Abstract

Multi-party random number generation is a key building-block in many practical protocols. While straightforward to solve when all parties are trusted to behave correctly, the problem becomes much more difficult in the presence of faults. In this context, this paper presents RandSolomon, a protocol that allows a network of $N$ processes to produce an unpredictable common random number among the non-faulty of them. We provide optimal resilience for partially-synchronous systems where $\lfloor \frac{N-1}{3} \rfloor$ of the participants might behave arbitrarily and, contrary to many solutions, we do not require at any point faulty-processes to be responsive.

1 Introduction and Motivation

In a Byzantine fault-tolerant random number generator (BFT-RNG) system, the participating processes are able to agree on a single random number which cannot be manipulated nor have its generation halted despite the presence of Byzantine processes. A process is said to be Byzantine if it can arbitrarily deviate from the prescribed algorithm. Examples of byzantine faults are commission and omission failures [18]. Intuitively, a commission fault exists when a process sends messages a correct process would not send, whereas an omission fault exists when a process does not send messages a correct process would send.

Existing distributed random generator protocols can have their algorithms divided into three phases:
1. **Generation and Commitment Phase** - each process generates some locally random data and then publicly commits to this value without revealing it.

2. **Reveal Phase** - the values previously committed are revealed.

3. **Result Computation Phase** - using the values revealed, the processes can decide on the resulting random number.

A problem which is closely related to **BFT-RNG** is that of Byzantine fault-tolerant **Consensus**. This is a fundamental problem in distributed computing where a set of processes interact by proposing each of them a value. In the end, these processes have to agree upon one of the inputs despite some of the participants being Byzantine. More formally it is a problem where the following conditions are met:

- **Termination**: eventually every correct process outputs a value;
- **Agreement**: every correct process outputs the same value;
- **Validity**: every value of the output was previously input by some process in the system.

The No-dealer paper [21] showed an important relationship between **BFT-RNG** and the **Consensus** problem, where the reliability of a **BFT-RNG** algorithm, i.e. the number of faulty process it tolerates, cannot surpass that of a consensus algorithm in the same system. This allows us to derive loose bounds on how many faults can possibly be tolerated given the different synchrony assumptions imposed on the system (as these bounds are well known for **Consensus**):

- **Asynchronous** In this kind of systems the time a message takes to arrive in a destination after being sent is unbounded. In this scenario it is impossible to have a **BFT-RNG** if at least one process might fail as this is the case for **Consensus** [15].

- **Synchronous** In these systems there exists a known amount of time $T$ such that every message takes less than $T$ units of time to arrive. With this condition, it is possible to solve **Consensus** with at least one correct process [28], meaning that the most resilient **BFT-RNG** in this scenario could tolerate $f \leq N - 1$ faults. In Appendix A we prove this to be a tight bound for **BFT-RNG** $f = N - 1$.

- **Partially Synchronous** Another less constraining synchrony assumption for a system is to assume that there exists an unknown amount of time after the system has started, known as the Global Stabilisation Time (GST), after which all the messages arrive i.e. that all messages are eventually delivered within an unknown upper-bound $\tau$ of time after they have been sent. The resilience bound for **Consensus** in this case is $\lfloor \frac{N - 1}{3} \rfloor$ [14], which we also show to be tight for **BFT-RNG** by presenting **RandSolomon**.

**Our contribution.** We present for the first time, to our knowledge, a **BFT-RNG** protocol capable of being executed in a partially-synchronous system of $N$ processes where at most \(\lfloor \frac{N - 1}{3} \rfloor\) of them are fully Byzantine, i.e. displaying arbitrary behaviour at any point of the execution. Moreover, we also show that the resilience bound for a **BFT-RNG** protocol for a given synchrony assumption are exactly the same as a consensus protocol.

**Related Work.** When designing a **BFT-RNG** algorithm there are two main challenges: (i) how to manage the access to data, so to prevent Byzantine processes from accessing the result beforehand in the **generation and commitment phase** while preventing them to halt the protocol by omitting; and (ii) how to compute correct results despite the Byzantine processes displaying commission faults. Existing protocols solve the first challenge by using techniques such as secret sharing [33], verifiable delay functions [11], threshold signatures [3][15], and fully homomorphic encryption [16] and the second by requiring a verifiable proof that a shared data was generated correctly.
Techniques. A \((t,n)\)-secret sharing [33] scheme allows a process during the generation and commitment phase to share a secret \(s\) with \(n\) other processes where any subset of size \(t\) among them might retrieve the original secret \(s\). In this way, even if a process refuses to disclose the original secret it has committed, the correct processes present in the system can still reconstruct it in the reveal phase by using the shares they were provided. Moreover, the values cannot be accessed too early as the number of shares held by the Byzantine processes does not surpass \(t\). It is also often useful in these systems to use multi-signature schemes or threshold signature schemes, such as Schnorr [3] or BLS [5] to indicate that a number of processes surpassing the threshold defined in the system agree with a certain value.

Another way to allow processes to commit to a value without revealing it beforehand and provide a manner to retrieve commitments from Byzantine agents is by using delay functions [4]. This technique guarantees that Byzantine processes cannot access the information shared by the correct processes fast enough to change their inputs accordingly, even if they use techniques of parallel computing. On the other hand, once a stipulated delay has expired, the correct processes can access the information presented by any process guaranteeing that the protocol is not halted.

The two homomorphic structures of most interest for BFT-RNG are Fully Homomorphic Encryption (FHE) [16] and homomorphic hashes. Given two sets \(A\) and \(B\), a map \(f : A \rightarrow B\) is said to be homomorphic if it preserves an existing operation \(\circ\) on both sets: \(\forall x,y \in A, f(x \circ y) = f(x) \circ f(y)\) [7]. FHE allows processes to make operations in ciphertexts without knowing the plaintexts and can be then used instead of secret sharing for solving the same problem of preventing misbehaving parties from accessing data too early on and denying the access of correct participants to the data when it must be shared. As for homomorphic hashes, they are, as the name indicates, hash functions with homomorphic properties (i.e. by performing some operations over some data and their associated hashes, one obtains a result and a consistent associated hash). Homomorphic hashes allow to solve the second challenge of BFT-RNG design: they provide a mean to check that an operation was correctly executed by observing the hashes of the inputs and the hash of the outputs and can therefore contribute in detecting commission failures.

Other kinds of proofs of well formed data include Verifiable Random Functions (VRF) and Public Verifiable Secret Sharing (PVSS). VRF [25] are functions that once provided with an input \(x\), output both a random number \(y\) and a proof \(\pi\) that allows any process using \(\pi\) to verify whether \(y\) was generated using \(x\) or not. Algorand’s VRF [17] uses a common coin (generated by the Algorand consensus) to correctly generate verifiable random numbers. PVSS-based proof [32] exchange together with secret shares some additional information that prove the data integrity without revealing any information of the original secret.

Protocols. In Table 1, which is a modified and expanded version of the table given in [31], we present a comparison including several existing BFT-RNG algorithms and the solution we present in this paper: RandSolomon. In some of these protocols, the networks (with \(N\) nodes) are partitioned into clusters of size \(c\) and, thus, this parameter appear in some of the complexity metrics given in the table. Additionally, \(f\) refers to the number of Byzantine processes in the system.

Synchrony. The second column of the comparison table shows which kind of synchrony the underlying system must provide in order to allow the deployment of each protocol. The algorithms are grouped by this column.

Vulnerability. It might seem impossible to have asynchronous implementations of BFT-RNG as we have already stated that this problem is impossible in the presence of at least one Byzantine participant in asynchronous systems. Notice, however, that one might introduce

Table 1 Comparison of distributed RNG solutions

additional assumptions on the failure model for these solutions to exist.

This is the case for Cachin’s solution which assumes that there exists a special process capable of generating and distributing a key. Other asynchronous solutions mentioned, as RandShare, RandHound and RandHerd, assume that all entities initially publish an information about their secret.

All these asynchronous protocols are not fully BFT, as an adversary might execute a Denial of Service attack on just one process halting the protocol. RandShare proposes a timeout to deal with this scenario, which would actually make their system synchronous. This assumption that Byzantine processes will not omit during the commitment phase of the protocol is also an exploitable vulnerability in the synchronous protocol Hyrand, although it can be modified to restart once there are missing contributions.

In case of Nguyen, a synchronous protocol, there must also be a trusted entity generating FHE keys, which can be considered as a client using the system, or a Requester.

Termination. Some protocols will always terminate in every execution, being labelled as having Deterministic termination, while others have a probability of not producing a result. In the case of RandHound, RandHerd and Dfinity protocols there is a probability corresponding to the event of a Byzantine adversary managing to fully corrupt a cluster, which depends on the parameters of the system, where the protocol halts before its termination. In the case of Algorand a failure happens when the set of nodes chosen to be proposers, with expected cardinality $c$, is empty. As for Nguyen’s protocol this happens if all selected contributors are Byzantine.

Complexity. Communication complexity corresponds to the amount of data exchanged and can be loosely translated into how many bits must be sent in the network for producing a result, while Computation Complexity measures how much time would it take to make the local computations given an input. The entry high was used to describe the complexity of delay functions, which is independent of the number of processes in the system (strictly meaning that their complexity is $O(1)$), but are very computationally heavy by design.

The No-Dealer algorithm specifies that the protocol must be restarted in case Byzantine processes produce some faults, but does not include this fact in its complexity. As there are at most $\frac{N}{2}$ Byzantine nodes, it might be necessary to restart an equal amount of times,
increasing their claimed complexity to the one presented in the table.

In Nguyen’s solution, despite claiming a constant time computation time, there is a summation on the secrets shared by the contributors and, as such, the computation complexity of the protocol is in fact linear in the number of contributors.

Finally, the two last columns Resilience and Techniques show how many Byzantine processes can be tolerated among the $N$ participants and the main techniques employed in each solution.

**Our protocol.** RandSolomon is the first BFT-RNG protocol providing deterministic termination in a partially asynchronous system with $f < \frac{N}{3}$. Interestingly, the protocol relies only on standard cryptographic primitives: a public key infrastructure [20], block erasure correcting codes which can be interpreted as our version of secret-sharing [24] and standard digital signatures. We have some similarities with SCRAPE with respect to our coding approach, but not only do we provide a partially synchronous solution in RandSolomon, we also introduce a new technique to cope with Byzantine commission failures: retraceability. In a nutshell, we consider the secrets produced by Byzantine processes without checking their integrity until the point where we need to compute the result in the last phase of the protocol. At this moment we can retrace all the steps that should have been taken and detect a commission failure. This then results in discarding incorrectly formed data in order to ensure correct result, among the non byzantine processes.

## 2 Formal system model and properties

Before turning to the RandSolomon protocol description, let us first duly formalise the system model as well as a set of properties that a protocol must have to be considered a distributed Byzantine fault-tolerant random number generator.

Our system is made up of $N$ nodes which run our protocol as a process which executes a prescribed sequence of steps. Among the participants, a portion $f < \frac{N}{3}$ of them might be Byzantine.

The nodes can communicate with each other via messages that are sent through a network. This network is available for all running processes and guarantees that if a message is sent through a channel, then it must be eventually delivered (in agreement with the partial-synchrony assumption).

Also, when a correct processes wishes to broadcast an information for the system, it does so by making means of a Reliable Broadcast [6] primitive. Thanks to this, Byzantine processes cannot stop the spread of information in the system. We now build on this to define the following broadcast primitive.

**Byzantine Reliable Broadcast.**

- **Validity** If $p_s$ is non-faulty and broadcasts $M$ in a byzantine reliably way then eventually some non-faulty process $p_i$ receives $M$.
- **Integrity** If a non-faulty $p_i$ receives $M$ with correct sender $p_s$, then $p_s$ previously broadcast $M$ in a byzantine reliably way.
- **Agreement** If a non-faulty process $p_i$ delivers $M$, then eventually every non-faulty process $p_j$ delivers $M$.

In this setup, any protocol having the following properties is a BFT-RNG:

- **Agreement** Every correct process decides on the same random number;
Unpredictability Prior to the end of the commitment phase, the execution of the protocol that generates $RAND$ as a random number is indistinguishable for all processes from all other executions where they decide a number $RAND' \neq RAND$;

Randomness The values decided by correct processes on independent runs of the protocol follow a uniform distribution;

Termination Eventually, every correct process decides on a value.

3 The RandSolomon protocol

Overview. From a high level viewpoint, what the protocol does is to aggregate enough locally generated random numbers such that at least one of them is truly random and the final result observes all the properties searched. Numbers are produced locally, then encoded using an erasure correcting code and encrypted before sharing. All non-Byzantine processes agree on which numbers should be used by solving consensus, while the result remains secret (sealed under an encryption layer) as no process holds all the information necessary for computing it prior to the reveal phase. The protocol cannot be stopped by the $f$ (or less) Byzantine adversaries, as prior to the consensus the progress of correct processes depends solely on themselves and after it, thanks to our use of the erasure correcting code, the correct processes can retrieve data without using the information held by their Byzantine counterparts.

Notation. We shall use $[N] = \{1, 2, \cdots, N\}$, $(\cdot)_i$ to indicate that the value enclosed by the parenthesis contains a signature of process $p_i$ and $\{\cdot\}_i$ to indicate that the value enclosed by the curly brackets was encrypted using $p_i$’s public key. Furthermore, $b$ will denote the number of symbols in the encoded value to be encrypted in a given encryption key; $z$ the size of the symbols used in a code; $t$ is the number of symbols an arbitrary code can correct; $l$ is the length of a code; $d$ the number of data symbols in a code.

3.1 Primitives

The system needs a deterministic encryption infrastructure where every process knows the public key of every other processes in the system, but each of them maintains its private key secret. Deterministic means that at any time if two processes encrypt the same number using the same key, then they get the same result [2].

Although the use of deterministic encryption is crucial for the correct execution of the protocol, these primitives are used only to encrypt long-enough (at least 256 bits) sequences of uniformly random bits. As such, the source of randomness in the cleartext themselves mitigates the usual issues which crop up when using deterministic encryption [27].

In order to ensure that each correct processes disposes of the same information, it is necessary to solve consensus. Thus, any partially-synchronous algorithm that tolerates $f$ byzantine failures among $3f + 1$ processes can be used, such as [8], [37] or [13]. This consensus component has an external consensus validity [10] where a proposed value $v$ is valid if it satisfies the predefined predicate denoted valid$(v)$. Values that do not verify it are discarded.

Definition 1 (Predicate valid). valid$(v)$ is true iff $v$ contains $f + 1$ signatures corresponding to $f + 1$ different processes.

Finally, let us consider a different perspective on secret sharing mechanisms [33]. In a classical Shamir secret-sharing protocol, when a dealer shares a secret $s$ with $N$ processes $p_1, p_2, \cdots, p_N$ using a threshold of $N - t$, it sends the shares $s_1, s_2, \cdots, s_N$ to their respective
processes. Out of these $N$ shares, only $N - t$ of them are necessary to retrieve $s$ and less than $N - t$ reveals nothing on the secret in question. Indeed, one could consider the string $s_1s_2\cdots s_N$ as a code, the non-received values as erasures and hence conclude that, in fact, the secret sharing scheme can be also analysed as an Erasure Correcting Code capable of correcting $t$ erasures \[24\].

In Information Theory, the number of substitutions required to change one string into another is known as Hamming Distance \[23\]. We can then conclude that we need in fact an Erasure Correcting Code with Hamming distance at least $t + 1$. The class of error-erasure correcting codes known as Reed-Solomon (RS) with the required distance is capable of correcting $t$ erasures (notice we do not treat it as an error corrector code, but an erasure corrector\[1\]). This means this class provides optimal block size known as Singleton Bound \[34\]. From a more pragmatic viewpoint, Reed-Solomon codes have free library implementations in many programming languages, they have deterministic parameters and encoding which are ideal for our requirements. Furthermore, most applications running our protocol will have relatively small block sizes and one can enhance the performances through hardware implementations \[20\]. It should be noted however, that any code complying with the following Abstract Code requirements can be used in our protocol.

**Abstract Code.**
- Be a block code\[2\]
- Have a code-word of size $b \times N$ symbols;
- Be able to correct up to $b \times f$ symbols erasures;
- $b \times z \geq 256$

Considering that we make use of Reed-Solomon codes we briefly present their general parameters:

**Abstract Reed-Solomon code**
- The symbols have size $z$-bits
- The data has length $d$ symbols
- The code-word has length $l$ where $l \leq 2^t - 1$ symbols
- It can correct up to $t$ erasures where, $t = l - d$

Adjusting the above Abstract RS code to match the Abstract code and the system requirements, leads to the following Concrete Reed-Solomon Code which is suitable for implementing our protocol.

**Concrete Reed-Solomon code**
- The symbols have size $z$-bits;
- Each block to be encrypted has a size $b$ of at least $\frac{256}{2}$ symbols;
- The data has a length of $b(\text{N} - f)$-symbols;
- The code-word has a length of $b \times N$ symbols.

It should be noted that because our protocol allows correct processes to retrace the execution followed by Byzantine processes and detect when they generate incorrect messages, we can use erasure correction instead of error correction. This drastically improves the coding

---

1. An error correcting code is capable of correcting a string with corrupted data placed in unknown locations, while an erasure correcting code needs to know the positions of the string which were corrupted.

2. Block codes are memoryless, i.e. the encoding of a block only depends on the contents of the block itself. This is opposed to a convolutional code, for example, where the result also depends on data contained on previous encodings.
performance as every error-erasure correcting code can correct twice more erasures than errors. This has two impacts on our protocol: first we need less parity bits; second, if we were to unnecessarily use the code for errors correction, the protocol would only tolerate up to \( \lceil \frac{N - 1}{4} \rceil \) Byzantine processes. The reason for the potential lost of resilience comes from the fact that we would need to correct \( 2f \) errors: \( f \) errors introduced by the Byzantine member during the generation and more \( f \) for the missing blocks due to asynchrony. Therefore the number of parity blocks would have to be at least \( 2(2f) = 4f \) blocks, while the code must have length \( N \) blocks. Because the length of a code is larger than the number of parity symbols, \( N > 4f \). This illustrates the contribution of retraceability: it implies simpler data reception by eliminating the need to generate proofs and to check them, and guarantees better resilience whilst maintaining the correctness of the protocol.

3.2 Algorithm

Generation and commitment. Each process \( p_i \) taking part in the protocol begins by initialising its variables (lines 1-3). Then, it generates a random number \( r_i \) of \( b(2f + 1) \) symbols and encode it using a Reed-Solomon encoder complying with the specification given in subsection 3.1 obtaining a number \( s_i \) of \( b(3f + 1) \) symbols (lines 4-5). This encoded number \( s_i \) is then split in \( N \) blocks of \( b \) symbols and each of these blocks are encrypted using the public key of the different processes in the system in order, signing the final result and obtaining the variable \( s_i \) (line 6).

Each process \( p_i \) share their \( s_i \) (line 7) and collect \( f + 1 \) numbers of this type, coming from \( f + 1 \) distinct processes according to their signatures. With this set of \( f + 1 \)-numbers they can engage in consensus and learn the same set, say \( \text{RNL} \), of \( (f + 1) \) numbers generated by \( f + 1 \) distinct processes (line 9).

Reveal. After obtaining the \( \text{RNL} \) set, each process can decrypt the blocks it is responsible for (line 11) and reveal them to the system via a Byzantine Reliable Broadcast (line 13). The processes gather the shares necessary for decoding the erasure correcting code, making sure that they truly are the decrypted versions of the \( \text{RNL} \) shares (line 15).

Result computation. Once a process has gathered at least \( N - f \) shares of each of the numbers in the \( \text{RNL} \) set, it can reconstruct all of them (line 17). If the decoded version \( \tilde{r}_j \) of a \( \text{RNL} \) number is again encoded and encrypted, leading to the same value for \( s_j \), then this implies that any \( N - f \) shares obtained by any correct process will give the same \( \tilde{r}_j \) making it consistent to be used in the final step computations.

Importance of verification Notice that if \( p_i \) is Byzantine, then it can generate a number \( r_i \) and insert \( f \) blocks with errors in \( s_i \). By colluding with other Byzantine processes in the system, a correct process \( p_j \) might get no response from \( f \) Byzatines and get these \( f \) erroneous blocks, essentially receiving a number with \( 2f \) incorrect blocks, which leads it to decode a number \( \tilde{r}_j \neq r_i \). Meanwhile a process \( p_k \) can get the Byzantine processes correct shares and not these blocks with errors, decoding \( \tilde{r}_k = r_i \), which would lead these two different correct processes producing two different random numbers in the end. This attack is nullified by the simple verification done in the line 18 and setting this number produced by a Byzantine process to 0, which is done by every process. It should be noted that because at least \( f + 1 \) numbers are used and that there are at most \( f \) Byzantines, at least one number will not be nullified.

Decision Finally the correct processes will hold the same decoded versions of the \( \text{RNL} \) numbers which are well formed and can produce the same final random number by taking an
Each function is entirely executed before executing the next

### 3.3 Execution example

We present now an example of a possible execution of our protocol with one Byzantine process and four processes in total illustrated in \textbf{Figure 2}. For pedagogical reasons we assume that the symbols have 8-bits and that each block to be encrypted contains 1 symbol \( (b = 1, z = 8) \), relaxing the requirement that \( b \times z \geq 256 \).
**RandSolomon:** optimally resilient multi-party random number generation protocol

**Figure 2** Example of a RandSolomon execution with one Byzantine process among a system of 4 processes.
The beginning of the protocol and the Generation and Commitment Phase, corresponding to lines from lines 1 to 6 of the algorithm is shown in Figure 2a. The correct processes $p_1, p_2$ and $p_3$ produce each a 3 bytes random number, correctly encoding into a 4 bytes reed-solomon codeword. The values $s_1, s_2, s_3$ ready to be shared are obtained by encrypting each of the 4 bytes from the codewords with the public keys of the $p_1, p_2, p_3$ and $p_4$, respectively. On the other hand, process $p_4$, who is Byzantine, maliciously produces two bad values: $s'_4$ with an error in its third byte and $s''_4$ with an error on its second byte.

Figure 2b then shows lines 7 and 8 where processes share their produced values and collect values coming from other processes. Notice that contrary to correct processes, Byzantine processes might send different values to different destinations.

Once each process has gathered two different values they propose what they know to the consensus component (line 9 and Figure 2c). Nothing prevents the Byzantine process $p_4$ of making more than one proposal to consensus, but any proposal which is not composed by $f+1$ signatures is discarded. Once the consensus algorithm terminates, any valid value might be returned, but all processes will get the same result (decided value equal to $s_1$ and $s'_4$).

The Reveal Phase illustrated in Figure 2d then begins, comprising lines 10 to 15. At this point processes openly share the symbols that were previously encrypted in their public keys. One deviation Byzantine processes might do is to send wrong numbers, but because of the deterministic encryption, the receiver can detect it by asserting that the encrypted version does not match the plain value received and discard it. Moreover, even if the Byzantine process does not send its share to every participant it does not matter, as $2f+1$ shares are available nonetheless.

Once processes gather $2f+1$ shares for each of the numbers agreed upon in consensus they can start the Result Computation Phase executing lines 16 to 19. Figure 2e shows how they first obtain the decoded version of the numbers and then redo both the reed solomon encoding and the encryption of the blocks to check that they correspond to the value decided in consensus. At this point they discard the value generated by $p_4$ nullifying its contribution and computing the final random number by XORing the other values (in this case just one) as shown in Figure 2f.

4 Formal analysis of the protocol

4.1 Correctness

This section is devoted to the proof that RandSolomon is a correct partially-synchronous BFT-RNG. We do so by showing that the protocol satisfies the set of properties stated in Section 2.

\[\text{Proposition 1. RandSolomon achieves Agreement.}\]

Proof. Because of the $(f+1)$-set consensus, every correct process has the same RNL set. Correct processes then use shares that have been verified and match the values agreed upon (line 15), allowing them to only access the original values generated in line 5.

If a RNL number $s_j$ passes the test in line 18 any $N-f$ correctly decrypted shares of this number shall yield the same number, as the encoded value contains no errors. It follows that every correct process will only use correctly decrypted shares and every correct process will hold the same number $\tilde{r}_j$ which will pass the test by our hypothesis.
If, however, this RNL number \( s_j \) does not pass the test, then there is an error in its encoding, as the test is merely checking if it was correctly done, and it will be visible to all correct processes in the system which will all proceed to ignore this number.

Therefore all \( RAND_i \) are equal, as they are formed by XORing all valid RNL numbers which every correct process agrees upon.

\[ \text{Proposition 2.} \quad \text{RandSolomon achieves Unpredictability.} \]

**Proof.** A process cannot distinguish between two encrypted values if it does not have the decryption key of, supposing it has limited computation power or less than \( N - f \) shares of a Reed-Solomon encoded number.

If Byzantine processes collude and share each others values before the different processes agree on which \( f+1 \) values at the end of the generation phase will compose the final result, they will know at most \( f \) full values. They will also possess \( f \) shares of the remaining chosen value but it is impossible for them to get the additional \( f+1 \) shares to reach the threshold of \( 2f+1 \) shares prior to correct processes entering the reveal phase and sending them this information.

As at least one of the numbers in the final XOR is truly random, the unpredictability of at least one of the RNL numbers makes the protocol trace (intermediate and final results) indistinguishable between different runs prior to correct processes entering the reveal phase.

\[ \text{Proposition 3.} \quad \text{RandSolomon achieves Randomness.} \]

**Proof.** By hypothesis, correct processes are capable of generating uniformly random numbers. The result of XORing a uniformly distributed random variable \( X \) in \( D \) with a constant \( c \) in \( D \) is a uniformly distributed random variable in \( D \). Also, the result of XORing two independent uniformly distributed variables \( X \) and \( Y \) over \( D \) is uniformly distributed.

\[ \text{Proposition 4.} \quad \text{RandSolomon achieves Termination.} \]

**Proof.** Every correct process generates their random numbers and propose a set of \( f+1 \) of them to the \((f+1)\)-set consensus component. This means that there will be at least \( N - f \) processes engaging in it, and because it can tolerate up to \( f \) failures, it will eventually give all correct processes their RNL sets.

Once \( N - f \) correct processes learn what the RNL set is, they will share their shards, meaning that each correct process is guaranteed to receive at least \( N - f \) correct shares of each of their RNL numbers, satisfying the conditions for entering the computation phase, where their progress becomes purely local as they do not depend on other processes anymore.

\subsection*{4.2 Complexity}

We shall analyse our algorithm in terms of *message complexity*: the maximum number of messages transmitted per random number generated; *bit complexity*: the maximum number of bits exchanged over the network per random number generated; *time complexity*: the number of message round trips required per random number generated; and *computational complexity*: the number of operations to be executed per process per random number generated.
In the generation and commitment phase each process executes one broadcast, meaning that there are $O(N)$ messages being sent at this phase. After consensus is reached on the value of $RNL$, each process executes exactly one more broadcast, leaving the message complexity of this part of the protocol on $O(N)$. The result computation phase in done locally, hence the message complexity of our protocol is $O(N)$ outside consensus.

In terms of bit complexity, the messages of the generation phase contain random numbers whose lengths are proportional to the number of processes in the system by design. Therefore, the bit complexity of this step is $O(N^2)$. Afterwards in the reveal phase, each process includes one decrypted block per number in the $RNL$ set. Each decrypted block has constant size and the cardinality of $RNL$ is $f+1$, so the bit complexity of this stage is also $O(N^2)$. Therefore, without taking consensus into account, the bit complexity of our protocol is $O(N^2)$.

With respect to time complexity, our protocol requires two round trips given the two identified broadcasts, each executed by all processes in parallel. As for computational complexity we present the analysis split on the three phases of the protocol in Table 2.

*Table 2* Computational complexity

If the erasure correcting code used is indeed Reed-Solomon, then the encoding and decoding complexities of a single number with length $O(N)$ is $O(N \log N)$ [35], meaning that the per-process computational complexity is $O(N^2 \log N)$ when this particular code is used.

When considering the complexity of the Consensus protocol, one can easily associate last generation PBFT consensus protocols developed in the context of blockchain-type ledgers. In this context, the Tendermint consensus protocol for instance can easily be associated to RandSolomon (please refer to [1] for a detailed analysis of the former). Doing so leads to an overall message complexity of $O(N^3)$ with the complexity of consensus dominating that of our protocol. As such, this illustrates that any system which already has the protocol machinery to solve consensus can implement RandSolomon without incurring a significant performance impact.

We summarise the full protocol complexity in Table 3.

*Table 3* Random Solomon Protocol complexities integrating Consensus as in [1]
5 Conclusion

We have presented in this article RandSolomon, a Byzantine fault tolerant protocol capable of generating a common random number in a partially-synchronous system. As we have previously shown, although the problem of generating randomness in multi-party systems has already been extensively discussed, the partially-synchronous systems still lacked a BFT solution with maximum resilience of $f$ Byzantine participants among $3f + 1$. Not only did we provide such a solution but we also relied on very simple public key cryptography by means of what we’ve called retraceability and we provided a modular approach using Consensus as a black box, easing future implementations of the protocol.

A note on Synchronous systems

Proposition 5. There exists a synchronous BFT-RNG with resilience $f = N - 1$

Proof. The Unicorn protocol was designed for a slightly different application. What the authors had in mind was the organisation of a raffle where any user can contribute to the final random number by sending an input. More specifically, they proposed the use of a particular hashtag in a social network which the servers running Unicorn would use to gather information. The resulting random number would be computed by taking the hash of the concatenated inputs and any user who contributed to the raffle would be able to verify that their value was used in the computation. The result is unpredictable as the hash is designed to be a delay function and the time necessary for computing it is greater than the window allocated for the users to propose their contributions, impeding any attempt of bias.

This protocol is particularly resilient and as long as at least one server performed an honest computation, the final result is correct. We note that it can be adapted to an approach where $N$ users wish to produce a common unpredictable random number by allowing participants to propose values and then solving $N$ parallel consensus instances. Each instance would correspond to one participant and would determine which contribution the matching participant proposed should be considered or whether it proposed no inputs at all. Then each user could concatenate the vector of values decided in consensus and execute unicorn.

The validity requirement from synchronous consensus prevents users from ignoring the contribution of a correct process. We can stipulate that values in the $i$-th input not signed by the $i$-th process are discarded and if any valid value is proposed then every correct process will decide a valid value. Moreover, because every correct participant has the same input as guaranteed by the synchronous consensus, then following the properties of unicorn, they will all obtain the same correct random value. The result will be unpredictable as the hash will be tuned to take longer than the synchronous consensus to conclude. Finally, any entity can check the result against the execution of the synchronous consensus and correctly decide whether it is correct or not.
