On the Compression of Neural Networks Using $\ell_0$-Norm Regularization and Weight Pruning

Felipe Dennis de Resende Oliveira, Eduardo Luiz Ortiz Batista, and Rui Seara, Senior Member, IEEE

Abstract—Despite the growing availability of high-capacity computational platforms, implementation complexity still has been a great concern for the real-world deployment of neural networks. This concern is not exclusively due to the huge costs of state-of-the-art network architectures, but also due to the recent push towards edge intelligence and the use of neural networks in embedded applications. In this context, network compression techniques have been gaining interest due to their ability for reducing deployment costs while keeping inference accuracy at satisfactory levels. The present paper is dedicated to the development of a novel compression scheme for neural networks. To this end, a new $\ell_0$-norm-based regularization approach is firstly developed, which is capable of inducing strong sparseness in the network during training. Then, targeting the smaller weights of the trained network with pruning techniques, smaller yet highly effective networks can be obtained. The proposed compression scheme also involves the use of $\ell_2$-norm regularization to avoid overfitting as well as fine tuning to improve the performance of the pruned network. Experimental results are presented aiming to show the effectiveness of the proposed scheme as well as to make comparisons with competing approaches.

Index Terms—Machine learning, neural networks, network compression, norm regularization, weight pruning.

I. INTRODUCTION

THE importance of neural networks in the machine learning and engineering contexts has been growing substantially over the last decades [1]–[3]. Factors contributing to this growth include notable improvements in the training algorithms and the increasing availability of high-capacity computational platforms, which have allowed the deployment of neural networks having larger numbers of internal layers. Such networks, termed deep neural networks (DNNs), have been successfully applied to a number of complex problems, such as the stock market prediction [4]–[6], sentiment analysis [7], [8], natural language processing [9], [10], speech recognition [11]–[13], and image processing [14]–[16].

Despite the aforementioned increasing computational power availability, computational costs still pose an important challenge for the use of deep neural networks in real-world applications. This is due to the fact that many effective deep neural networks deal with a huge number of parameters (weights). One particular example is AlexNet (winner of the 2012 Imagenet Large Scale Visual Recognition Challenge) [16], which comprises more than 60 million learnable weights. The training of networks with so many parameters, in spite of being computationally costly and time consuming, is a more tractable problem since it is typically an offline process. In contrast, deployment costs tend to be more critical and often prohibitive for large networks, especially in applications involving real-time processing and/or embedded systems. Aiming to address this hindrance, considerable research efforts have been dedicated to the development of network compression techniques. Some of these techniques are based on using matrix decompositions to find suitable network approximations with reduced computational complexity [17]–[20]. Other techniques exploit hardware implementation characteristics to achieve computational cost reductions [21]–[23]. Moreover, neuron- or weight-pruning approaches have also been considered for developing network compression techniques [24]–[29].

Specifically in the context of network compression via pruning approaches, strategies that combine norm-penalization-based regularization with pruning have been gaining significant attention [30]–[34]. This is due to the fact that such regularization techniques tend to induce network sparseness, which potentially increases the effectiveness of a subsequent weight and/or neuron pruning. In [30], for instance, the association of $\ell_q$-norm regularization with weight pruning produced 12-times reductions on the number of network weights without affecting its performance. Moreover, in [34], 38-times reductions were obtained at the cost of small performance losses using a combination of $\ell_1$-norm regularization and weight pruning. When neuron pruning is desired, group-based regularization techniques have led to promising results [33], [34]. Moreover, as shown in [32], it is possible to combine neuron and weight penalization to increase the network compression.

The focus of the present research work is on the development of a new strategy for neural network compression based on norm regularization and weight pruning. The idea here is to use the $\ell_0$ norm instead of the commonly used $\ell_1$ or $\ell_2$ norms, since $\ell_0$-norm penalization typically has a stronger sparseness-inducing effect [35]. Other types of $\ell_0$-norm regularizations have also been exploited in [35] and [36]. However, the focus here is on speeding up the training process, whereas the main goal here is to reduce the complexity of the resulting trained network. Other important differences between [35], [36] and the present work are on the adopted pruning strategy (neuron pruning here and weight pruning here) and also on the approach used to circumvent the non-convexity of the $\ell_0$-norm function. In particular, here we rely on the exponential approximation of the $\ell_0$ norm discussed in [37] to make tractable the optimization problem that gives
rise to the training algorithm. As a result, a very effective regularization approach is obtained, leading to a stronger zero-attraction effect that results in networks with larger numbers of prunable weights. This approach is, however, not as effective for avoiding model overfitting, which may impair network inference performance. To circumvent this problem, we also introduce a combined $\ell_2$-$\ell_0$-norm regularization which, in association with weight pruning, gives rise to the network compression scheme proposed in this paper. It is important to highlight that the combined $\ell_2$-$\ell_0$-norm regularization is general in the sense that it can also be used together with other compression techniques, such as the one from [33]. A set of experimental results are also presented in this paper aiming to show the effectiveness of the proposed compression scheme as well as to make comparisons with other competing strategies.

The remainder of this paper is organized as described in the following. Section II presents a review of classic regularization methods based on vector norms. The proposed approach is discussed in Section III. Finally, Sections IV-A and V are dedicated to present, respectively, experimental results and concluding remarks.

II. BACKGROUND ON NORM-BASED REGULARIZATION AND WEIGHT PRUNING

In general terms, norm-based regularization strategies aim at preventing the overfitting by means of introducing a norm-dependent penalization into the training process [1]. This operation is carried out by considering an objective function in the following form to derive the network training algorithm:

$$
\tilde{J}(\mathbf{w}, \mathbf{x}, \mathbf{y}) = J(\mathbf{w}, \mathbf{x}, \mathbf{y}) + \alpha \Omega(\mathbf{w})
$$

where $J(\mathbf{w}, \mathbf{x}, \mathbf{y})$ corresponds to a standard (non-regularized) cost function, $\Omega(\mathbf{w})$ is the penalization function, and $\alpha$ is a parameter that allows controlling the penalization level. Note that $\Omega(\mathbf{w})$ is a function exclusively of the weight vector $\mathbf{w}$ (containing all network weights), whereas $J(\mathbf{w}, \mathbf{x}, \mathbf{y})$ depends also on $\mathbf{x}$ and $\mathbf{y}$, which correspond, respectively, to the input and output data from the training dataset.

The minimization of (1) is generally pursued by means of adjusting $\mathbf{w}$ using gradient-descent-based methods [1]. Thus, the update expression for the $j$th weight can be represented as

$$
w_j \leftarrow w_j - \eta \frac{\partial J(\mathbf{w}, \mathbf{x}, \mathbf{y})}{\partial w_j} + \alpha \frac{\partial \Omega(\mathbf{w})}{\partial w_j}
$$

with $\eta$ denoting the learning rate. Note that, for $\alpha = 0$, (2) becomes the standard (non-regularized) weight-update rule, which is given by

$$
w_j \leftarrow w_j - \eta \frac{\partial J(\mathbf{w}, \mathbf{x}, \mathbf{y})}{\partial w_j}.
$$

A. $\ell_2$-Norm Regularization

One of the most popular regularization techniques that use norm penalties is the $\ell_2$-norm regularization. This technique is developed by making

$$
\Omega(\mathbf{w}) = \|\mathbf{w}\|_2^2 = \sum_{j \in \phi} w_j^2
$$

in (1), with $\phi$ representing the set of all penalized network parameters. By substituting (4) into (2), considering that $\partial \|\mathbf{w}\|_2^2/\partial w_j = 2w_j$, and manipulating the resulting expression, the following update equation is obtained:

$$
w_j \leftarrow w_j - 2\eta \alpha w_j - \eta \frac{\partial J(\mathbf{w}, \mathbf{x}, \mathbf{y})}{\partial w_j}.
$$

By comparing (5) with the standard (non-regularized) update equation given in (3), one can notice that the $\ell_2$-norm regularization introduces an extra term, given by $-2\eta \alpha w_j$, on the weight update equation. Since $2\eta \alpha$ is always positive and generally much smaller than one (for the sake of algorithm convergence), this extra term produces a reduction of $2\eta \alpha |w_j|$ on the weight magnitude and is thus called penalization term. Such a penalization contributes significantly for avoiding the overfitting [1].

B. $\ell_1$-Norm Regularization

In the case of the $\ell_1$-norm regularization, the penalization function is given by

$$
\Omega(\mathbf{w}) = \|\mathbf{w}\|_1 = \sum_{i \in \phi} |w_i|.
$$

Then, considering (2), (6), and also that $\partial \|\mathbf{w}\|_1/\partial w_j = \text{sign}(w_j)$, the following weight-update equation is obtained:

$$
w_j \leftarrow w_j - \eta \alpha \text{sign}(w_j) - \eta \frac{\partial J(\mathbf{w}, \mathbf{x}, \mathbf{y})}{\partial w_j}.
$$

Note that (7) corresponds to (3) with the inclusion of the penalization term $-\eta \alpha \text{sign}(w_j)$. Since $0 < \eta \alpha < 1$, this term also tends to produce a weight magnitude reduction, in a similar way as the penalization term of the $\ell_2$-norm-regularized update.

C. Network Compression via Norm-Based Regularization and Weight Pruning

As previously mentioned, both $\ell_2$- and $\ell_1$-norm regularizations result in weight-update penalization terms that induce weight magnitude reductions during the network training. Such a zero-attraction effect, besides preventing model overfitting, also tends to produce networks with several weights having very small magnitude values. Most of these weights have a negligible contribution to the network output and, thus, they can be pruned out. This idea is the basis for many network compression techniques, in which a magnitude threshold is considered for pruning weights after a norm-regularized training process. In doing so, effective implementations of neural networks can be obtained, presenting significantly-reduced computational complexity along with a negligible performance reduction [30], [31], [33], [36], [38].

III. PROPOSED SCHEME

In this section, the focus is on the main contributions of the present paper. The first is an $\ell_0$-norm-based regularization approach for network training, which aims at producing networks having larger amounts of prunable weights. Then, a discussion is presented regarding the zero-attraction characteristics of the
A. Proposed $\ell_0$-Norm-Based Regularization Approach

The $\ell_0$ norm is well known for being a strict measure of vector sparseness, since it is formally defined as the number of nonzero coefficients in a vector [33], [37], [39]. Due to this fact, the $\ell_0$ norm has been considered in applications involving optimization and sparseness induction [33], [36]–[39], which share important similarities with the network compression strategies of interest in the present research work. Thus, aiming to develop a novel regularization approach, let us start with the formal definition of the $\ell_0$ norm of a weight vector $w$, which is given by

$$||w||_0 = \sum_{j \in \Phi} f(w_j)$$  \hfill (8)

with

$$f(w_j) = \begin{cases} 1 & \text{if } w_j \neq 0 \\ 0 & \text{otherwise} \end{cases}$$  \hfill (9)

Note that (8) is a non-convex and non-differentiable function. These characteristics pose important difficulties for the development of regularization strategies as those described in Section II, especially due to the central role of gradient descent optimization methods [see (2)]. To circumvent this problem, we consider here an approximate differentiable version of the $\ell_0$ norm described in [37]. More specifically, (9) is approximated by

$$f'(w_j) = 1 - e^{-\beta|w_j|},$$  \hfill (10)

with $\beta \geq 1$. Thus, using (10) in lieu of $f(w_j)$ in (8), the following $\ell_0$ norm approximation is obtained:

$$||w||_0 \approx ||w||_0' = \sum_{j \in \Phi} (1 - e^{-\beta|w_j|}).$$  \hfill (11)

Parameter $\beta$ determines the degree of similarity between the approximation and the $\ell_0$ norm (i.e., as $\beta \to \infty$, $||w||_0' \to ||w||_0$).

By considering $\Omega(w) = ||w||_0'$ in (7), we have

$$w_j \leftarrow w_j - \eta\alpha \frac{\partial ||w||_0'}{\partial w_j} - \frac{\partial J(w, X, y)}{\partial w_j}. \hfill (12)$$

Now, taking the gradient of (11) with respect to $w_j$, we get

$$\frac{\partial ||w||_0'}{\partial w_j} = \beta \text{sign}(w_j) e^{-\beta|w_j|}. \hfill (13)$$

Finally, replacing (13) in (12), the following $\ell_0$-norm-regularized weight update rule is obtained:

$$w_j \leftarrow w_j - \eta\alpha \beta \text{sign}(w_j) e^{-\beta|w_j|} - \frac{\partial J(w, X, y)}{\partial w_j}. \hfill (14)$$

Note that (14) corresponds to (3) with the inclusion of a penalization term given by $-\eta\alpha \beta \text{sign}(w_j) e^{-\beta|w_j|}$, which again exerts a zero-attraction over the weight since in practice $0 \leq \eta\alpha \beta e^{-\beta|w_j|} \ll 1$.

Fig. 1. Penalization provided by the proposed $\ell_0$-norm regularization for different values of $\beta$.

B. Zero-Attraction for the Different Norm-Based Regularization Strategies

As mentioned in Section II-C the penalization terms present in (5) ($\ell_2$-norm-regularized weight update) and (7) ($\ell_1$-norm-regularized weight update) exert a form of attraction towards zero over the network weights. This is also the case for the $\ell_0$-norm-regularized weight update given in (14). The characteristics of these zero-atraction effects are however significantly different, as described in the following.

In the case of the $\ell_2$-norm regularization, since the penalization term is given by $-2\eta\alpha w_j$, the resulting penalization is proportional to the weight magnitude. As a result, larger-magnitude weights are subjected to larger penalization, which is interesting to avoid overfitting. However, the smaller the weight magnitude, the smaller the penalization term, resulting in a weak zero-atraction for small weights. In terms of training dynamics, the small weights will tend to present a smooth approximation towards zero, eventually requiring too many training epochs in order to fall below the weight-pruning threshold of a network compression strategy.

For the $\ell_1$-norm regularization, the penalization term $-\eta\alpha \text{sign}(w_j)$ is not proportional to the weight magnitude. As a consequence, smaller weights face the same level of penalization as the larger ones, resulting in a zero-attraction effect that does not vanish as weights become small. However, the relatively smaller penalization applied to larger weights tend to harm the capability of the training algorithm to avoid the overfitting.

The first aspect to notice regarding the penalization term $-\eta\alpha \beta \text{sign}(w_j) e^{-\beta|w_j|}$ for the proposed $\ell_0$-norm regularization approach is that it tends to become very small for larger weights (since as $|w_j| \to \infty$, $e^{-\beta|w_j|} \to 0$). Thus, one can infer that the proposed $\ell_0$-norm regularization leans to be less effective in avoiding overfitting. On the other hand, in terms of a zero-attraction for the smaller coefficients, the proposed $\ell_0$-norm regularization have a stronger effect that increases as the weight becomes smaller. This characteristic is illustrated in Fig. 1 for $\eta = 0.04$ and $\alpha = 0.01$, as well as for different values of $\beta$. As a result, during network training, a weight that becomes small is increasingly accelerated towards zero, taking a smaller number of epochs to reach the weight-pruning threshold.
C. Network Compression Scheme Based on Combined $\ell_2$-$\ell_0$-Norm Regularization

From the discussion presented in the previous section, it becomes clear that the proposed $\ell_0$-norm-based regularization is very attractive for obtaining networks having larger numbers of prunable weights, at the cost of a poorer overfitting-avoidance capability. In contrast, the $\ell_2$-norm regularization is effective at avoiding overfitting, at the cost of a poorer capability for producing prunable weights. Thus, the idea here is to exploit such complementarity between the $\ell_2$- and $\ell_0$-norm-based regularizations to obtain highly-compressible networks that are also very effective in terms of inference performance. In this context, considering $\Omega(w) = |w|^2_2 + |w|^0_0$ and taking the steps described in Section III-A to derive the proposed $\ell_0$-norm regularization strategy, the following weight-update rule is obtained:

$$w_j \leftarrow w_j - 2\eta\alpha_2 w_j - \eta\alpha_0 \beta \text{sign}(w_j) e^{-\beta|w_j|} - \eta \frac{\partial J(w; X, y)}{\partial w_j}.$$

(15)

Note that two different norm-penalization parameters ($\alpha_2$ and $\alpha_0$) are used in (15) to allow controlling the penalization level for each norm independently. Finally, in possession of (15), we can define the proposed scheme for compression of neural networks, which is based on network training using the combined $\ell_2$-$\ell_0$-norm regularization followed by pruning the less significant weights of the resulting network. In the next section, the effectiveness of such an scheme is assessed.

IV. EXPERIMENTS

This section is focused first on assessing the ability of the proposed $\ell_0$-norm regularization approach on inducing sparseness during network training and then on evaluating the performance of the proposed network compression scheme based on combined $\ell_2$-$\ell_0$-norm regularization. In this context, three different experiments are considered. In the first, the idea is to compare the sparseness induction capability of the proposed $\ell_0$-norm regularization with those of the more standard $\ell_2$- and $\ell_1$-norm regularizations, as well as to evaluate their impact when different pruning strategies are used. In the second experiment, the proposed network compression scheme is used for obtaining compressed versions of the Lenet-300-100 and Lenet-5-Caffe networks applied to the MNIST dataset. Finally, the third experiment involves the application of the proposed network compression scheme to the more challenging task of compressing a residual network called ResNet20 applied to the CIFAR-10 dataset. In all experiments, the networks are assessed in terms of their accuracy versus compression trade-off. Comparisons with other results from the open literature are also presented.

A. Experiment 1: Sparseness Induction Comparison Between Different Norm-based Regularization Strategies

The aim of this experiment is to assess the sparseness-induction capability of the proposed $\ell_0$-norm regularization as compared with both the standard $\ell_2$- and $\ell_1$-norm-based regularizations. In this context, neural networks inspired on the Lenet-5-Caffé\(^1\) are trained for the image classification task of the MNIST dataset. To assess the trade-off between accuracy and network compression, the networks obtained after training are increasingly compressed (starting with a factor of 2) and the resulting accuracy is evaluated for each compression level. The network compression is carried out by using three different weight-pruning strategies\(^{[14]}\): i) global magnitude pruning (GP), where the less significant weights of the network as a whole are targeted for pruning; ii) layerwise magnitude pruning (LP), where the less significant weights in each layer are targeted (resulting in the same compression level for each layer); and iii) random pruning (RP), where weights are randomly selected for pruning, regardless of their magnitude. Fine tuning\(^{[14]}\) (i.e., network retraining after pruning) is also considered in this experiment.

Figs. 2 and 3 present the curves of accuracy versus compression level obtained without and with fine tuning, respectively. The first aspect to highlight, from these figures, is the superiority of both global and layerwise weight pruning with respect to random pruning. This fact demonstrates the effectiveness of...
of network compression via magnitude-based weight pruning. Now, regarding the capability of the different norm-based regularization techniques to induce sparseness and thus provide higher compression levels, the curves from Figs. 2 and 3 show that the proposed $\ell_0$-norm-based regularization significantly outperforms the regularizations based on both $\ell_1$ and $\ell_2$ norms. This conclusion is evident from the superior results obtained by using the proposed regularization with either global or layerwise weight pruning. Moreover, the inferior performance obtained by the proposed regularization with random pruning is also illustrative of its sparseness inducing capability, since a higher sparseness level implies more concentration of energy in fewer weights, with some of these more significant weights inevitably targeted by a random pruning strategy. Another important aspect to point out is that the use of fine tuning leads to significantly better results in all cases, even though the proposed $\ell_0$-norm-based regularization has obtained very good results even without using fine tuning (see Fig. 2).

B. Experiment 2: Network Compression for the MNIST Dataset

In this experiment, we consider the MNIST dataset and compare other pruning-based network compression approaches from the literature with the network compression scheme proposed in the present paper. In this context, two network topologies are considered, namely, the Lenet-300-100 and Lenet-5-Caffe ones. The pruning strategy of choice is the global pruning due to the superior results observed in the first experiment. For setting the training hyperparameters, we consider two different strategies. The first, denoted NORM, is based on using layer-size normalized values for $\alpha_{\ell_2}$ and $\alpha_{\ell_0}$ [36]. In this case, three global hyperparameter values ($\alpha_{\ell_2}$, $\alpha_{\ell_0}$, and $\beta$) have to be tuned, besides the learning rate $\eta$. In the second strategy, called SEP, individual values of $\alpha_{\ell_2}$, $\alpha_{\ell_0}$, and $\beta$ are tuned for each network layer. In general terms, NORM is simpler to use, whereas SEP tends to produce better results due to the increased degrees of freedom.

The first aspect evaluated in this experiment is the trade-off between accuracy and compression obtained using the proposed approach. Figs. 4 and 5 depict such a trade-off for the Lenet-300-100 and Lenet-5-Caffe networks, respectively, considering both NORM and SEP strategies, as well as fine tuning (FT). From these figures, one can notice that very high compression rates can be obtained by using the proposed approach with negligible performance loss for the cases considered here. As expected, the best results are obtained by using the combination of SEP strategy with fine tuning (around 100× compression for the Lenet-300-100 and more than 300× for the Lenet-5-Caffe). However, even the simpler NORM strategy was capable of leading to satisfactory values (around 90× for the Lenet-300-100 and 200× for the Lenet-5-Caffe).

The results obtained by using the proposed approach are now confronted with those obtained by using the following pruning-based compression methods from the literature: threshold pruning (THP) [30], dynamic network surgery (DNS) [26], group horseshoe (BC-GHS) [42], $\ell_0$ augment-reinforce-merge ($L_0$-ARM) [36], sparse variational dropout (SVD) [43], and cutting plane algorithm (CPA) [44]. Such a comparison is presented in Table I. From this table, one can notice that the proposed approach is very competitive, generally resulting in superior trade-offs between accuracy and compression, as compared with the other approaches from the literature.
For this third experiment, we consider the image classification task of the CIFAR-10 dataset using a residual network called ResNet20 [45]. Residual networks (ResNets) have been introduced with the aim of preventing the accuracy degradation problem [45] and thus make the training of deeper networks more efficient and easy. In this context, such networks have been showing satisfactory results with reduced amounts of parameters. For instance, the ResNet20, which is implemented with 22 layers and about 274 thousand parameters, obtains an error rate of 7.8% for the CIFAR-10 dataset, whereas the well-known VGG-16 [46] obtains an error rate of 6.75% with around 15 million parameters. As a consequence, the parameter pruning of residual networks, such as the ResNet20, tends to be a more challenging task than that of other types of networks. This becomes evident by comparing the compression rates in the order of two to three times obtained for ResNets [47]–[50] with those in the order of dozens to hundreds for networks such as LeNets, AlexNet, and VGG [26], [30], [50].

In this experiment, we again consider NORM and SEP strategies for adjusting the hyperparameters of the proposed compression scheme, as well as fine tuning (FT). The curves of accuracy versus compression level obtained by using the different combinations of these strategies are presented in Fig. 6. These results demonstrate the effectiveness of the proposed scheme applied to ResNets, leading to relatively high compression levels (up to 5 times) with acceptable performance loss. One important aspect to highlight in this case is that the difference between NORM and SEP strategies is very small (contrasting with the more significant results from Experiment 2), whereas FT has resulted in more important performance gains.

Few works can be found in the literature involving the compression of the ResNet20 aiming at the CIFAR-10 classification task. In general, the reported results are obtained with filter or channel pruning approaches [47]–[49]. The results obtained by using these techniques are shown in Table IV-C along with those obtained by using the compression scheme proposed here. From these results, one observes that the proposed scheme outperforms the other approaches from the open literature, demonstrating again the effectiveness of the association of combined $\ell_2-\ell_0$-norm regularization and weight pruning.

V. CONCLUDING REMARKS

The focus of this paper was on the development of a novel neural-network compression scheme based on sparseness-inducing training followed by weight pruning. In this context, a new $\ell_0$-norm-based regularization approach was introduced aiming to strengthen the sparseness induction during training and thus obtain effective networks with larger numbers of prunable weights. Such a regularization approach is however not as effective in avoiding model overfitting. Thus, a combined $\ell_2-\ell_0$-norm regularization is considered for the implementation of the proposed network compression scheme. A set of experimental results is presented, confirming the effectiveness of the proposed scheme in scenarios involving fully-connected, convolutional, and residual networks.
