(Dated: November 20, 2021)

We re-analyze the Cepheid data used to infer the value of the Hubble constant H_0 by calibrating Type Ia supernovae. We do not enforce a universal value of the empirical Cepheid calibration parameters R_W (Cepheid Wesenheit color-luminosity parameter) and M_H^W (Cepheid Wesenheit H-band absolute magnitude). Instead we allow for variation of either of these parameters for each individual galaxy. We also consider the case where these parameters have two universal values: one for low galactic distances $D < D_c$ and one for high galactic distances $D > D_c$ where D_c is a critical transition distance. We find hints for a 3σ level mismatch between the low and high galactic distance parameter values. We then use model selection criteria (AIC and BIC) which penalize models with large numbers of parameters, to compare and rank the following types of R_W and M_H^W parameter variations: Base models: Universal values for R_W and M_H^W (no parameter variation), I: Individual fitted galactic R_W with one universal fitted M_H^W , II: One universal fixed R_W with individual fitted galactic M_H^W , III: One universal fitted R_W with individual fitted galactic M_H^W , IV: Two universal fitted R_W (near and far) with one universal fitted M_H^W , V: One universal fitted R_W with two universal fitted M_H^W (near and far), VI: Two universal fitted R_W (near and far) with two universal fitted M_H^W (near and far). We find that the AIC and BIC model selection criteria consistently favor model IV instead of the commonly used Base model where no variation is allowed for the Cepheid empirical parameters. The best fit value of the SnIa absolute magnitude M_B and of H_0 implied by the favored model IV is consistent with the inverse distance ladder calibration based on the CMB sound horizon $H_0 = 67.4 \pm 0.5 \text{ km s}^{-1} \text{ Mpc}^{-1}$. Thus in the context of the favored model IV the Hubble crisis is not present. This model may imply the presence of a fundamental physics transition taking place at a time more recent than 100 *Myrs* ago.

I. INTRODUCTION

A number of challenges of the standard Λ CDM model has been emerging during the past few years as the accuracy of cosmological observations improves. There are signals in cosmological and astrophysical data that appear to be in some tension (2σ or larger) with the standard Λ CDM model as defined by the Planck18 parameter values [1] (for a review, see Ref. [2] and for a list of papers, see [3]).

The most intriguing large scale tension is the Hubble crisis. Using a distance ladder approach, the local (late or low redshift) measurements of the Hubble constant H_0 lead to values that are significantly higher than those inferred using the angular scale of fluctuations of the cosmic microwave background (CMB) in the context of the Λ CDM model. Local direct measurements of H_0 are in more than 4σ tension with CMB indirect measurements of H_0 (for a review, see Refs. [2, 4, 5]).

The local (late or low redshift) determination of the Hubble constant H_0 using a distance ladder approach depends on a chain of distance measurements. In the cosmic distance ladder approach each step of the distance ladder uses parallax methods and/or the known intrinsic luminosity of a standard candle source to determine the absolute (intrinsic) luminosity of a more luminous standard candle residing in the same galaxy. Thus highly

luminous standard candles are calibrated for the next step in order to reach out to high redshift luminosity distances. If one of these distance measures is subject to systematics or new physics all the subsequent rungs of the cosmic distance ladder are off.

The distance ladder approach is based on a method pioneered by Henrietta Swan Leavitt. She realized that a type of pulsating stars known as Cepheid variable has a period of pulsation that depends on its luminosity. This period–luminosity (PL) relation is called the Leavitt law [6, 7]. Knowing the luminosity of a Cepheid means that its luminosity distance can be determined just by observing its brightness which has been dimmed by that distance. Therefore the Cepheids whose luminosities are correlated with their periods of variability can be the first standard candles in the cosmic distance ladder [8–15]. Trigonometric parallax methods (geometric anchors) may be used to calibrate the Cepheid variable star standard candles at the local Universe (primary distance indicators). Then using the measured luminosity distances of the calibrated Cepheid stars, the intrinsic luminosity of nearby ($D \approx 20 - 40 \text{ Mpc}$) incredibly bright type Ia supernova (SnIa) residing in the same galaxies as the Cepheids is obtained. This calibration of the new type of standard candle SnIa fixes its absolute magnitude M_B and is then used for SnIa at more distant galaxies (in the Hubble flow) to measure H_0 ($z \in [0.01, 0.1]$) and $H(z)$ ($z \in [0.01, 2.3]$) via the measurement of their luminosity distances.

The angular diameter distance of standard rulers can also be used for the estimation of $H(z)$. The Λ CDM best fit value obtained from the sound horizon at recombina-

† f.skara@uoi.gr

tion standard ruler calibrated by the CMB anisotropy spectrum peaks, leads to the measurement $H_0 = 67.4 \pm 0.5 \text{ km s}^{-1} \text{ Mpc}^{-1}$ [1]. The local measurements based on Cepheid calibrators indicate the value $H_0 = 74.03 \pm 1.42 \text{ km s}^{-1} \text{ Mpc}^{-1}$ [16] (4.4σ , 9%). A more recent analysis by the Supernovae H_0 for the Equation of State (SH0ES) Team [16–18] using the recently released Gaia Early Data Release 3 (EDR3) parallaxes [19] has reached 1.8% precision by improving the calibration. Thus, a value of $H_0 = 73.2 \pm 1.3$ was obtained [20]. This is in a 4.2σ tension with the prediction from Planck18 CMB observations [1].

The values of H_0 determined in the late Universe with a calibration based on the Cepheid distance scale and the derived values of H_0 from analysis of the CMB anisotropy spectrum data are shown in Fig. 1. The uncertainties in these values have been decreasing for both methods and the recent measurements disagree beyond 4σ . The Hubble constant H_0 values at 68% CL through direct and indirect measurements obtained by the different methods are illustrated in Fig. 2, from which is evident that the SnIa distance scale calibrated by Cepheid variables is in tension with the CMB sound horizon scale.

If the Hubble tension is not due to systematic errors [4, 33–38], it could be an indication of incorrect estimate of the sound horizon scale due e.g. to early dark energy [39] or to late phantom dark energy [40]. A Gpc scale underdensity [41] has also been proposed as a possible cause of the Hubble tension. Theoretical models addressing this discrepancy utilize either a recalibration of the Λ CDM standard ruler (the sound horizon) assuming new physics before the time of recombination [42–45] or a deformation of the Hubble expansion rate $H(z)$ at late times [40, 46, 47] or an abrupt transition of the SnIa absolute luminosity due to late time new physics [48] (for a review, see Refs. [2, 4, 5], for approaches, see Refs. [49, 50] and for a relevant talk, see Ref. [51]).

The authors of Ref. [48] have pointed out that the H_0 crisis may be viewed as a mismatch between the SnIa absolute magnitude calibrated by Cepheids at $z < 0.01$ [52, 53]

$$M_B^< = -19.244 \pm 0.037 \text{ mag} \quad (1.1)$$

and the SnIa absolute magnitude obtained using the parametric free inverse distance ladder calibrating SnIa absolute magnitude using the sound horizon scale [54]

$$M_B^> = -19.401 \pm 0.027 \text{ mag} \quad (1.2)$$

Since the two measurements are obtained at different redshifts they may indicate a transition in the absolute magnitude with amplitude $\Delta M_B = M_B^> - M_B^< \simeq -0.2 \text{ mag}$ at a transition redshift $z_t \lesssim 0.01$ (roughly 100–150 million years ago) [48, 55]. Note that hints of a possible weak evolution of the absolute magnitude M_B have been recently pointed out in Refs. [56, 57].

Such a transition may occur due to a transition of the strength of the gravitational interactions G_{eff} which modifies the SnIa intrinsic luminosity L by changing the value

of the Chandrasekhar mass M_{Ch} . The simplest assumption leads to [58, 59]

$$L \sim M_{Ch} \sim G_{\text{eff}}^{-3/2} \quad (1.3)$$

even though corrections may be required to the above simplistic approach [60].

Using the normalized effective Newton constant $\mu_G \equiv G_{\text{eff}}/G_N$ (where G_N is the locally measured Newton's constant and $\mu_G = 1$ for $z < z_t \lesssim 0.01$) and assuming the power law dependence Eq. (1.3) the absolute magnitude of SnIa M_B is expected to change as [59, 61–63]

$$\Delta M_B = \frac{15}{4} \log_{10}(\Delta \mu_G - 1) \quad (1.4)$$

Thus for $\Delta M_B \simeq -0.2 \text{ mag}$ it is straightforward to show that the change of μ_G [48]

$$\Delta \mu_G \equiv \mu_G^> - \mu_G^< \simeq -0.12 \quad (1.5)$$

where $\mu_G^>$ corresponds to $z > z_t$ and $\mu_G^<$ corresponds to $z < z_t$ in the context of a Λ CDM background $H(z)$.

This connection indicates that a 10% smaller G_{eff} for $z > z_t$ could potentially provide the required decrease of the absolute magnitude (increase of luminosity) at early times for the resolution of the Hubble tension. In fact such a decrease would also lower the growth rate of cosmological perturbations thus helping in the resolution of the growth tension [48, 64]. Thus, the smaller G_{eff} ($G_{\text{eff}} < 1$) for $z > z_t$ hints towards weaker gravity as indicated by studies discussing the growth tension [65–71].

Interestingly, an analysis of recent Tully-Fisher data [72] has identified hints for a transition of the values of the Tully-Fisher parameters which depend on gravitational physics at a distance scale close to 20 Mpc . The magnitude and sign of the transition are consistent with the proposed mechanism albeit at somewhat more recent times: about 70 million years ago, corresponding to $z_t \simeq 0.005$.

A recent analysis [73], has analyzed the color-luminosity relation of Cepheids in anchor galaxies and SnIa host galaxies by identifying the color-luminosity relation for each individual galaxy instead of enforcing a universal color-luminosity relation to correct the near infrared (NIR) Cepheid magnitudes. This analysis finds a systematic brightening of Cepheids at distances larger than about 20 Mpc (see Fig. 4 in Ref. [73]). As pointed out in [73] this brightening could be enough to resolve the Hubble tension. The authors attribute it to variation of dust properties but there is currently a debate on the actual cause of this brightening.

In the present study we reproduce and extend the analysis of Ref. [73] by considering a varying among individual galaxies color-luminosity relation and (in a separate analysis) allowing the Cepheid absolute magnitude M_H^W to vary among individual galaxies instead of enforcing a universal absolute magnitude. We also explore the possibility that there are two universal absolute magnitudes: one applicable for low distance D Cepheids ($M_H^{W,<}$ for

FIG. 1. The Hubble constant as a function of publication date, using a set of different tools. Symbols in orange denote the values of H_0 determined in the late Universe with a calibration based on the Cepheid distance scale (Key Project (KP) [21], SH0ES [16–18, 20, 22, 23], Carnegie Hubble Program (CHP) [24]). Symbols in purple denote the derived values of H_0 from analysis of the CMB data based on the sound horizon standard ruler (First Year WMAP (WMAP1) [25], Three Year WMAP (WMAP3) [26], Five Year WMAP (WMAP5) [27], Seven Year WMAP (WMAP7) [28], Nine Year WMAP (WMAP9) [29], Planck13 (P13) [30], Planck15 (P15) [31], Planck18 (P18) [1], BAO [32]). The orange and purple shaded regions demonstrate the evolution of the uncertainties in these values which have been decreasing for both methods. The most recent measurements disagree at greater than 4σ (from Ref. [2]).

$D < D_c$) and a second, applicable for high distance D Cepheids ($M_H^{W,>}$ for $D > D_c$). We then test the consistency among the two absolute magnitudes searching for hints of a physics transition at some critical distance (time) D_c (D_c/c).

We thus address the following questions:

- Are there indications for variation of the color-luminosity relation and of the Cepheid absolute magnitude among individual galaxies?
- Is the color-luminosity relation and/or absolute magnitude of nearby Cepheids consistent with the corresponding properties of Cepheids in more distant galaxies?
- Are there indications for a Cepheid luminosity transition similar to the one required for the resolution of the Hubble tension?

In order to address these questions we use the same data and similar method as those used in Ref. [73] but in addition we extend the types of parameter variations allowed while implementing model selection criteria in

order to compare the different allowed types of parameter variations (models) with the Base model which assumes universal Cepheid empirical parameter values. The data are obtained from Refs. [16, 18, 20] and displayed in the Appendix B. Our generalized approach is based on two extensions

- We break the assumption of universality not only on the color-luminosity relation but also on the absolute magnitude of Cepheids.
- In addition to fitting the Cepheid color-luminosity relation (or the absolute magnitude) for each galaxy separately, we also consider the case of two universality classes one for nearby and one for more distant galaxies thus introducing only one new parameter in each case compared to the standard universal approach.

The structure of this paper is the following: In the next Section II we present a brief review of the theoretical background and we describe the method used in our analysis as well as the data considered. In Section III we present our results focusing on the consistency of nearby

FIG. 2. The Hubble constant H_0 values with the 68% CL constraints derived by recent measurements. The value of the Hubble constant H_0 is derived by early time approaches based on sound horizon, under the assumption of a Λ CDM background. The shaded orange and purple bands show the tension between the values inferred from Cepheid calibrated SnIa and CMB observation (from Ref. [2]).

and more distant samples with each other. We also compare with a Monte Carlo uniformized dataset in order to verify that any observed peculiar signal disappears in a Monte Carlo constructed homogeneous dataset. In Section IV we consider various cases (models) allowing for different types of empirical parameter variation and use criteria for model selection and model comparison. In Section V we investigate the impact of the allowed types of parameter variation on the SnIa absolute magnitude M_B and on the corresponding derived value of H_0 . Finally in Section VI we summarize our methods and results and discuss possible extensions of our analysis. We also compare our results with previous analyses searching for similar transition effects in different datasets.

II. THEORETICAL BACKGROUND-METHOD-DATA

In this section, we present a brief review of the theoretical expressions and describe the method and the dataset used.

II.1. Standard candles

In an expanding flat Universe, where the energy is not conserved due to the increase of the photon wavelength and period with time, the luminosity distance can be expressed as [74, 75]

$$d_L(z) = c(1+z) \int_0^z \frac{dz'}{H(z')} \quad (2.1)$$

The luminosity distance is an important cosmological observable that is measured using standardizable candles like SnIa ($z < 2.3$) [76] and gamma-ray bursts (GRBs) ($0.1 < z \lesssim 9$) [77–82].

Surveys can indicate the distance-redshift relation of SnIa by measuring their peak luminosity that is tightly correlated with the shape of their characteristic light curves (luminosity as a function of time after the explosion) [83] and the redshifts of host galaxies.

The use of SnIa in the measurement of H_0 and $H(z)$ relies on a basic assumption that they are standardizable and after proper calibration they have a fixed absolute magnitude independent of redshift in the redshift range $z \in [0.01, 2.3]$ [83]. This assumption has been tested in Refs. [49, 56, 57, 84–90]. The possibility for intrinsic luminosity evolution of SnIa with redshift was first highlighted by Ref. [91]. Also, the assumption that the luminosity of SnIa is independent of host galaxy properties (e.g. host age, host morphology, host mass) and local star formation rate has been discussed in Refs. [92–96].

The apparent magnitude m_B of SnIa at redshift z with absolute magnitude M_B in the context of a specified form of $H(z)$, is related to their luminosity distance $d_L(z)$ in

Mpc as

$$m_B(z) = M_B + 5 \log_{10} \left[\frac{d_L(z)}{\text{Mpc}} \right] + 25 \quad (2.2)$$

Using now the dimensionless Hubble free luminosity distance

$$D_L(z) = \frac{H_0 d_L(z)}{c} \quad (2.3)$$

the apparent magnitude can be written as

$$m_B(z) = M_B + 5 \log_{10} [D_L(z)] + 5 \log_{10} \left[\frac{c/H_0}{\text{Mpc}} \right] + 25 \quad (2.4)$$

Using the degenerate combination

$$\mathcal{M} = M_B + 5 \log_{10} \left[\frac{c/H_0}{\text{Mpc}} \right] + 25 \quad (2.5)$$

into Eq. (2.4) we obtain

$$m_B(z) = \mathcal{M} + 5 \log_{10} [D_L(z)] \quad (2.6)$$

The use of Eq. (2.4) to measure H_0 using the measured apparent magnitudes of SnIa requires knowledge of the value of the SnIa absolute magnitude M_B . This can be obtained using calibrators of local SnIa at $z < 0.01$ (closer than the start of the Hubble flow) in the context of a distance ladder approach (e.g. [97]). Calibrators like Cepheid stars which are bright, variable supergiants are used in this context.

II.2. Cepheid calibration

The Milky Way (MW), the Large Magellanic Cloud (LMC) and NGC 4258 are used as distance anchor galaxies. For Cepheids in the anchor galaxies there are three different ways of geometric distance calibration of their luminosities: parallaxes in the MW [20, 23, 98–103], detached eclipsing binary stars (DEBs) in the LMC [104] and water masers¹ in NGC 4258 [107]. The DEBs method relies on surface-brightness relations and is one-step distance determination to nearby galaxies independent from Cepheids [108]. The Andromeda galaxy (M31) could serve as an anchor in the cosmic distance ladder but the uncertainty in its distance measurements is difficult to reduce [109].

The empirically-determined period-magnitude relationship of a Cepheid can be expressed as (e.g. [36])

$$m_H - R_H E(V - I) = \mu + M_H + b_H [P] + Z_H [M/H] \quad (2.7)$$

¹ Very long baseline interferometric (VLBI) observations of water megamasers which are found in the accretion disks around supermassive black holes (SMBHs) in active galactic nuclei (AGN) have been demonstrated to be powerful one-step geometric probes for measuring extragalactic distances [105, 106].

where m_H is the observed apparent magnitude in the near-infrared H (F160W) band which is centered at $\lambda_H \sim 1.63 \mu m$, V (F555W) and I (F814W) are the optical mean apparent magnitudes which are centered at $\lambda_V \sim 0.555 \mu m$ and $\lambda_I \sim 0.79 \mu m$ respectively, in the HST system², $E(V - I)$ is the color excess, R_H is the total to selective extinction parameter at H band³, $\mu \equiv 5 \log_{10} [d_L(z)/Mpc] + 25$ is the inferred distance modulus to the Cepheid, M_H is the absolute magnitude of a period $P = 10 d$ Cepheid (d for days), b_H and Z_H are the slope parameters that represent the dependence of magnitude on both period and metallicity.

The $[M/H]$ is a measure of the metallicity of the Cepheid. The usual bracket shorthand notation for the metallicity $[M/H]$ represents the Cepheid metal abundance compared to that of the Sun

$$[M/H] \equiv \log(M/H) - \log(M/H)_\odot = \Delta \log(M/H) \quad (2.8)$$

where M and H is the number of metal (any element other than hydrogen or helium) and hydrogen atoms per unit of volume respectively. The unit often used for metallicity is the dex (decimal exponent) defined as $n \text{ dex} = 10^n$.

Also, the bracket shorthand notation for the period $[P]$ is used as (P in units of days)

$$[P] \equiv \log P - 1 \quad (2.9)$$

The color excess characterizes the amount of reddening associated with interstellar extinction, a combined effect of absorption and scattering of blue more than red light by dust and other matter [110, 111]. The color excess depends on the properties of dust and is defined as

$$E(V - I) \equiv A_V - A_I = (V - I) - (V - I)_0 \quad (2.10)$$

where $V - I$ and $(V - I)_0$ are the observed and the intrinsic (normal) Cepheid color respectively. The latter is the hypothetical true Cepheid color which would be observed if there was no extinction.

Following the same formulation used by the SH0ES team [16, 18] in order to minimize the impact of extinction correction uncertainties for distance measurements and determination of the Hubble constant H_0 , we use the replacement $E(V - I) \rightarrow V - I$ in Eq. (2.7), the Hubble Space Telescope (HST) NIR H -band and the reddening-free "Wesenheit" magnitudes [112]

$$m_H^W \equiv m_H - R_W(V - I) = \mu + M_H^W + b_W[P] + Z_W[M/H] \quad (2.11)$$

where the empirical parameter R_W is the reddening-free "Wesenheit" color ratio and is different from R_H which

can be derived from a dust law (e.g. the Fitzpatrick law [113]). The parameter R_W corrects for both dust and intrinsic variations applied to observed blackbody colors $V - I$. Eq. (2.11) can be derived from Eq. (2.7) using Eq. (2.10) with a constant fixed parameter R_W under the important assumption that the intrinsic Cepheid color $(V - I)_0$ can be assumed to have the same distribution for all galaxies. This allows the absorption of the term $R_H(V - I)_0$ by the Cepheid absolute magnitude M_H thus defining the Cepheid Wesenheit H -band absolute magnitude M_H^W in Eq. (2.11). An additional logarithmic dependence of the intrinsic color on the Cepheid period is also allowed and would be absorbed by the parameter b_H leading to the parameter b_W . Thus, if there was a transition in the intrinsic Cepheid color $(V - I)_0$ at a given galactic distance, this transition would manifest itself as a shift of any or all of the parameters M_H^W , b_W and/or R_W at the same distance.

For distances based on NIR ($1 < \lambda < 2.5 \mu m$) measurements, both the impact of extinction by dust (gauged using the observed color $V - I$) and the impact of metallicity on the luminosities and colors of Cepheids, are less significant compared to the corresponding optical measurements [8, 114–116] (for the metallicity effects which are still largely debated, see Refs. [117–121]). However the NIR measurements of Cepheids still suffer from crowding and blending (photometric contamination) from redder Red Giant Branch (RGB) and Asymptotic Giant Branch (AGB) disk stars, particularly as the distance increases [122–124].

Wesenheit magnitudes have the advantage of smaller dispersion in the PL relation caused by differential extinction and the nonzero temperature width of the Cepheid instability strip⁴ (see e.g. Ref. [128]).

Following Ref. [18] and breaking the slope of the Leavitt law at a period of 10 days ($P = 10 d$) we include two different slopes b_W^s and b_W^l parameters in Eq. (2.11) for short and long period Cepheids with $P < 10 d$ and $P > 10 d$ respectively (for a discussion about the presence of a broken PL slope at $P = 10 d$, see Refs. [129–134]).

Ref. [18] considers a universal reddening law in all galaxies and thus assume a global fixed value $R_W = 0.386$. This value is derived from the reddening law of Ref. [113] using a ratio of total to selective extinction at the B and V bands⁵ of the Johnson-Morgan or UB V (Ultraviolet, Blue, Visual) photometric system [135] $R_V = 3.3$ to parameterize the shape of the extinction curve. In the literature the parameter R_W ranges

² HST uses the same three-band photometric system with the Wide Field Camera 3 (WFC3) with two optical filters (F555W and F814W) and one near-infrared filter (F160W).

³ The total to selective extinction parameter at H band R_H is defined as $R_H \equiv A_H/(A_V - A_I) = A_H/E(V - I)$ (where A_H is the extinction due to dust along the line of sight).

⁴ The instability strip refers to a narrow, almost vertical temperature (spectral type) region on the Hertzsprung-Russell (H-R) diagram which contains several types of pulsating variable stars including Cepheid variables (see e.g. Refs. [125–127]). The Classical Cepheids (Population I Cepheids) are F6-K2 type supergiants ($\sim 4 - 20 M_\odot$) with a period of 1 to 70 days with an amplitude variation of 0.1 to 2.0 magnitudes.

⁵ The total to selective extinction at B and V bands R_V is defined as $R_V \equiv A_V/E(B - V)$

from 0.3 to 0.5 at H band (e.g. $R_W = 0.41$ in Ref. [17]) and the universal parameter R_V ranges from 1 to 6 (the average value for the MW is $R_V = 3.1$) [136–146] depending on the reddening law [147–149].

As noted recently by Ref. [73] a global fixed value for parameter R_W could result in a systematic error in distance measurements and the determination of the Hubble constant H_0 . Refs. [73, 150] motivated by the observed variation in dust properties allowing for the parameter R_W to vary between galaxies. However these studies make no attempt to search for possible transitions within the low z galaxy data. In the present analysis we search for transition effects in Cepheid data at $z \lesssim 0.01$ ($\lesssim 40$ Mpc).

II.3. Datasets

We use a sample of 1630 Cepheids in the anchor galaxies and in the SnIa host galaxies. For 74 MW Cepheids including GAIA parallax measurements we use the dataset from Table 1 in Ref. [20] and for 70 LMC Cepheids we use the dataset from Table 2 in Ref. [16]. These data are shown in Tables IV and V of the Appendix B. Fitting the distance ladder with the system of equations for the 70 LMC Cepheids an intrinsic scatter of 0.08 mag is added to the error estimates given in Table 2 of Ref. [16] (note that Ref. [16] include a intrinsic LMC dispersion of 0.07 mag) which is necessary in order to obtain a reduced chi-square of unity $\chi_{red}^2 = \chi_{min}^2/dof = 1$ [151].

We obtain data for 1486 Cepheids in the anchor galaxy NGC 4258, in the M31 galaxy and in the 19 SnIa host galaxies from Table 4 in Ref [18] (for details, see Ref. [152]). This data are shown in Table VI of the Appendix B.

We consider the revised distance modulus to NGC 4258 of $\mu_{N4258} = 29.397 \pm 0.032$ mag (7.576 ± 0.112 Mpc) reported by Ref. [107] using water masers data. Also we consider the distance modulus to the LMC of $\mu_{LMC} = 18.477 \pm 0.0263$ mag derived by Ref. [104] with 1% precision based on enhanced samples of late-type DEBs. This distance modulus is increased from that in Ref. [18] by 0.5%.

Finally for SnIa B-band magnitudes we adopt the data from Table 5 in Ref. [18], derived from the version 2.4 of SALT2⁶ modeling of SnIa light curves by Ref. [158]. These data are shown in Table VII of the Appendix B.

Following Ref. [16] for all LMC Cepheids we adopt the mean metallicity of -0.33 dex from Ref. [159] and -0.27 dex from Ref. [160], $[Fe/H] = -0.30$ dex which is slightly different than the value of -0.25 dex adopted

by Ref. [18]. Also following Ref. [16] we adopt $[O/H] = [Fe/H]$ (where O and Fe is the number of oxygen and iron atoms per unit of volume respectively) and we measure the metallicity in units of $Z = 12 + \log(O/H)$ (with Solar metallicity in these units $Z_\odot = 12 + \log(O/H)_\odot = 8.824$ [150]).

Note that since we use the datasets from Refs. [16, 18, 20] with the same filters we do not need to apply further corrections. The full datasets are available in [161].

III. SEARCH FOR TRANSITION

Our analysis is closely related to the results of study by Ref. [73]. Using the same datasets that were used by Ref. [73] we first reproduce their results and then we search for a transition signal of the best fit parameter values R_W and M_H^W between data subsamples at low and high distances.

From Eq. (2.11) using the Wesenheit magnitude of the j th Cepheid in the i th galaxy, including the host and the anchor galaxies, here MW, NGC 4258 and the LMC, separating PL relations for short and long period Cepheids we have

$$\begin{aligned} m_{H,i,j}^W &\equiv m_{H,i,j} - R_{W,i}(V - I)_{i,j} \\ &= \mu_i + M_{H,i}^W + b_W^s[P]_{i,j}^s + b_W^l[P]_{i,j}^l + Z_W[M/H]_{i,j} \end{aligned} \quad (3.1)$$

where $[P]_{i,j}^s = 0$ for Cepheids with $P > 10$ d and $[P]_{i,j}^l = 0$ for Cepheids with $P < 10$ d.

In the case where i th galaxy is the MW the distance modulus for the j th Cepheid is estimated using parallaxes in units of mas (mas for milliarcsec)

$$\pi_j + zp = 10^{-0.2(\mu_j - 10)} \quad (3.2)$$

where zp is a residual parallax calibration offset.

Thus

$$\begin{aligned} \mu_j &= 10 - \frac{5}{\ln 10} \left[\ln \pi_j + \ln \left(1 + \frac{zp}{\pi_j} \right) \right] \\ &\simeq 10 - \frac{5}{\ln 10} \left[\ln \pi_j + \frac{zp}{\pi_j} \right] \end{aligned} \quad (3.3)$$

where higher order terms $\mathcal{O}(zp/\pi_j)^2$ are negligible. Using Eq. (3.3) into Eq. (3.1) in the case of MW Cepheids we obtain

$$\begin{aligned} m_{\pi,j}^W &= m_{\pi,j} - R_W(V - I)_j \\ &= M_H^W + b_W^s[P]_j^s + b_W^l[P]_j^l + Z_W[M/H]_j + \frac{5}{\ln 10} \frac{zp}{\pi_j} \end{aligned} \quad (3.4)$$

where we use

$$m_{\pi,j}^W = m_{H,j}^W - 10 + \frac{5}{\ln 10} \ln \pi_j \quad (3.5)$$

⁶ Spectral Adaptive Light Curve Template (SALT) is an empirical spectro-photometric model that is used in SnIa light curve fitting [153–155] (for SALT tests with simulations, see [156]). SALT is publicly available at [157].

FIG. 3. Fitting individual R_W to Cepheid data as derived from our work (red points) and from Ref. [73] (blue points). For illustration purposes, the D_L axis has been shifted slightly for our values so that the error bars do not overlap. The red and blue dotted lines correspond to $R_W = 0.366$ and $R_W = 0.369$ respectively. These R_W values are taken using the derived individual parameters of anchor galaxies and M31 (due to its proximity) $R_{W,k}$.

and

$$m_{\pi,j} = m_{H,j} - 10 + \frac{5}{\ln 10} \ln \pi_j \quad (3.6)$$

Also in order to combine the measurements of SnIa and Cepheids we use the calibrated SnIa B-band peak magnitude in the i th host

$$m_{B,i} = \mu_i + M_B \quad (3.7)$$

Using the data (see Section II.3) for observed Cepheid magnitudes m_H , colors $V - I$, periods $[P]$, metallicities $[M/H]$, MW Cepheid parallaxes π , anchor distances μ_k together with the SnIa magnitudes m_B , we can fit simultaneously for R_W , b_W^s , b_W^l , Z_W , the host and the anchor galaxy distances μ_i , the parallax offset zp , the Cepheid absolute magnitude M_H^W and the SnIa absolute magnitude M_B .

Combining the equations for apparent magnitudes for Cepheids, Eqs. (3.1), (3.4), and for SnIa, Eq. (3.7), we relate data and parameters through the matrix equation

$$\mathbf{Y} = \mathbf{A}\mathbf{X} \quad (3.8)$$

with $\mathbf{Y}$ the matrix of measurements, $\mathbf{X}$ the matrix of parameters and $\mathbf{A}$ the equation (or design) matrix. Using these matrices with the measurement error matrix $\mathbf{C}$ we fit the data by minimizing the chi squared χ^2 statistic expressed as

$$\chi^2 = (\mathbf{Y} - \mathbf{A}\mathbf{X})^T \mathbf{C}^{-1} (\mathbf{Y} - \mathbf{A}\mathbf{X}) \quad (3.9)$$

Note that we can solve the following expression for the maximum likelihood parameters $\mathbf{X}$ analytically:

$$\mathbf{X}_{\text{best}} = (\mathbf{A}^T \mathbf{C}^{-1} \mathbf{A})^{-1} \mathbf{A}^T \mathbf{C}^{-1} \mathbf{Y} \quad (3.10)$$

The standard errors for the parameters in $\mathbf{X}_{\text{best}}$ are given by the covariance matrix

$$\Sigma = (\mathbf{A}^T \mathbf{C}^{-1} \mathbf{A})^{-1} \quad (3.11)$$

In the Appendix A we present the schematic form of the $\mathbf{C}$, $\mathbf{Y}$, $\mathbf{X}$ and $\mathbf{A}$ matrices. We adopt 2D fit including errors in the error matrix $\mathbf{C}$ in both $\mathbf{Y}$ and $\mathbf{X}$ "axes". In particular we do not neglect to include in the error matrix $\mathbf{C}$ the errors in the colors V and I . These errors for MW and LMC Cepheids as provided by the SH0ES team (see in Table 1 of Ref. [20] and in Table 2 of Ref. [16]) are shown in Table IV and in Table V of the Appendix B respectively. For Cepheids in galaxies (other than MW and LMC) where the SH0ES team does not provide separate color errors we use total statistical uncertainties where the color errors are included. These total statistical uncertainties derived by the SH0ES team (see in column 8 of the Table 4 of Ref. [18]) are shown in Table VI of the Appendix B).

In the following subsections we study three cases where the questions mentioned in Introduction I will be addressed.

FIG. 4. The best fit $R_{W,bf}$ for various Σ_1 and Σ_2 datasets as a function of the critical dividing distance $D_c \in [0.01, 37] \text{ Mpc}$ as derived using the individual R_W (red points in Fig. 3). The dark red points correspond to the dataset with galaxies that have distance below D_c , whereas the red points regard galaxies with distances above D_c .

III.1. Case I: Fitting individual R_W and global M_H^W

We first allow, as done in Ref. [73], the parameter R_W to vary between galaxies and we consider a global value of the Cepheid absolute magnitude M_H^W . Despite slight differences in the analysis method, the results are in very good agreement with the results in Ref. [73] as illustrated in Fig. 3. Fitting individual parameters of galaxies $R_{W,i}$ to Cepheid data as derived from our work and from Ref. [73] correspond to red and blue points respectively. The inferred best fit value of the Cepheid absolute magnitude is $M_H^W = -5.958 \pm 0.028 \text{ mag}$. The red and blue dotted lines correspond to $R_W = 0.365$ and $R_W = 0.369$. These R_W values are taken using the derived individual parameters of anchor galaxies (here MW, NGC 4258, and LMC) and M31 (due to its proximity) $R_{W,k}$ and minimizing the $\chi^2(R_W)$ with respect to the R_W

$$\chi^2(R_W) = \sum_{k=1}^N \frac{(R_{W,k} - R_W)^2}{\sigma_{R_{W,k}}^2 + \sigma_s^2} \quad (3.12)$$

where $N = 4$. We fix the scatter to $\sigma_s = 0.08$ obtained by demanding that $\chi_{min}^2/N = 1$ (where χ_{min}^2 is the minimized value of χ^2).

Using the obtained best fit individual values for all galaxies $R_{W,i}$ (see red points in Fig. 3) we focus on a particular type of evolution, sharp transition of these best fit values at low and high distances. We thus use the Distance Split Sample (DSS) method which consists of the following steps:

- We consider a critical dividing distance $D_c \in [0.01, 37] \text{ Mpc}$ and split the sample of galaxies in two subsamples Σ_1 and Σ_2 with distances $D < D_c$ and $D > D_c$ respectively.

FIG. 5. The σ -distances between the various Σ_1 and Σ_2 datasets as a function of the critical dividing distance D_c as derived using the individual values of R_W . The red and blue lines correspond to the red (our results) and blue (the results in Ref. [73]) points of Fig. 4 respectively. A transition of the σ -distance at $D_c \simeq 22 \text{ Mpc}$ is apparent.

- For each subsample we use the maximum likelihood method to find the best fit parameters $R_{W,bf}$ ($R_W^<$ and $R_W^>$) by minimizing $\chi_1^2(R_W^<)$ and $\chi_2^2(R_W^>)$ using a similar equation as Eq. (3.12). The best fit values $R_{W,bf}$ for various Σ_1 and Σ_2 datasets as a function of the critical distances D_c are shown in Fig. 4.

- We evaluate the $\Delta\chi_{12}^2(D_c)$ of the best fit of each subsample Σ_1 with respect to the likelihood of the other subsample Σ_2 and vice versa

$$\Delta\chi_{12}^2(D_c) \equiv \chi_2^2(R_W^<)(D_c) - \chi_{2,min}^2(R_W^>)(D_c) \quad (3.13)$$

$$\Delta\chi_{21}^2(D_c) \equiv \chi_1^2(R_W^>)(D_c) - \chi_{1,min}^2(R_W^<)(D_c) \quad (3.14)$$

- Using these values we evaluate the distances $d_{\sigma,12}(D_c)$ and $d_{\sigma,21}(D_c)$ as a solution of the equation

$$\Delta\chi_{ij}^2 = 2Q^{-1} \left[\frac{M}{2}, 1 - \text{Erf} \left(\frac{d_{\sigma,ij}}{\sqrt{2}} \right) \right] \quad (3.15)$$

where $ij = 12, 21$, M is the number of parameters to fit i.e $M = 1$, Q^{-1} is the inverse regularized incomplete Gamma function and Erf is the error function.

- We then define the σ -distance $d_\sigma(D_c)$ as the minimum of the distances $d_{\sigma,12}(D_c)$ and $d_{\sigma,21}(D_c)$ i.e.

$$d_\sigma(D_c) \equiv \text{Min} [d_{\sigma,12}(D_c), d_{\sigma,21}(D_c)] \quad (3.16)$$

The anticipated value of d_σ is in the range of 1 – 2 in the context of a homogeneous sample as verified below using Monte Carlo simulations. We thus address the question: 'Does the real Cepheid sample have this property?'

FIG. 6. Fitting individual M_H^W to Cepheid data for global R_W with a fixed value 0.386. Anchor galaxies are denoted with dark red points and SNIa host galaxies with green points. The dotted line corresponds to $M_H^W = -5.98 \text{ mag}$ as derived using the individual values of anchor galaxies and M31 (due to its proximity) $M_{H,k}^W$.

Fig. 5 shows the σ -distance $d_\sigma(D_c)$ between the various Σ_1 and Σ_2 datasets as a function of the critical distances D_c as derived using the individual values of R_W . The red and blue lines correspond to the red (our results) and blue (the results in Ref. [73]) points of Fig. 4 respectively.

Clearly, the Cepheid best fit $R_{W,bf}$ parameter indicates the presence of a transition at a critical distance D_c in the range between 8 Mpc and 18 Mpc or at a time between 25 Myrs and 55 Myrs ago. For this range of D_c the best fit value of $R_W^< = 0.388 \pm 0.042$ differs from the best fit value of $R_W^> = 0.206 \pm 0.033$ at a level more than 4σ with $\Delta R_W \equiv R_W^> - R_W^< = -0.182 \pm 0.056$.

III.2. Case II: Fitting individual M_H^W with fixed global R_W

In this case we allow the value of the Cepheid absolute magnitude M_H^W to vary between galaxies and we consider a global fixed parameter $R_W = 0.386$ in agreement with Refs. [16, 18, 20].

The results of fitting individual M_H^W to Cepheid data are illustrated in Fig. 6. Anchor galaxies are denoted with dark red points and SNIa host galaxies with green points. We see that Cepheids in nearby galaxies are fainter. The dotted line corresponds to $M_H^W =$

FIG. 7. The best fit $M_{H,bf}^W$ for various Σ_1 and Σ_2 datasets as a function of the critical distances D_c as derived using the individual values of M_H^W (points in Fig. 6). The dark green points correspond to the dataset with galaxies that have distance below D_c , whereas the green points regard galaxies with distances above D_c .

-5.98 mag as derived using the individual parameters of anchor galaxies (here MW, NGC 4258, and LMC) and M31 (due to its proximity) $M_{H,k}^W$ and minimizing

$\chi^2(M_H^W)$ with respect to the M_H^W

$$\chi^2(M_H^W) = \sum_{k=1}^N \frac{(M_{H,k}^W - M_H^W)^2}{\sigma_{M_{H,k}^W}^2 + \sigma_s^2} \quad (3.17)$$

where $N = 4$. We fix the scatter to $\sigma_s = 0.08$ obtained by demanding that $\chi_{min}^2/N = 1$.

Using the obtained best fit individual values for all galaxies $M_{H,i}^W$ (see Fig. 6) we focus on a particular type of evolution, sharp transition of these best fit values at low and high distances. We follow the same DSS method as in the previous subsection. Thus

- First we consider a critical dividing distance $D_c \in [0.01, 37] \text{ Mpc}$ and split the sample of galaxies in two subsamples Σ_1 and Σ_2 with distances $D < D_c$ and $D > D_c$ respectively.
- For each subsample we use the maximum likelihood method to find the best fit parameters $M_{H,bf}^W$ ($M_H^{W,<}$ and $M_H^{W,>}$) by minimizing $\chi_1^2(M_H^{W,<})$ and $\chi_2^2(M_H^{W,>})$. The best fit values of the $M_{H,bf}^W$ for various Σ_1 and Σ_2 datasets as a function of the critical distances D_c are shown in Fig. 7.
- We consider the $\Delta\chi_{12}^2(D_c)$ of the best fit of each subsample Σ_1 with respect to the likelihood of the other subsample Σ_2 and vice versa

$$\Delta\chi_{12}^2(D_c) \equiv \chi_2^2(M_H^{W,<})(D_c) - \chi_{2,min}^2(M_H^{W,>})(D_c) \quad (3.18)$$

$$\Delta\chi_{21}^2(D_c) \equiv \chi_1^2(M_H^{W,>})(D_c) - \chi_{1,min}^2(M_H^{W,<})(D_c) \quad (3.19)$$

- We evaluate the distances $d_{\sigma,12}(D_c)$ and $d_{\sigma,21}(D_c)$ as a solution of the corresponding Eq. (3.15).
- We then find the σ -distances $d_\sigma(D_c)$ as the minimum of the distances $d_{\sigma,12}(D_c)$ and $d_{\sigma,21}(D_c)$.

In Fig. 8 with the green line we show the σ -distances $d_\sigma(D_c)$ between the various Σ_1 and Σ_2 datasets as a function of the critical distances D_c as derived using the individual values of M_H^W . As in the previous case we see that the Cepheid best fit $M_{H,bf}^W$ parameter indicates the presence of a transition at a critical distance D_c in the range between 8 Mpc and 18 Mpc . For this range of D_c the best fit value of $M_H^{W,<} = -5.974 \pm 0.042 \text{ mag}$ differs from the best fit value of $M_H^{W,>} = -6.126 \pm 0.036 \text{ mag}$ at a level more than 3σ with $\Delta M_H^W \equiv M_H^{W,>} - M_H^{W,<} = -0.152 \pm 0.055 \text{ mag}$.

In order to secure the robustness of our approach we use a Monte Carlo simulation allowing the galactic distances to vary randomly using their error bars. In particular, the simulations have been performed for randomly varying galaxy distance values with a Gaussian probability distribution (normal distribution) with mean equal to the measured distance and standard deviation equal

FIG. 8. The green line represents the σ -distances between the various Σ_1 and Σ_2 datasets as a function of the critical distances D_c as derived using the individual values of M_H^W . In contrast the yellow lines correspond to 68% (one standard deviation) range of the σ -distances as a function of the critical distances D_c produced by a Monte Carlo simulation of 100 sample datasets assuming artificial homogeneity of the M_H^W data. The simulations have been performed for randomly varying M_H^W values with a Gaussian probability distribution with mean $M_H^W = -6 \text{ mag}$ provided by the full M_H^W data-points and standard deviation equal to the corresponding 1σ error.

FIG. 9. The σ -distances as a function of the critical distances D_c for 100 sample datasets with random distance values, normally distributed inside their individual 1σ range as derived using the individual values of M_H^W . A transition of the σ -distance at $D_c \simeq 22 \text{ Mpc}$ remains present for practically all of the Monte Carlo samples.

to the corresponding 1σ error. In Fig. 9 we show the σ -distances as a function of the critical distances D_c for 100 sample datasets with random distance values, normally distributed inside their individual 1σ range as derived using the individual values of M_H^W . Clearly, the random variation of the galactic distances does not change the transition effect. The 68% (one standard deviation) range of the σ -distances as a function of the critical dis-

FIG. 10. The green lines represent the 68% range of the σ -distances as a function of the critical distances D_c produced by a Monte Carlo simulation of 100 sample datasets. The simulations have been performed for randomly varying galaxy distance values with a Gaussian probability distribution with mean equal to the measured distance and standard deviation equal to the corresponding 1σ error. In contrast the pink region correspond to a Monte Carlo simulation of 100 sample datasets assuming artificial homogeneity of the M_H^W data. In addition to this homogeneity the simulations have been performed for randomly varying galaxy distance values with a Gaussian probability distribution.

tances D_c produced by the Monte Carlo simulation of 100 sample datasets is shown in Fig. 10 with the green lines. Evidently, the Monte Carlo simulation demonstrates the robustness of the identified transition with respect to variation of galactic distances.

We now test if the effect would disappear in the context of homogenized Monte-Carlo Cepheid datasets. In Fig. 8, we examine if this obvious transition of this case could be due to a systematic uncertainty of the Cepheid absolute magnitude value. Thus, the yellow region corresponds to the 68% range of the σ -distances as a function of the critical distances D_c produced by a Monte Carlo simulation of 100 sample datasets assuming artificial homogeneity of the M_H^W data. The simulations have been performed by randomly varying the M_H^W values with a Gaussian probability distribution with mean $M_H^W = -6 \text{ mag}$ as obtained by the full dataset with a universal M_H^W and standard deviation of each global universal fit which is equal to the corresponding 1σ error. For this Monte Carlo uniformized data there is no transition. This demonstrates that the observed transition is due to the actual Cepheid data and not to the method we used. As expected the same result persists if in addition to homogenizing the sample with respect to M_H^W we also randomly vary the galactic distances as described above assuming a Gaussian distribution (pink region in Fig. 10). Thus the observed transition effect as illustrated in Figs. 8 and 10 is robust with respect to random variation of the galactic distances and disappears only if we artificially homogenize the data in the context of Monte

Carlo simulations.

III.3. Case III: Fitted individual M_H^W and a global R_W

In this case we assume a free to fit global parameter R_W and allow the value of the Cepheid absolute magnitude M_H^W to vary between galaxies. The results of fitting individual M_H^W to Cepheid data are illustrated in Fig. 11. The dotted line corresponds to $M_H^W = -5.90 \text{ mag}$ as derived using the individual parameters of anchor galaxies and M31 (due to its proximity) $M_{H,k}^W$ and minimizing $\chi^2(M_H^W)$ in Eq. (3.17) with respect to the M_H^W .

In this case we obtain the best fit value of the parameter $R_W = 0.310 \pm 0.021$ which is smaller than the global fixed value $R_W = 0.386$ used by Refs. [16, 18, 20]. We attribute this difference to the fact that we have used the full Cepheid sample for its determination and not just the anchor galaxies and we have not used a global value of the absolute magnitude M_H^W common for all Cepheids.

Using the same DSS method as in the two previous cases we find the best fit values of the $M_{H,bf}^W$ ($M_H^{W,<}$ and $M_H^{W,>}$) for various Σ_1 and Σ_2 datasets as a function of the critical distances D_c . As the previous cases the presence of a transition at a critical distance D_c in the range between 8 Mpc and 18 Mpc is obvious. For this range of D_c the best fit value of $M_H^{W,<} = -5.904 \pm 0.042 \text{ mag}$ differs from the best fit value of $M_H^{W,>} = -6.092 \pm 0.035 \text{ mag}$ at a level more than 4σ with $\Delta M_H^W \equiv M_H^{W,>} - M_H^{W,<} = -0.188 \pm 0.055 \text{ mag}$.

In this case, we do not plot here the result since it is very similar to that plotted in the figures of previous cases but are available in our publicly available numerical analysis files [161].

IV. MODEL SELECTION

As pointed out in the previous subsections where we study three cases (I, II, and III) both the Cepheid best fit absolute magnitude and color luminosity parameters indicate the presence of a transition effect at a critical distance D_c in the range between 8 Mpc and 18 Mpc (see Fig. 12). This transition however becomes apparent when additional parameters are introduced (the individual R_W or M_H^W for each galaxy). Thus the questions we address in this section is the following:

- Is the introduction of additional parameters favored by model selection criteria like the Akaike Information Criterion (AIC) [168] and the Bayesian Information Criterion (BIC) [169]?

Model	Best Fit Parameters (with 1σ ranges) $\sigma_{LMC} = 0.08$ ($\sigma_{LMC} = 0$)	Model Selection Criteria	Intrinsic scatter of LMC Cepheids	
			$\sigma_{LMC} = 0$	$\sigma_{LMC} = 0.08$

TABLE I. Fitting results and model comparison tests for different models. For the ΔAIC and ΔBIC the comparisons are made respect to base (base-SH0ES) models. The value of H_0 derived using the Eq. (5.1) (black font) and the Eq. (5.3) (green font). The best fit parameters of SnIa absolute magnitude M_B and the value of H_0 in the parentheses correspond to intrinsic scatter of LMC Cepheids $\sigma_{LMC} = 0$.

FIG. 11. Fitting individual M_H^W to Cepheid data with a free global R_W . Anchor galaxies are denoted with cyan points and SNIa host galaxies with magenta points. The dotted line corresponds to $M_H^W = -5.90 \text{ mag}$ as derived using the individual values of anchor galaxies and M31 (due to its proximity) $M_{H,k}^W$.

FIG. 12. The one dimensional relative probability density values of the color luminosity parameter and the Cepheid absolute magnitude as derived using the DSS method for the cases I, II, and III. All measurements are shown as normalized Gaussian distributions. Notice that the best fit values one for galaxies at distances $D < D_c$ and one for galaxies at $D > D_c$ are inconsistent with each other at a level larger than 3σ .

FIG. 13. The best fit values of the parameter R_W for base/base-SH0ES, I and IV models as derived using Cepheid data. Note that in terms of the AIC and BIC, fitting for two universal values of R_W with global M_H^W is the preferred model (case IV, green region).

ΔAIC			ΔBIC			
Level of empirical support for the model with the smaller AIC			Evidence against the model with the larger BIC			
0-2	4-7	> 10	0-2	2-6	6-10	> 10
Substantial	Strong	Very strong	Weak	Positive	Strong	Very strong

TABLE II. The interpretation of differences ΔAIC and ΔBIC according to the calibrated Jeffreys' scale [162] (see also Refs. [163–167]). However, it should be noted that the Jeffreys' scale has to be interpreted with care [164] because has been shown to lead to different qualitative conclusions.

- Could the introduction of a smaller number of parameters lead to more favored phenomenological models?

following⁷:

- **Base-SH0ES**: Like previous studies of SH0ES team we consider universality on the color-luminosity relation with a global fixed parameter

In order to address these questions we use model selection tests for eight cases with different number of free parameters. The additional five considered cases are the

⁷ Note that for all cases we fit other 27 additional parameters (see the schematic form of the matrix of parameters $\mathbf{X}$ in Appendix A)

FIG. 14. The best fit values of the parameter M_H^W for base/base-SH0ES, III and V models as derived using the Cepheid data. Note that in terms of the AIC and BIC, fitting for two universal values of M_H^W with global R_W is the preferred model among the models shown (case V, cyan region).

Ranking	AIC		BIC	
	$\sigma_{LMC} = 0$	$\sigma_{LMC} = 0.08$	$\sigma_{LMC} = 0$	$\sigma_{LMC} = 0.08$
1	I	I	IV	IV
2	IV	IV	Base	Base
3	VI	VI	VI	VI
4	Base	V	Base-SH0ES	V
5	V	Base	V	Base-SH0ES
6	Base-SH0ES	III	I	I
7	III	Base-SH0ES	II	III
8	II	II	III	II

TABLE III. Ranking of models according to AIC and BIC criteria. We see that in terms of the AIC and BIC fitting for two universal values of R_W with global M_H^W is the preferred model (case IV).

$R_W = 0.386$ [16, 18, 20] and universality on the absolute magnitude of Cepheids SnIa calibrators with a global M_H^W to be fit by the Cepheid data. Thus in this case we use the base, commonly used parameter set in the field.

- **Base:** We consider universality on the color-luminosity relation with a global parameter R_W

to be fit by data and universality on the absolute magnitude of Cepheids SnIa calibrators with global M_H^W .

- **IV:** We consider a global M_H^W and two universal R_W ($R_W^<$ for galaxies at distances $D < 16$ Mpc and $R_W^>$ for galaxies at distances $D > 16$ Mpc).
- **V:** We consider a global R_W and two universal M_H^W

FIG. 15. The ΔAIC and ΔBIC of models with different free parameter set compared to base (subindex 1) and base-SH0ES (subindex 2) models. Clearly, the case IV (two universal R_W and a global M_H^W) is the best model and on the other hand, the case II (a global R_W and individual M_H^W) is the worst one.

($M_H^{W,<}$ for galaxies at distances $D < 16 \text{ Mpc}$ and $M_H^{W,>}$ for galaxies at distances $D > 16 \text{ Mpc}$).

- **VI:** We consider two universal R_W ($R_W^{<}$ for galaxies at distances $D < 16 \text{ Mpc}$ and $R_W^{>}$ for galaxies at distances $D > 16 \text{ Mpc}$) and two universal M_H^W ($M_H^{W,<}$ for galaxies at distances $D < 16 \text{ Mpc}$ and $M_H^{W,>}$ for galaxies at distances $D > 16 \text{ Mpc}$).

In order to compare the models we construct Table I with the fitting parameters for all cases. The best fit values of the parameter R_W for base/base-SH0ES, I and IV models are shown in Fig. 13 and the best fit values of the parameter M_H^W for base/base-SH0ES, III and V models are shown in Fig. 14. Various methods for model selection have been developed and model comparison techniques used [163, 170–172]. In table I we show the value of the minimum χ^2 (χ_{min}^2) for all cases and the reduced chi-squared which is a very popular method for model comparison. This is defined by

$$\chi_{red}^2 = \frac{\chi_{min}^2}{dof} \quad (4.1)$$

where $dof = N - M$ is typically the number of degrees of freedom (with N is the number of datapoints used in

the fit and M is the number of free parameters) for each model.

We also use the model selection methods like Akaike Information Criterion (AIC) [168] and the Bayesian Information Criterion (BIC) [169] that penalize models with additional parameters. For a model with M parameters and a dataset with N total observations these are defined through the relations [163, 170, 171]

$$AIC = -2\ln\mathcal{L}_{max} + 2M = \chi_{min}^2 + 2M \quad (4.2)$$

$$BIC = -2\ln\mathcal{L}_{max} + M\ln N = \chi_{min}^2 + M\ln N \quad (4.3)$$

where $\mathcal{L}_{max} \equiv e^{-\chi_{min}^2/2}$ (e.g. [164, 173]) is the maximum likelihood of the model under consideration. Note that a version of the AIC corrected for small sample sizes is important [174, 175]. This version is given by [176] (see also Refs. [170, 177])

$$AIC_{cor} = AIC + \frac{2M(M+1)}{N-M-1} \quad (4.4)$$

For large samples as in our case ($N \gg M$) the correction term disappears but for small samples gives a more accurate answer.

FIG. 16. The one dimensional relative probability density value of SnIa absolute magnitude M_B for all cases studied in this paper compared to that obtained using CMB calibration. All measurements are shown as normalized Gaussian distributions. Clearly, for all cases where we do not consider the universality of parameters R_W and M_H^W (i.e. I, II, III, IV, V, VI) the M_B is consistent with the CMB determination value.

The results for each candidate model are shown in Table I and the "preferred model" is the one which minimizes AIC and BIC. The absolute values of the AIC and BIC are not informative. Only the relative values between different competing models are relevant. Hence when comparing one model versus the base/base-SH0ES we can use the model differences ΔAIC and ΔBIC .

The differences ΔAIC and ΔBIC with respect to the base/base-SH0ES model defined as

$$\Delta AIC = AIC_i - AIC_s = \Delta\chi_{min}^2 + 2\Delta M \quad (4.5)$$

$$\Delta BIC = BIC_i - BIC_s = \Delta\chi_{min}^2 + \Delta M(\ln N) \quad (4.6)$$

where the subindex i refers to value of AIC (BIC) for the model i and AIC_s (BIC_s) is the value of AIC (BIC) for the base/base-SH0ES model. The resulting ΔAIC and ΔBIC are shown in Table I and in Fig. 15. Note that a positive value of ΔAIC or ΔBIC means a preference for base/base-SH0ES model.

According to the calibrated Jeffreys' scales [162] showed in the Table II (see also Refs. [163–167]) a range $0 < |\Delta AIC| < 2$ means that the two comparable models have about the same support from the data, a range $4 < |\Delta AIC| < 7$ means this support is considerably less for the model with the larger AIC while for $|\Delta AIC| > 10$ the model with the larger AIC have no support i.e. the

model is practically irrelevant. Similarly, for two competing models a range $0 < |\Delta BIC| < 2$ is regarded as weak evidence, a range $2 < |\Delta BIC| < 6$ is regarded as positive evidence, while for $|\Delta BIC| > 6$ the evidence is strong against the model with the larger value.

Ranking of the models considered according to AIC and BIC criteria are presented in Table III. Clearly, in terms of the AIC and BIC, fitting for two universal values of R_W with global M_H^W is the preferred model (case IV). Base/base-SH0ES model is considerable less supported by data with respect to the IV model (ΔAIC) and there is a positive/very strong evidence against it (ΔBIC). We attribute the difference between ΔAIC and ΔBIC for the models considered to the fact that the BIC penalizes additional parameters more strongly than the AIC as inferred by the Eqs. (4.2) and (4.3) for the used dataset with $\ln N > 2$ (see Refs. [163, 171, 178]).

V. TRANSITION AS A POSSIBLE SOLUTION OF HUBBLE TENSION

In this section, we investigate whether the existence of transition of the Cepheid parameters can impact on the inferred value of Hubble constant H_0 and its corresponding uncertainties. Using the best fit values of SnIa

FIG. 17. The one dimensional relative probability density value of H_0 as derived using the Eq. (5.1) (solid lines) and the Eq. (5.3) (dashed lines) for all cases studied in this paper compared to that from the Planck CMB measurement (grey line). All measurements are shown as normalized Gaussian distributions. It is evident that for all cases where we break the assumption of universality of the parameters R_W and M_H^W (i.e. I, II, III, IV, V, VI) the derived values of H_0 are consistent with the corresponding predicted Planck CMB best fit value.

absolute magnitude M_B the Hubble constant is given by

$$H_0 = 10^{0.2M_B + \alpha_B + 5} \quad (5.1)$$

where the term α_B is the intercept of the SnIa magnitude-redshift relation defined as [18]

$$\alpha_B = \log \left[cz \left(1 + \frac{1}{2}(1 - q_0)z - \frac{1}{6}(1 - q_0 - 3q_0^2 + j_0)z^2 + \mathcal{O}(z^3) \right) \right] - 0.2m_B \quad (5.2)$$

where $q_0 \equiv -\frac{1}{H_0^2} \frac{d^2 a(t)}{dt^2} \Big|_{t=t_0}$ and $j_0 \equiv \frac{1}{H_0^3} \frac{d^3 a(t)}{dt^3} \Big|_{t=t_0}$ are the deceleration and jerk parameters respectively.

The intercept α_B using 217 observed SnIa at redshifts $0.023 < z < 0.15$ with the deceleration and jerk parameters set to $q_0 = -0.55$ and $j_0 = 1$ is determined to be $\alpha_B = 0.71273 \pm 0.00176$ by Ref. [18].

Alternatively, using the the best fit value of degenerate combination $\mathcal{M} = 23.803 \pm 0.007$ as derived by Ref. [57] for full Pantheon dataset in Eq. (2.5) the Hubble constant can be estimated

$$H_0 = c 10^{0.2(M_B - \mathcal{M}) + 5} \quad (5.3)$$

In Table I we show the best fit value of SnIa absolute magnitude M_B and the corresponding Hubble constant H_0 as derived using the Eq. (5.1) and the Eq. (5.3) (the values in the parentheses) for all cases studied in this paper. Also the one dimensional relative probability density values of M_B and H_0 as derived using the Eq. (5.1) and the Eq. (5.3) (the values in the parentheses of table I) compared to that from the Planck CMB measurement assuming flat Λ CDM are shown in Fig. 16 and Fig. 17 respectively.

Clearly, for all cases which break the assumption of universality of the parameters R_W and M_H^W (i.e. I, II, III, IV, V, VI) the best fit value of SnIa absolute magnitude M_B and the derived values of H_0 decrease and become consistent with the corresponding predicted CMB best fit values. For the preferred model (case IV) we obtain $H_0 = 68.06 \pm 1.80 \text{ km s}^{-1} \text{ Mpc}^{-1}$ with Planck tension $< 1\sigma$. Therefore the transition in the Cepheid calibrator parameters at $D_c \simeq 16 \text{ Mpc}$ can provide a resolution of the Hubble tension.

VI. CONCLUSION-DISCUSSION

In the present study we have used Cepheid SnIa calibrator data to investigate the effects of variation of

the Cepheid calibration empirical parameters. We have shown that models where such a variation is allowed are favored on the basis of model selection criteria AIC and BIC. The models that are consistently favored by both AIC and BIC involve a transition in either the color-luminosity parameter R_W or the Cepheid absolute magnitude M_H^W , at a distance in the range between 10 and 20 Mpc . In the context of a homogeneous Universe where the cosmological principle is respected this would be a transition in time between about 25 $Myrs$ and 70 $Myrs$ ago. Models involving a transition in R_W are slightly favored over models where there is a transition in M_H^W . Both classes of models, lead to values of H_0 that are consistent with the CMB inferred values thus eliminating the Hubble tension.

Such a transition of Cepheid parameters could be induced by a fundamental physics transition. The magnitude of the transition is consistent with the magnitude required for the resolution of the Hubble tension in the context of a fundamental gravitational transition occurring by a sudden increase of the strength of the gravitational interactions G_{eff} by about 10% [48] at a redshift $z_t \lesssim 0.01$ ($\lesssim 150$ million years). Such a transition would abruptly increase the SNIa absolute magnitude by $\Delta M_B \simeq 0.2$ [48, 55] (from $M_B = -19.401 \pm 0.027 mag$ for $z > z_t$ [54] to $M_B = -19.244 \pm 0.037 mag$ for $z < z_t$ [52, 53]). The distance range/timescale corresponding to this transition is consistent with a recent analysis indicating a similar transition in the context of the Tully-Fisher data [72].

An alternative origin of the observed effect is based on a scenario where the parameter R_W could vary across different sightlines and different galaxy distances, morphologies, environments and properties. Dust extinction differences between galaxies could be the origin for a systematic "mass step" (at $\sim 10^{10} M_\odot$) in the data [179, 180]: after standardization, SNIa in a high-mass galaxy appear brighter than those in a low-mass galaxy [76, 181–185]. Such an alternative scenario is testable using the methods presented here and it could also lead to a resolution of the Hubble tension. Such an extension is beyond the goals of the present analysis.

Other interesting extensions of the present analysis include the following:

- The search for transition in other parameters that can be constrained using the Cepheid data (for example the SNIa absolute magnitude M_B and its effect on the estimation of H_0).
- If the transition is physical and due to fundamental gravitational physics it would be interesting to search for possible constraints or remnants of such a transition in the solar system. For example what could be the relevance of such a transition on the observed increased rate of impactors on Earth and Moon by a factor of 2-3 during the past 290 Myrs [186] which may also be related with the Cretaceous–Paleogene (K-Pg) extinction event (also

known as the Cretaceous–Tertiary (K–T) extinction) (e.g. [187]) that eliminated several species on Earth about 66 Myrs ago [188] including dinosaurs (e.g. [189]). According to the impact hypothesis or Alvarez hypothesis [190, 191] this extinction event was caused by an asteroid impact producing the $\sim 200 km$ wide Chicxulub impact crater.

- It would be interesting to search for a similar transition in the other SNIa calibrator such as the Tip (a sharp discontinuity) of the Red Giant Branch (TRGB) in the Hertzsprung–Russell diagram [192]. The Red Giant stars have nearly exhausted the hydrogen in their cores and have just began helium burning by the triple- α process (helium flash phase). The brightness of TRGB stars can be standardized using DEBs combined with parallax calibration. They can serve as excellent alternative standard candles [193] visible in the local Universe for the subsequent calibration of SNIa [194–197] and thereby provide an independent determination of the Hubble constant H_0 [198, 199].

The indicated transition at a distance of about 10 – 20 Mpc could be interpreted as violating the cosmological principle according to which the distance of any galaxy from us should not impact its properties. The cosmological principle however is not necessarily violated in the transition models because a spatial transition can not be observationally distinguished from a temporal transition. If the transition is temporal and occurred at a specific time then there is no violation of the cosmological principle.

Even if the transition is spatial it could be interpreted as a result of a first order phase transition occurring very recently due to a decay of the false vacuum [200]. Then we could live in 20 Mpc true vacuum bubble where a first order scalar-tensor physics transition has occurred. If the bubble was created at recent cosmological times (e.g. last 100 $Myrs$) in the context of a decay of a false vacuum (see e.g. Ref. [200]) then we would not have been able to see the other true vacuum bubbles since light from them may not have reached us yet. Thus even in that case there would be no apparent large-scale violation of the cosmological principle. The phenomenology of such recent false vacuum decay in the context of scalar-tensor theories is another interesting extension of our analysis. In this context it may be shown that for a transition energy scale similar to the present Hubble constant the typical scale of the true vacuum bubbles produced would be 15 – 20 Mpc . Fine tuning questions also arise in the context of the indicated transition: 'What is special about the scale of 15 – 20 Mpc where the transition signal appears to exist?'. In the context of a false vacuum decay bubble there is no more fine tuning than in the Λ CDM. If we accept the scale of the cosmological constant and the fact that there is a first order phase transition to another vacuum of a similar energy scale ($\sim 0.002 eV$) then the predicted spatial scale of the produced bubbles is theo-

retically predicted to be about 15 Mpc . If we allow for some true vacuum bubble growth (they expand with the speed of light) it could increase to the scale of 20 Mpc . This generic result may be demonstrated as follows [200–203]: For a very recent false vacuum decay with vacuum energy comparable to the cosmological constant the scale of the produced bubbles is

$$R_b = \delta / H_0 \quad (6.1)$$

where δ depends logarithmically on the ratio of the Planck mass M_P to the transition temperature energy scale $T_c = 2.7^\circ \text{K} \simeq 2 \times 10^{-4} \text{eV}$ as [201]

$$\delta \simeq [4B_1 \ln(M_P/T_c)]^{-1} \quad (6.2)$$

where B_1 is a constant of $O(1)$. Using Eqs. (6.1) and (6.2) with $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$ we obtain $R_b \simeq 15 \text{ Mpc}$ which is clearly within the range of transition scales favored by the Cepheid data by the present analysis and by the Tully-Fisher data as indicated by Ref. [200, 202, 203].

In conclusion the revolutionary improvement in the quality and quantity of data from existing and upcoming missions/experiments raises the expectation of determining the origin of the existing transition effect shown in our analysis. One possible origin would be the presence of systematic errors affecting the adopted calibration method. Alternatively, if the source of the demonstrated transition is physical it could lead to new cosmological physics beyond the standard model which

may include a very recent false vacuum decay.

Appendix A: MATRICES OF SYSTEM OF EQUATIONS

In this Appendix we present the schematic form of the error matrix $\mathbf{C}$, the matrix of measurements $\mathbf{Y}$, the matrix of parameters $\mathbf{X}$ and the equation (or design) matrix $\mathbf{A}$ used in the system of equations of our analysis (see Eqs. (3.8), (3.9), (3.10) and (3.11) in Section III).

The schematic form of the error matrix $\mathbf{C}$ is

$$\mathbf{C} = \begin{pmatrix} \sigma_{MW,j}^2 & 0 & \dots & & & 0 \\ 0 & \sigma_{tot,j}^2 & 0 & \dots & & \vdots \\ 0 & 0 & \sigma_{LMC,j}^2 & 0 & \dots & \vdots \\ \vdots & & & \ddots & & \\ & & & & \sigma^2(\mu_{N4258}) & \\ & & & & & \sigma^2(\mu_{LMC}) \\ & & & & & & \sigma^2(m_{B,1}) \\ & & & & & & & \ddots \\ 0 & & & & & & & & \sigma^2(m_{B,19}) \end{pmatrix} \quad (A1)$$

where $\sigma(\mu_{LMC}) = 0.0263$ is the error of the distance modulus to the LMC reported by Ref. [104], $\sigma(\mu_{N4258}) = 0.032$ is the error of the distance modulus to the NGC 4258 reported by Ref. [107] and $\sigma(m_{B,k})$ ($k = 1, \dots, 19$) are the errors of SnIa B-band magnitudes obtained from Table 5 in Ref. [18] (see our Table VII of the Appendix B).

For MW j th Cepheid we use a total statistical uncertainty arising from the quadrature sum of four terms (higher order terms $\mathcal{O}(zp/\pi_j)^2$ are negligible)

$$\sigma_{MW,j}^2 = \sigma^2(m_{H,j}) + \left(\frac{5}{\ln 10} \frac{1}{\pi_j} \right)^2 \sigma^2(\pi_j) + R_W^2 \sigma^2(V_j) + R_W^2 \sigma^2(I_j) \quad (A2)$$

and for LMC Cepheids we use a total statistical uncertainty arising from the quadrature sum of four terms:

$$\sigma_{LMC,j}^2 = \sigma^2(m_{H,j}) + \sigma^2(\mu) + R_W^2 \sigma^2(V_j) + R_W^2 \sigma^2(I_j) \quad (A3)$$

We see that for the MW and LMC Cepheids where the color errors are provided by SH0ES team (see in Table 1 of Ref. [20] and in Table 2 of Ref. [16] or our Table IV and our Table V of the Appendix B respectively) we have included them in the error matrix $\mathbf{C}$ in the proper 2D manner (i.e. 2D fit including errors in both $\mathbf{Y}$ and $\mathbf{X}$ "axes").

For the j th Cepheid in the i th galaxy (other than MW and LMC) where SH0ES does not provide separate color errors we use a total statistical uncertainty σ_{tot} arising from the quadrature sum of four terms: NIR photometric error, color error, intrinsic width and random-phase as derived by SH0ES team and shown in column 8 of Table 4 of Ref. [18]

$$\sigma_{tot,j}^2 = \sigma_{sky}^2 + \sigma_{col}^2 + \sigma_{int}^2 + (f_{pf}\sigma_{ph})^2 \quad (\text{A4})$$

These total statistical uncertainties σ_{tot} are shown in our Table VI of the Appendix B. Note that even though the color errors are included implicitly in our fit, in order to make a full 2D fit we will need the separate color errors which are not publicly available for these Cepheids by SH0ES team.

The schematic form of the matrix of measurements $\mathbf{Y}$ and the matrix of parameters $\mathbf{X}$ are

$$\mathbf{Y} = \begin{pmatrix} m_{\pi,j} \\ m_{H,1,j} \\ \vdots \\ m_{H,19,j} \\ m_{H,N4258,j} \\ m_{H,M31,j} \\ m_{H,LMC,j} \\ \mu_{N4258} \\ \mu_{LMC} \\ m_{B,1} \\ \vdots \\ m_{B,19} \end{pmatrix}, \quad \mathbf{X} = \begin{pmatrix} R_{W,LMC} \\ R_{W,MW} \\ R_{W,1} \\ \vdots \\ R_{W,19} \\ R_{W,N4258} \\ R_{W,M31} \\ \mu_1 \\ \vdots \\ \mu_{19} \\ \mu_{N4258} \\ \mu_{M31} \\ \mu_{LMC} \\ M_{H,MW}^W \\ M_{H,1}^W \\ \vdots \\ M_{H,19}^W \\ M_{H,N4258}^W \\ M_{H,M31}^W \\ M_{H,LMC}^W \\ b_W^s \\ b_W^l \\ Z_W \\ zp \\ M_B \end{pmatrix} \quad (\text{A5})$$

The schematic form of the equation (or design) matrix $\mathbf{A}$ is

$$\mathbf{A} = \begin{pmatrix} 0 & (V-I)_{MW,1} & 0 & \cdot & \cdot & 0 \dots & 10 \dots & [P]_{MW,1}^s & [P]_{MW,1}^l & [M/H]_1 & \frac{-5\pi_1}{\ln 10} & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & (V-I)_{MW,N} & 0 & \cdot & \cdot & 0 \dots & 10 \dots & [P]_{MW,N}^s & [P]_{MW,N}^l & [M/H]_{19} & \frac{-5\pi_N}{\ln 10} & 0 \\ 0 & 0 & (V-I)_{1,1} & 0 & \dots & 10 \dots & 010 \dots & [P]_{1,1}^s & [P]_{1,1}^l & [M/H]_{1,1} & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & (V-I)_{1,N} & 0 & \dots & 10 \dots & 010 \dots & [P]_{1,N}^s & [P]_{1,N}^l & [M/H]_{1,N} & 0 & 0 \\ 0 & 0 & 0 & (V-I)_{2,1} & 0 \dots & 010 \dots & 0010 \dots & [P]_{2,1}^s & [P]_{2,1}^l & [M/H]_{2,1} & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & (V-I)_{2,N} & 0 \dots & 010 \dots & 0010 \dots & [P]_{2,N}^s & [P]_{2,N}^l & [M/H]_{2,N} & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdot & \cdot & (V-I)_{M31,1} & 0 \dots & 10 & [P]_{M31,1}^s & [M/H]_{M31,1} & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdot & \cdot & (V-I)_{M31,N} & 0 \dots & 10 & [P]_{M31,N}^s & [M/H]_{M31,N} & 0 & 0 \\ (V-I)_{LMC,1} & 0 & 0 & \cdot & \cdot & \cdot & 0 \dots & 01 & [P]_{LMC,1}^s & [M/H]_{LMC,1} & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ (V-I)_{LMC,N} & 0 & 0 & \cdot & \cdot & \cdot & 0 \dots & 01 & [P]_{LMC,N}^s & [M/H]_{LMC,N} & 0 & 0 \\ 0 & \cdot & \cdot & \cdot & \cdot & 0 \dots & 1000 \dots & \cdot & \cdot & \cdot & \cdot & 1 \\ 0 & \cdot & \cdot & \cdot & \cdot & 0 \dots & 0010 \dots & \cdot & \cdot & \cdot & \cdot & 1 \\ 0 & \cdot & \cdot & \cdot & \cdot & 10 \dots & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ 0 & \cdot & \cdot & \cdot & \cdot & 010 \dots & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & \cdot & \cdot & \cdot & \cdot & 0 \dots & 100 \dots & \cdot & \cdot & \cdot & \cdot & 1 \end{pmatrix}$$
