel $\sigma$-algebra and the cylindrical $\sigma$-algebra on $C(D)$ agree.
2. The dual space $C(D)^*$ is the space of Radon measures on $D$ and (by Riesz-Markov-Kakutani) for all $l \in C(D)^*$ : $\exists \lambda$ Radon measure on $D$ such that

$$\forall f \in C(D) : l(f) = \int f \, d\lambda.$$ 

A.1. Equivalence of Gaussian Process and Gaussian measure. When considering the Banach space of continuous functions $C(D)$ over a compact Euclidean domain $D$, one can show that a Gaussian measure on $C(D)$ defines an equivalent Gaussian process on $D$ with continuous trajectories, and vice-versa. This allows one to work with Gaussian measures and Gaussian processes interchangeably on this Banach space. The equivalence is ensured by the following two theorems, which are multidimensional equivalents of the one presented in Rajput and Cambanis (1972).

We first show that a Gaussian process on $D$ with continuous sample paths induces a Gaussian measure on $C(D)$. Indeed, given such a Gaussian process $Z$, one may try to induce a Gaussian measure $\mu_Z := P \circ \Phi^{-1}$, where $\Phi := Z (\cdot; \omega)$. The next theorem guarantees that this indeed defines a Gaussian measure.

**Theorem A.1.** Let $(\Omega, \mathcal{F}, \mathbb{P}; Z(\omega, x), x \in D)$ be a Gaussian process on a compact subset $D \subset$
$\mathbb{R}^d$ with continuous sample paths. Then the induced measure

$$\mu_Z := P \circ \Phi^{-1}$$

is well-defined (as a Borel measure) and Gaussian.

On the other hand, given a Gaussian measure, the following theorem ensures that the measure induces a Gaussian process.

**Theorem A.2.** Let $\mu$ be a Gaussian measure on $C(D)$, for a compact subset $D \subset \mathbb{R}^d$. Then, letting $\Omega = C(D)$ and $\mathcal{F}$ be the Borel sigma algebra on $C(D)$, the collection of random variables

$$Z_t : (\Omega, \mathcal{F}, \mu) \to (\mathbb{R}, \mathcal{B} (\mathbb{R})), \omega \mapsto \delta_t (\omega)$$

for all $t \in D$ is a Gaussian process with paths in $C(D)$ which induces $\mu$ on $C(D)$.

In order to prove those theorems, we start with an approximation result that will be useful for proving measurability properties and Gaussianity of the measure induced by a GP.

**Lemma A.3 (Approximation by box functions).** Let $D$ be a compact subset of $\mathbb{R}^d$. Since compact subsets of Euclidean space are just closed bounded subsets, we can fit $D$ inside a square:

$$D \subset \prod_{i=1}^d [-a,a] =: A, \text{ such that } \partial D \cap \partial A = \emptyset.$$ 

Now, for fixed $n \in \mathbb{N}$, we can partition $D$ into disjoint squares (modulo edge effects):

$$D = \bigcup_{k_1,\ldots,k_d=0}^{n-1} A^{(n)}_{k_1,\ldots,k_d},$$

where

$$A^{(n)}_{k_1,\ldots,k_d} := \prod_{j=1}^d \left[ t^{(n)}_{k_j}, t^{(n)}_{k_j+1} \right] \cap D, \quad t^{(n)}_{i} := -a + (i/2)2a$$

Now, given any continuous function $f \in C(D)$, define

$$(A.1) \quad f_n := \sum_{k_1,\ldots,k_d=0}^{n-1} f \left( t^{(n)}_{k_1}, \ldots, t^{(n)}_{k_d} \right) I_{A^{(n)}_{k_1,\ldots,k_d}}.$$ 

**Claim:** $f_n \to f$ uniformly on $D$.

**Proof.** By Heine-Cantor, $f$ is uniformly continuous on $D$. Let $\epsilon > 0$ and let $\delta > 0$ such that for all $x, y \in D$: $||x - y|| < \delta \implies |f(x) - f(y)| < \epsilon$. Now let $n \in \mathbb{N}$ such that $2a/n < \delta$. Then

$$||f - f_n||_{\infty} = \max_{k_1,\ldots,k_d} \left| f \left| A^{(n)}_{k_1,\ldots,k_d} \right| - f \left( t^{(n)}_{k_1}, \ldots, t^{(n)}_{k_d} \right) \right| < \epsilon$$

which proves the claim.

We now show that, for stochastic processes on compact Euclidean domains, having continuous sample paths is enough to ensure product measurability.

**Theorem A.4.** Let $(\Omega, \mathcal{F}, P; Z(x; \omega), x \in D)$ be a stochastic process on a compact subset $D \subset \mathbb{R}^d$ with continuous sample paths. Then it is measurable as a mapping $(D \times \Omega, \mathcal{B}(D) \times \mathcal{F}) \to (\mathbb{R}, \mathcal{B}(\mathbb{R}))$ (product measurable).

This manuscript is for review purposes only.
Proof. This is a direct consequence of Mackey (1952, Lemma 9.2).

We now have all the ingredients to prove the main theorems about equivalence of process and measure.

Proof. (Theorem A.1) By Theorem A.4, the only thing left to prove is that for all \( l \in C(D)^* \) the real random variable \( l \circ \Phi \) is Gaussian. By the Riesz-Markov representation theorem, there exists a Radon measure \( \lambda \) on \( D \) representing \( \lambda \). Now, for each \( \omega \in \Omega \), use Lemma A.3 to get a uniform approximation \( Z_n (\cdot ; \omega) \to Z (\cdot ; \omega) \) as in (A.1). We then have:

\[
l \circ \Phi (\omega) = l \left( \lim_{n \to \infty} Z_n (\cdot ; \omega) \right) = \lim_{n \to \infty} \int \sum_{k_1, \ldots, k_d = 0}^{n-1} Z \left( t_{k_1}^{(n)}, \ldots, t_{k_d}^{(n)} ; \omega \right) \delta_{A_{k_1, \ldots, k_d}^{(n)}} d\lambda \\
= \lim_{n \to \infty} \sum_{k_1, \ldots, k_d = 0}^{n-1} Z \left( t_{k_1}^{(n)}, \ldots, t_{k_d}^{(n)} ; \omega \right) \lambda \left( A_{k_1, \ldots, k_d}^{(n)} \right).
\]

Now, as a convergent series of Gaussian random variables, the above is Gaussian (use characteristic functions and Lévy convergence theorem).

Proof. (Theorem A.2) Let \( \Omega = C(D) \) and \( \mathcal{F} \) be the Borel sigma algebra on \( C(D) \) and define a collection of random variables

\[
Z_t : (\Omega, \mathcal{F}, \mu) \to (\mathbb{R}, \mathcal{B}(\mathbb{R})), \ \omega \mapsto \delta_t (\omega)
\]

for all \( t \in D \). Since for all \( t \in D \), the Dirac functionals \( \delta_x \) belong to the dual of \( C(D) \), we have that \( Z_t \) is a Gaussian real random variable for all \( t \). Now, for \( t_1, \ldots, t_n \in D \), any linear combination of the components of the vector \( (Z_{t_1}, \ldots, Z_{t_n}) \) may be written an element of \( C(D)^* \), and will hence be Gaussian distributed by Gaussianity of the measure. This shows that \( Z \) is a Gaussian process on \( D \).

From the above theorems, it is also clear that if \( Z \) is the process induced by a Gaussian measure on \( C(D) \), then for any \( x \in D \), we have

\[
(A.2) \quad \mathbb{E}_\mu [f(x)] = \mathbb{E} [Z_x]
\]

and the same is true if \( Z \) is a GP on \( D \) with trajectories in \( C(D) \) and \( \mu \) is the measure induced by the process. This allows us to translate everything from process to measure and back without needing to worry about the details. Finally, using the fact that the Dirac deltas belong to the dual we may also prove Lemma 2.2 about the correspondence between mean element and covariance operator of the induced measure and mean and covariance function of the process.

*This manuscript is for review purposes only.*
Proof. (Lemma 2.2) For \( x, y \in D \), let:

\[
m_x : = \langle m_\mu, \delta_x \rangle = \int_{C(D)} f(x) d\mu(f) = \mathbb{E}_\mu[f(x)] = \mathbb{E}[Z_x]
\]

\[
k(x, y) : = \langle \delta_x, C_\mu \delta_y \rangle = \delta_x \left[ \int_{C(D)} f(y) f d\mu(f) - m_y m_\mu \right]
\]

\[
= \mathbb{E}_\mu[f(x)f(y)] - \mathbb{E}_\mu[f(x)] \mathbb{E}[f(y)]
\]

\[
= \mathbb{E}[Z_x Z_y] - \mathbb{E}[Z_x] \mathbb{E}[Z_y] .
\]

Note that exchanging Dirac deltas and integration is allowed by Fubini since Gaussian measures are finite measures and the last equalities are consequences of (A.2).

A.2. Conditioning, Disintegration and link to finite-dimensional formulation. We now turn to the proof of our main theorem (Theorem 2.5).

Proof. (Theorem 2.5) To prove the theorem, we have to adapt the proof of Tarieladze and Vakhania (2007)[Theorem 3.11] to the non-centered case. Compared to the original theorem, the conditional covariance operator \( \hat{C}_\mu \) hasn’t changed, whereas the conditional mean \( \tilde{m}(y) \) clearly still defines a continuous mapping satisfying \( \hat{G}\tilde{m}(y) = y \) for all \( y \) in the range of \( C_\nu \). Hence, for all \( y \in Y \), we can still use Tarieladze and Vakhania (2007)[Lemma 3.8] to define \( \mu_{G^{-1}(y)} \) as a Gaussian measure having mean element \( \tilde{m}(y) \) and covariance operator \( \hat{C}_\mu \). What is left to check is that it satisfies the conditions in Definition 2.4 to be a disintegration of \( \mu \) with respect to \( G \).

In the following, let \( y \in Y \) and \( A \in \mathcal{A} \) be arbitrary.

• The measurability of the mapping \( y \mapsto \mu_{G^{-1}(y)}(A) \) for fixed \( A \) holds since, compared to the centered case, the conditional mean \( \tilde{m}(y) \) is only translated by an element that does not depend on \( y \).

• Define \( Y_0 := Gm_\mu + C_\nu(Y^*) \). We have \( \mu \circ G^{-1}(Y_0) = 1 \) by Tarieladze and Vakhania (2007)[Lemma 3.3] and Tarieladze and Vakhania (2007)[Corollary 3.7]. Following the exact same reasoning as in the proof of Tarieladze and Vakhania (2007)[Theorem 3.11] we have that \( \mu_y(G^{-1}(y)) = 1 \).

• By Tarieladze and Vakhania (2007)[Proposition 3.2], the last thing we have to check is that

\[
\hat{\mu}(x^*) = \int_Y \hat{\mu}_{G^{-1}(y)}(x^*) d\nu(y) , \quad \forall x^* \in X^*,
\]

where \( \hat{\mu}(\cdot) \) denotes the characteristic functional of \( \mu \) (see Tarieladze and Vakhania (2007)[Section 3.2]. Compared to the original proof, only the mean element is changed, so for the sake of simplicity we only consider the steps of the proof that differ from the original ones.

We have that

\[
\int_Y \exp \left[ i \langle \tilde{m}(y), x^* \rangle \right] d\nu(y) = \exp \left[ i \langle m_\mu, x^* \rangle \right] \int_y \exp \left[ i \left\langle \sum_{i=1}^n \langle y - Gm_\mu, y_i^* \rangle C_\mu G y_i^*, x^* \right\rangle \right] d\nu(y) ,
\]

This manuscript is for review purposes only.
The last theorem we have to prove is the one about the transitivity of disintegrations.

**Proof.** (Theorem 2.10) By unicity of disintegrations (Tarieladze and Vakhania, 2007)[Remark 3.12], we only have to prove that the family

\[
\left(\left(\mu_{|G_1=y_1}\right)_{|G_2=y_2}\right)_{(y_1,y_2)\in Y_1 \oplus Y_2}
\]

defines a disintegration of \(\mu\) with respect to \((G_1, G_2)\).

First a word of caution: there exist no canonical norm on the direct sum of Banach spaces. However, there are several norms on the direct sum that induce the product topology (Bühler and Salamon, 2018)[Exercise 1.30]. We here work with any of these. Then, the Borel \(\sigma\)-algebra on the direct sum is given by the product of the Borel \(\sigma\)-algebras of the components (Billingsley, 1999)[p.244].

Here, by construction, for any \((y_1, y_2) \in Y_1 \oplus Y_2\), the measure \(\left(\mu_{|G_1=y_1}\right)_{|G_2=y_2}\) is defined as a Gaussian measure having mean element

\[
\tilde{m}^{(1)}(y_1) + \sum_{i=1}^{p_1} \left\langle y_2 - G_2 \tilde{m}^{(1)}(y_1), y_i^{(2)} \right\rangle \tilde{C}_\mu^{(1)} G_2 y_i^{(2)*},
\]

and covariance operator

\[
\tilde{C}^{(1,2)}_\mu := \tilde{C}^{(1)}_\mu - \sum_{i=1}^{p_2} \left\langle \tilde{C}^{(1)}_\mu G_2 y_i^{(2)*}, \cdot \right\rangle \tilde{C}^{(1)}_\mu G_2 y_i^{(2)*},
\]

where \(\tilde{m}^{(1)}\) and \(\tilde{C}^{(1)}_\mu\) denote the mean element and covariance operator of \(\mu_{|G_1=y_1}\) and \(\left( y_i^{(2)} \right)_{i=1,...,p_2}\) is any representing sequence for \(G_2 \tilde{C}^{(1)}_\mu G_2^*\). Since for all \(y_1 \in Y_1\) the measure \(\mu_{|G_1=y_1}\) is Gaussian, we have by Theorem 2.5 that \(\left(\mu_{|G_1=y_1}\right)_{|G_2=y_2}\) is Gaussian.

As in the previous proof, we have to check the three conditions of Definition 2.4.

- For fixed \(A\), the mapping \((y_1, y_2) \mapsto \left(\mu_{|G_1=y_1}\right)_{|G_2=y_2}(A)\) is an addition of a \(\mathcal{B}(Y_1)\)-measurable mapping with a \(\mathcal{B}(Y_2)\)-measurable mapping, and, as such, measurable with respect to the product \(\sigma\)-algebra.

- Let \(Y := Y_1 \oplus Y_2\) and note that \(Y^* = Y_1^* \oplus Y_2^*\) (dual of direct sum is the direct sum of the duals). Then define \(Y_0 = Gm_{\mu} + GC_{\mu} G^* (Y_1^* \oplus Y_2^*)\). Note that the Gaussian measure \(\mu \circ G^{-1}\) has mean \(Gm_{\mu}\) and covariance operator \(GC_{\mu} G^*\), hence \(\mu \circ G^{-1}(Y_0) = 1\) by Tarieladze and Vakhania (2007)[Lemma 3.3].

For any \((y_1, y_2) \in Y_0\) we have that the Gaussian measure \(\left(\mu_{|G_1=y_1}\right)_{|G_2=y_2} \circ G^{-1}\) has covariance operator \(GC_{\mu}^{(1,2)} G^*\). Computing the operator componentwise, we have that:

\[
G_2 \tilde{C}^{(1,2)}_\mu G_2^* = G_2 \tilde{C}^{(1)}_\mu G_2^* - \sum_{i=1}^{p_2} \left\langle \tilde{C}^{(1)}_\mu G_2 y_i^{(2)*}, G_2 \right\rangle G_2 \tilde{C}^{(1)}_\mu G_2 y_i^{(2)*} = 0,
\]

This manuscript is for review purposes only.
where the last equality follows from Tarieladze and Vakhania (2007)[Lemma 3.4, (c)] since \( y_i^{(2)*} \) is a \( G_2 \hat{C}_{\mu}^{(1)} G_2^* \)-representing sequence. An analogous computation for the other components shows that they all vanish.

Defining \( \mu_{y_1,y_2}^{(1,2)} := (\mu_{|G_2 = y_1})|_{G_2 = y_2} \), the last point to show is that

\[
\hat{\mu}(x^*) = \int Y_1 \int Y_2 \hat{\mu}_{y_1,y_2}^{(1,2)}(x^*) \, d\nu_1(y_1) \, d\nu_2(y_2), \quad \forall x^* \in C(D)^* ,
\]

where we have defined the measures \( \nu_1 := \mu \circ G_1^{-1} \) and \( \nu_2 := \mu_{|G_1 = y_1} \circ G_2^{-1} \), omitting the dependence on \( y_1 \) for simplicity. Using the fact that \( \mu_{|G_1 = y_1} \) is a disintegration of \( \mu \) with respect to \( G_1 \), defining \( x_j^{(2)*} := G_2^* y_j^{(2)*} \) and performing a change of variables, we have that

\[
\int Y_1 \int Y_2 \hat{\mu}_{y_1,y_2}^{(1,2)}(x^*) \, d\nu_1(y_1) \, d\nu_2(y_2) = \hat{\mu}(x^*) + \int Y_1 \int Y_2 \exp \left[ i \sum_j \langle y_j^{(2)*}, \nu_j \rangle \langle C^{(1)}_\mu x_j^{(2)*}, x^* \rangle \right] + \frac{1}{2} \sum_j \langle C^{(1)}_\mu x_j^{(2)*}, x^* \rangle \langle C^{(1)}_\mu x_j^{(2)*}, x^* \rangle .
\]

Now defining \( M(y_2) := \sum_j \langle y_j^{(2)*}, C^{(1)}_\mu x_j^{(2)} \rangle \) and \( R_1 := \sum_j \langle C^{(1)}_\mu x_j^{(2)*}, x^* \rangle \), we can simplify the first summand by noticing that it amounts to the characteristic function of a Gaussian measure:

\[
\int Y_2 \exp \left[ i \langle M(y_2), x^* \rangle \right] \, d\nu_2(y_2) = \nu_2(M^* (x^*)) = \int Y_2 \exp \left[ - \frac{1}{2} \langle C_{\nu_2} M^* (x^*), M^* (x^*) \rangle \right] = \int Y_2 \exp \left[ - \frac{1}{2} \sum_j \langle C^{(1)}_\mu x_j^{(2)*}, x^* \rangle^2 \right] \, d\nu_2(y_2) = \int Y_2 \exp \left[ - \frac{1}{2} R_1 x^* \right] \, d\nu_2(y_2) ,
\]

where the penultimate equality follows from \( C_{\nu_2} \)-orthogonality of the \( y_i^{(2)*} \) sequence. This concludes the proof. Note when computing the characteristic function of \( \nu_2 \), we have omitted the mean term due to the change of variable performed earlier (to be perfectly rigorous, one should use a different notation for the transformed measure).

**Link to Finite Dimensional case** When the inversion data is finite-dimensional, that is the
observation operator $G$ maps into $\mathbb{R}^n$ and $\mathbb{R}^n$ is considered as a Banach space with respect to the 2-norm. One can then canonically identify $\mathbb{R}^n$ with its dual using the dot product: $v \mapsto \langle v, \cdot \rangle$. In the following, when elements of $\mathbb{R}^n$ are involved, the duality bracket $\langle \cdot, \cdot \rangle$ will denote the dot product, also, $e_i, i = 1, \ldots, n$ will be used to denote the canonical basis of $\mathbb{R}^n$.

**Proof.** (Remark 2.7) First of all, the $y_i$ form a $C_\nu$-orthonormal family since

$$\langle C_\nu y_i, y_j \rangle = \langle C_\nu^{1/2} y_i, C_\nu^{1/2} y_j \rangle = \langle e_i, e_j \rangle = \delta_{ij},$$

where the first equality follows by self-adjointness of $C_\nu$. Also remember that since here we are working over $\mathbb{R}^n$, the duality bracket denotes the dot product and $\mathbb{R}^n$ is identified with its dual. Finally, according to Tarieladze and Vakhania (2007)[Lemma 3.4], the last thing we have to show is that for any $v \in \mathbb{R}^n$:

$$C_\nu v = \sum_{i=1}^n \langle C_\nu y_i, v \rangle C_\nu y_i.$$

Note that since $C_\nu$ is a positive self-adjoint operator, the $y_i$’s form a basis of $\mathbb{R}^n$, and we can thus write $v = \sum_{i=1}^n v_i y_i$ for some component $v_i$. Then

$$\sum_{i=1}^n \langle C_\nu y_i, v \rangle = \sum_{i,j=1}^n \langle C_\nu y_i, v_j y_j \rangle = v^i C_\nu y_i = C_\nu v \quad \square$$

**Proof.** (Corollary 2.9) In order to get closed-form formulae for the posterior under such operators, we need to be able to compute the action of the adjoint $G^*$. We begin by recalling the definition of the adjoint of a linear operator $T : X \rightarrow Y$ between Banach spaces:

$$T^* : Y^* \rightarrow X^*$$

$$y^* \mapsto (x \mapsto \langle y^*, Tx \rangle).$$

Now if we consider the simple linear operator $G_j : C(D) :\rightarrow \mathbb{R} : f \mapsto \int_D f(x)d\lambda_j(x)$ for some Radon measure $\lambda_j$, then adjoint is given by:

$$\delta_x^* : \mathbb{R} \rightarrow C(D)^*$$

$$a \mapsto \left( f \mapsto a \int_D f(x)d\lambda_j(x) \right).$$

So the adjoint of the observation operator may be written as:

$$G^* : \mathbb{R}^n \rightarrow C(D)^*$$

$$(a_1, \ldots, a_n) \mapsto \left( f \mapsto a_1 \int_D f(x)d\lambda_1(x) + \ldots + a_n \int_D f(x)d\lambda_n(x) \right).$$

There is one last computation that we need to perform before getting the mean and covariance:

$$\left\langle C_\mu G^* y^{(i)}, \delta_x \right\rangle = \left\langle C_\mu \delta_x, G^* y^{(i)} \right\rangle = y^{(i)} \cdot G \left( C_\mu \delta_x \right) = y^{(i)} \cdot G \left( k(\cdot, x) \right) = y^{(i)} \cdot \left( \int_D k(y, x)d\lambda_j(x) \right)_{j=1, \ldots, n} = y^{(i)} \cdot K_{xG}.$$
Putting everything together we are now able to express the covariance operator:

\[
\tilde{k}(x_1, x_2) = k(x_1, x_2) - \sum_{i=1}^{n} y^{(i)} \cdot K_{x_1G} y^{(i)} \cdot K_{x_2G}
\]

\[
= k(x_1, x_2) - \sum_{i=1}^{n} K_{x_1G}^T y^{(i)} \left( y^{(i)} \right)^T K_{x_2G}
\]

\[
= k(x_1, x_2) - \sum_{i=1}^{n} K_{x_1G}^T C^{-1/2}_\nu e_i e_i^T C^{-1/2}_\nu K_{x_2G}
\]

\[
= K_{x_1G}^T K^{-1}_{GG} K_{x_2G}
\]

Where we have used the fact that \(\sum_{i=1}^{n} e_i e_i^T = I_n\) and that:

\[
e_i \cdot G C \mu G^* e_j = \int_D \langle C \mu G^* e_j, \delta_x \rangle d\lambda_i(x)
\]

\[
= \int_D \int_D k(x, z) d\lambda_i(x) d\lambda_j(z).
\]

The same reasoning applies for the mean.

Proof. (Lemma 3.2) We proceed by induction. The case \(n = 1\) follows from (3.3). The induction step is directly given by Theorem 3.1.

Proof. (Lemma 3.4) The product is computed using Algorithm 1. It involves multiplication of \(A\) with the prior covariance, which costs \(O(m^2 q)\) and multiplication with all the previous intermediate matrices, which contribute \(O(mp_c q)\) and \(O(mp^2 c)\) respectively, at each stage.

Proof. (Lemma 3.5) The cost of computing the \(i\)-th pushforward \(\tilde{K}_i\) is \(O(m^2 p_c + i(mp^2_c + p^3_c))\). Summing this cost for all stages \(i = 1, \ldots, n\) then gives \(O(m^2 P + mP^2 + p^2 P_c)\). To that cost, one should add the cost of computing \(R_{i}^{-1}\), which costs \(O(p^2_i)\) at each stage, yielding a \(O(Pp^2_c)\) contribution to the total cost, which is dominated by \(P^2 p_c\) since \(p_c < P\).

Appendix B. Bayesian Inversion and Bayesian Set Estimation. Given a generic Bayesian linear inverse problem with unknown function \(\rho: D \rightarrow \mathbb{R}\) and prior \(Z\), there exists several approaches to approximate the excursion set \(\Gamma^* = \{x \in D : \rho(x) \geq T\}\) using the posterior. For example, a naive estimate for \(\Gamma^*\) may be obtained using the plug-in estimator:

\[
\hat{\Gamma}_{\text{plug-in}} := \{x \in D : \hat{m}_x \geq T\}
\]

where \(\hat{m}_x\) denotes the posterior mean function of the GP prior. In this work, we will focus on recently developed more sophisticated approaches to Bayesian excursion set estimation (Azzimonti et al., 2016; Chevalier et al., 2013) based on the theory of random sets (Molchanov, 2005). We here briefly recall some theory taken from the aforementioned source.

In the following, let \(\hat{Z}\) denote a random field on \(D\) that is distributed according to the posterior distribution. Then, the posterior distribution of the field gives rise to a random closed
One can then consider the probability for any point in the domain to belong to that random set. This is captured by the coverage function:

\[
p_T : D \rightarrow [0, 1] \\
\quad x \mapsto P[x \in \Gamma].
\]

The coverage function allows us to define a parametric family of set estimates for \( \Gamma \), the Vorob'ev quantiles:

\[
\text{(B.2)} \\
Q_{\alpha} := \{ x \in D : p_T(x) \geq \alpha \}.
\]

The family of quantiles \( Q_{\alpha} \) gives us a way to estimate \( \Gamma \) by controlling the (pointwise) probability \( \alpha \) that the members of our estimate lie in \( \Gamma \). There exists several approaches for choosing \( \alpha \). One could for example choose it so as to produce conservative estimates of the excursion set (Azzimonti et al., 2019). Another approach is to choose it such that the volume of the resulting quantile is equal to the expected volume of the excursion set. This gives rise to the Vorob'ev expectation.

**Definition B.1. (Vorob'ev Expectation)** The Vorob'ev expectation is the quantile \( Q_{\alpha_V} \) with threshold \( \alpha_V \) chosen such that

\[
\mu(Q_{\alpha_V}) \leq \mathbb{E}[V(\Gamma)] \leq \mu(Q_{\alpha_V}), \quad \forall \alpha > \alpha_V,
\]

where \( V(\cdot) \) denotes the volume under the Lebesgue measure on \( \mathbb{R}^d \).

Note that the expected excursion volume may be computed using Robbins’s theorem, which states that under suitable conditions:

\[
\bar{V}_\Gamma := \mathbb{E}[\lambda(\Gamma)] = \int_D p_T(x)dx.
\]

We refer the reader to Robbins (1944) and Molchanov (2005) for more details.

To illustrate the various Bayesian set estimation concepts introduced here, we apply them to the simple one-dimensional inverse problem from Figure 2 to estimate the excursion set above 1.0. Results are shown in Figure 17.

**Appendix C. Forward operator for Gravimetric Inversion.** Given some subsurface density \( \rho : D \rightarrow \mathbb{R} \) inside a domain \( D \subset \mathbb{R}^3 \) and some location \( s \) outside the domain, the vertical component of the gravitational field at \( s \) is given by:

\[
\text{(C.1)} \\
\mathcal{G}_s[\rho] = \int_D \rho(x)g(x,s)dx,
\]

with Green kernel

\[
\text{(C.2)} \\
g(x,s) = \frac{x^{(3)} - s^{(3)}}{\|x - s\|^3},
\]
where \( x^{(3)} \) denotes the vertical component of \( x \).

We discretize the domain \( D \) into \( m \) identic cubic cells \( D = \bigcup_{i=1}^{m} D_i \) with centroids \( X = (X_1, \ldots, X_m) \) and assume the mass density to be constant over each cell, so the field \( \rho \) may be approximated by the vector \( \rho_X \). The vertical component of the gravitational field at \( s \) is then given by:

\[
\int_{\bigcup_{i=1}^{m} D_i} g(x,s)\rho(x)dx \approx \sum_{i=1}^{m} \left( \int_{D_i} g(x,s)dx \right) \rho_{X_i} := G_s\rho_X.
\]

Integrals of Green kernels over cuboids may be computed using the Banerjee formula (Banerjee and Das Gupta, 1977).

**Theorem C.1 (Banerjee).** The vertical gravity field at point \((x_0, y_0, z_0)\) generated by a prism

---

This manuscript is for review purposes only.
with corners \((x_h, x_l, y_h, y_l, \ldots)\) of uniform mass density \(\rho\) is given by:

\[
g_z = \frac{1}{2} \gamma N \rho \left[ x \log \left( \frac{\sqrt{x^2 + y^2 + z^2 + y}}{\sqrt{x^2 + y^2 + z^2 - y}} \right) + y \log \left( \frac{\sqrt{x^2 + y^2 + z^2 + x}}{\sqrt{x^2 + y^2 + z^2 - x}} \right) - 2z \arctan \left( \frac{xy}{z\sqrt{x^2 + y^2 + z^2}} \right) \right] \bigg|_{x_h-x_0}^{x_l-x_0} \bigg|_{y_h-y_0}^{y_l-y_0} \bigg|_{z_h-z_0}^{z_l-z_0}
\]

**Appendix D. Supplementary Experimental Results.** We here include more detailed analysis of the results of subsection 4.3 that do not fit in the main text.

Figures 13 and 14 showed that there are differences in detection performance for the different ground truths. These can be better understood by plotting the actual location of the excursion set for each of the ground truths as well as the observation locations chosen by the wIVR criterion, as done in Figure 18.

One sees that the (comparatively) poor performance shown by Figure 14 for Sample 2 in the small scenario may be explained by the fact that, for this ground truth, the excursion set is located mostly outside of the accessible data collection zone (island surface), so that the strategy is never able to collect data directly above the excursion.

*This manuscript is for review purposes only.*
Figure 18: True excursion set and visited locations (wIVR strategy). Island boundary is shown in blue.
