Concave Utility Reinforcement Learning with Zero-Constraint Violations

Mridul Agarwal, Qinbo Bai, Vaneet Aggarwal

Abstract

We consider the problem of tabular infinite horizon concave utility reinforcement learning (CURL) with convex constraints. Various learning applications with constraints, such as robotics, do not allow for policies that can violate constraints. To this end, we propose a model-based learning algorithm that achieves zero constraint violations. To obtain this result, we assume that the concave objective and the convex constraints have a solution interior to the set of feasible occupation measures. We then solve a tighter optimization problem to ensure that the constraints are never violated despite the imprecise model knowledge and model stochasticity. We also propose a novel Bellman error based analysis for tabular infinite-horizon setups which allows to analyse stochastic policies. Combining the Bellman error based analysis and tighter optimization equation, for $T$ interactions with the environment, we obtain a regret guarantee for objective which grows as $O(1/\sqrt{T})$, excluding other factors.

1. Introduction

Reinforcement Learning is being increasingly applied to various interesting Markov Decision Processes (MDP) setups where the system model is not known apriori Sutton and Barto (2018); Recht (2019). Various algorithms have been developed to learn efficient policies using deep neural networks Mnih et al. (2015); Schulman et al. (2017); Haarnoja et al. (2018). Much work is also done to develop algorithms that are provably sample-efficient Jaksch et al. (2010); Agrawal and Jia (2017); Jin et al. (2018). However, in many applications, the learning agent (or algorithm) needs to satisfy certain constraints while maximizing an objective Altman and Schwartz (1991).

For example, in robotics, a good policy for reaching a target pose should avoid hazardous poses which may damage the environment Achiam et al. (2017). Also, consider the example of autonomous vehicles, the goal is not just to reach the destination as early as possible, but also to ensure the safety of the surroundings Le et al. (2019); Tessler et al. (2018). Further, there are certain environments in which the agent is required to ensure the constraint violations are reduced while optimizing the objective as well Leike et al. (2017); Ray et al. (2019).

Owing to the importance of RL with constraints, recently, there has been significant work in the area. For episodic setup, there is a significant line of work ranging from model based algorithms Brantley et al. (2020); Yu et al. (2021) to primal-dual based model-free algorithms Ding et al. (2021). Much recently, Wei et al. (2021) proposed TripleQ algorithm which achieves zero constraint violations\footnote{We note that even with zero constraint violations, an agent can violate constraints in the initial learning periods. Hence, zero constraints violations should be treated as $O(1/T)$, i.e., $O(1)$ violations in time $T$.} at the expense of an increased regret order of $O(T^{-1/5})$. However, for the episodic setup, the majority of the current work considers the weaker regret definition specified by Efroni et al. (2020). Averaging over value function of multiple episodes allows for oscillations for constraints values around bounds, and does not imply that the policy (and the corresponding value function) necessarily converge to the optimal policy (and the corresponding value function) which satisfies the constraints.

We note that the definition which considers the average over time makes sense when considering an infinite horizon setup as the long-term average is naturally defined Puterman (2014). For a tabular infinite-horizon setup, Singh et al. (2020) proposed an epoch-based algorithm which bounds the regret by $O(S\sqrt{A/T})$ with
convergence in policy. We improve on this result by three folds, first by reducing the regret order from $O(T^{-1/4})$ to $O(T^{-1/2})$, second by considering convex function for objectives and constraints, and last by providing algorithm which can bound the constraint violations with $O(1/T)$. We compare the algorithms with different related works in Table 1.

In this work, we consider the problem of maximizing concave utility of the expected rewards while also ensuring that a set of convex constraints of the expected rewards are also satisfied. Moreover, we aim to develop algorithms that can also ensure that the constraints are not violated during the training phase as well. We work with tabular MDP with infinite horizon. For such setup, our algorithm updates policies as it learns the system model. Further, our approach also bound the accumulated observed constraint violations as compared to the expected constraint violations.

Table 1: Overview of work for constrained reinforcement learning setups. For infinite horizon (IH) setups, $D$ denotes diameter of the MDP and $T$ is the time for which algorithm runs. For finite horizon (FH) setups, $H$ is the episode length and $K$ is the number of episodes for which the algorithm runs. $L$ is the Lipschitz constant.

To achieve this result, we propose UC-CURL algorithm which proceeds in epochs $e$. At each epoch, we solve for a policy which considers constraints tighter by $\epsilon_e$ than the true bounds. Further, as the knowledge of the model improves with increased interactions with the environment, we reduce this tightness. This $\epsilon_e$-sequence is critical to our algorithm as, if the sequence decays too fast, the constraints violations cannot be bounded by zero. And, if this sequences decays too slow, the objective regret may not decay fast enough. Further, using the $\epsilon_e$-sequence, we do not require the knowledge of the total time $T$ for which the algorithm runs.

We bound our regret by bounding the gap between the optimal policy in the feasible region and the optimal policy for the optimization problem with $\epsilon_e$ tight constraints. We bound this gap with a multiplicative factor of $O(1/\delta)$, where $\delta$ is Slater’s parameter. Based on our analysis using the Slater’s parameter $\delta$, we consider a case where a lower bound $T_l$ on the time horizon $T$ is known. This knowledge of $T_l$ allows us to relax our assumption on $\delta$.

Further, the regret analysis of the proposed UC-CURL algorithm is also novel. We define and use Bellman error for infinite horizon setup to bound the difference between the performance of optimistic policy on the optimistic MDP and the true MDP. Compared to analysis of Jaksch et al. (2010), this allows us to work with stochastic policies. Further, with our analysis, we are also able to eliminate the linear growth in regret in the number of epochs (which was the case in Jaksch et al. (2010)), as the policy at every time step is learnt using more data than before.

Combining these two tricks, we bound our regret as $\tilde{O}(\frac{1}{2}LdDS\sqrt{A/T})$ and constraint violations as $O(1/T)$, where $S$ and $A$ are the number of states and actions respectively, $L$ is the Lipschitz constant of the objective and constraint functions, $d$ is the number of costs the agent is trying to optimize, and $D$ is the diameter of the MDP. We note that ours is the first result with a suitable regret definition, on non-linear objective and constraints, and the result achieves zero-constraint violations.
2. Related Works

Unconstrained RL: Much work has been done to understand finite time performance of algorithms for the tabular setup. Jaksch et al. (2010) provided epoch based UCRL2 algorithm which achieves a regret bound of \( O(DS\sqrt{A/T}) \) for infinite horizon setup using optimism and proved a lower bound of \( O(\sqrt{DSA/T}) \) for MDPs with diameter \( D \). Fruit et al. (2018) provided an improved epoch based SCAL algorithm with regret \( O(D\sqrt{SA/T}) \). However, the analysis of both UCRL2 and SCAL algorithm have an additional regret which increases linearly in the number of epochs. However, the algorithm bound the number of epochs in logarithmic order of time horizon \( T \).

Constrained RL: The work by Altman (1999) summarized the requirements for the study of constrained reinforcement learning, along with the formulation for constrained MDPs and algorithms for obtaining policies with known transition models. Similar to the unconstrained setup, recently there is progress towards understanding the convergence properties of the algorithms along with finite time performance. (Zheng and Ratliff, 2020) considered an episodic CMDP and use an optimism based algorithm to bound the constraint violation as \( O(1/T^{0.25}) \) with high probability. (Kalagarla et al., 2020) also considered the episodic setup to obtain PAC-style bound for an optimism based algorithm. (Ding et al., 2021) considered the setup of \( H \)-episode length episodic CMDPs with \( d \)-dimensional linear function approximation to bound the constraint violations as \( O(d\sqrt{H^5/T}) \) by mixing the optimal policy with an exploration policy. (Efroni et al., 2020) proposes a linear-programming and primal-dual policy optimization algorithm to bound the regret as \( O(S\sqrt{H^3/T}) \).

(Qu et al., 2020) proposed an algorithm which obtains a regret bound of \( O(S\sqrt{AH^2/T}) \) for the problem of adversarial stochastic shortest path. (Wei et al., 2021) considered the problem of ensuring zero constraint violations using a model-free algorithm for tabular MDPs with linear rewards and constraints. However, they achieve that result at the expense of an increased regret bound of \( O(T^{-1/5}) \). Compared to these works, we focus on setting with infinite horizon long-term average constraints.

Xu et al. (2020) consider an infinite horizon discounted setup with constraints and obtain global convergence using policy gradient algorithms. Ding et al. (2020) also considers an infinite horizon discounted setup. They use a natural policy gradient to update the primal variable and sub-gradient descent to update the dual variable. Singh et al. (2020) considered the setup of infinite-horizon CMDPs with long-term average constraints with an optimism based algorithm and forced explorations. We consider a similar setting with unichain CMDP and propose an optimism based algorithm to bound the regret as \( O(LdDS\sqrt{A/T}) \) using explorations assisted by the ergodicity of the MDP. Very recently, Gattami et al. (2021) analyzed the asymptotic performance for Lagrangian based algorithms for infinite-horizon long-term average constraints, however they only show convergence guarantees without explicit convergence rates.

Concave Utility RL: Another major research area related to constrained RL is concave utility RL. Hazan et al. (2019). Along this direction, Cheung (2019) considered a concave function of expected per-step vector reward and developed an algorithm using Frank-Wolfe gradient of the concave function for tabular infinite horizon MDPs. Agarwal and Aggarwal (2019) also considered the same setup, but proposed a posterior sampling based algorithm. Recently, Brantley et al. (2020) combined concave utility reinforcement learning and constrained reinforcement learning for an episodic setup. Yu et al. (2021) also considered the case of episodic setup with concave utility RL. However, both Brantley et al. (2020) and Yu et al. (2021) consider the weaker regret definition by Efroni et al. (2020), and Cheung (2019) and Yu et al. (2021) do not target the convergence of the policy. Further, these works do not target zero-constraint violations.

Compared to prior works, we consider the constrained reinforcement learning with convex constraints and concave objective function. Using infinite-horizon setup, we consider the tightest possible regret definition. Further, we achieve zero constraint violations with objective regret tight in \( T \) using an optimization problem with decaying tightness. A quick comparative survey of prior works and our work is also presented in Table 1.
### 3. Problem Formulation

We consider a tabular infinite-horizon constrained Markov Decision Process $\mathcal{M} = (\mathcal{S}, \mathcal{A}, r, f, c_1, \cdots, c_d, g, P)$ with bounded diameter $D$. $\mathcal{S}$ is finite set of $S$ states, and $\mathcal{A}$ is a finite set of $A$ actions. $P : \mathcal{S} \times \mathcal{A} \to \Delta(\mathcal{S})$ denotes the transition probability distribution such that on taking action $a \in \mathcal{A}$ in state $s \in \mathcal{S}$, the system moves to state $s' \in \mathcal{S}$ with probability $P(s'|s,a)$. $r : \mathcal{S} \times \mathcal{A} \to [0,1]$ and $c_i : \mathcal{S} \times \mathcal{A} \to [0,1], i \in 1,\cdots, d$ denotes the average reward obtained and average costs incurred in state action pair $(s,a) \in \mathcal{S} \times \mathcal{A}$.

The agent interacts with $\mathcal{M}$ in time-steps $t \in 1,2,\cdots$ for a total of $T$ time-steps. We note that $T$ is possibly unknown. At each time $t$, the agent observes state $s_t$, plays action $a_t$. The agent selects an action on observing the state $s$ using a policy $\pi : \mathcal{S} \to \Delta(\mathcal{A})$, where $\Delta(\mathcal{A})$ is the probability simplex on the action space. On following a policy $\pi$, the long-term average reward of the agent is denoted as:

$$\lambda^P = \lim_{\tau \to \infty} \mathbb{E}_{\pi,P} \left[ \frac{1}{\tau} \sum_{t=1}^{\tau} r(s_t, a_t) \right]$$

(1)

where $\mathbb{E}_{\pi,P}[\cdot]$ denotes the expectation over the state and action trajectory generated from following $\pi$ on transitions $P$. The long-term average reward can also be represented as:

$$\lambda^P = \lim_{\gamma \to 1} (1 - \gamma)V_{\pi,P}^\gamma(s) \forall s \in \mathcal{S}$$

(2)

$$= \sum_{s,a} \rho^P(s,a) r(s,a)$$

(3)

where $V_{\pi,P}^\gamma(s)$ is the discounted cumulative reward on following policy $\pi$, and $\rho^P \in \Delta(\mathcal{S} \times \mathcal{A})$ is the steady-state occupancy measure generated from following policy $\pi$ on MDP with transitions $P$ Puterman (2014).

Similarly, we also define the long-term average costs as follows:

$$\zeta^P(i) = \lim_{\tau \to \infty} \mathbb{E}_{\pi,P} \left[ \frac{1}{\tau} \sum_{t=1}^{\tau} c_i(s_t, a_t) \right]$$

(4)

$$= \lim_{\gamma \to 1} (1 - \gamma)V_{\pi,P}^\gamma(s;i) \forall s \in \mathcal{S}$$

(5)

$$= \sum_{s,a} \rho^P(s,a) c_i(s,a)$$

(6)

The agent interacting with the CMDP $\mathcal{M}$ aims to maximize a function $f : [0,1] \to \mathbb{R}$ of the average per-step reward. Further, the agent attempts to ensure that a function of average per-step costs $g : [0,1]^d \to \mathbb{R}$ is at most 0. The goal is represented mathematically as:

$$\max_{\pi} f(\lambda^P)$$

(7)

$$s.t. \ g(\zeta^P(1), \cdots, \zeta^P(d)) \leq 0,$$

(8)

**Remark 1** Note that the model, the proposed algorithm, and the analysis can be easily extended to $M$ convex constraints $g_1, \cdots, g_M$ by applying union bounds.

We are now ready to introduce our initial assumptions on the MDP $\mathcal{M}$.

**Assumption 1** The rewards $r(s,a)$, the costs $c_i(s,a);\forall i$ and the functions $f$ and $g$ are known to the agent.

We note that in most of the problems, rewards are engineered according to the problem. Hence, Assumption 1 is justified in many setups. However, the system dynamics are stochastic and typically not known.

Our next assumption is on the functions $f$ and $g$. We have
Assumption 2 The scalarization function \( f \) is jointly concave and the constraints \( g \) are jointly convex. Hence for any arbitrary distributions \( D_1 \) and \( D_2 \), the following holds.

\[
\begin{align*}
    f (E_{x \sim D_1} [x]) & \geq E_{x \sim D_1} [f (x)] \\
    g (E_{x \sim D_2} [x]) & \leq E_{x \sim D_2} [g (x)]; \; x \in \mathbb{R}^d
\end{align*}
\]  

(9) (10)

Many practically implemented fairness objectives are concave (Kwan et al., 2009), or the agent want to explore all possible state action pairs by maximizing the entropy of the long-term state-action distribution (Hazan et al., 2019), or the agent may want to minimize divergence with respect to a certain expert policy (Ghasemipour et al., 2020).

We impose an additional assumption on the functions \( f \) and \( g \). We assume that the functions are continuous and Lipschitz continuity in particular. We have,

Assumption 3 The function \( f \) and \( g \) are assumed to be a \( L \)-Lipschitz function, or

\[
\begin{align*}
    |f (x) - f (y)| & \leq L |x - y|; \; x, y \in \mathbb{R} \\
    |g (x) - g (y)| & \leq L \|x - y\|_1; \; x, y \in \mathbb{R}^d
\end{align*}
\]

(11) (12)

Lipschitz continuity is a common assumption for optimization literature (Bubeck et al., 2015; Jin et al., 2017; Zhang et al., 2020). Additionally, in practice this assumption is validated, often by adding some regularization.

Next, we assume the following Slater’s condition to hold.

Assumption 4 There exists a policy \( \pi \), and one constant \( \delta > LdSD\sqrt{A} \) such that

\[
g (\zeta^P_1 (1), \cdots, \zeta^P_d (d)) \leq -\delta
\]

(13)

Further, if the agent has access to a lower bound of time-horizon, \( T_i \geq \exp (1) \), then we only require \( \delta > LdSD\sqrt{A (\log T_i) / T_i} \). This assumption is again a standard assumption in the constrained RL literature (Efroni et al., 2020. Ding et al. 2021 2020 Wei et al. 2021). \( \delta \) is referred as Slater’s constant. (Ding et al., 2021) assumes that the Slater’s constant \( \delta \) is known. (Wei et al., 2021) assumes that the number of iterations of the algorithm is at least \( \Omega (SAH / \delta)^5 \) for episode length \( H \). On the contrary, we simply assume the existence of \( \delta \) and a lower bound on the value of \( \delta \) which can be relaxed as the agent acquires more time to interact with the environment.

Any online algorithm starting with no prior knowledge will require to obtain estimates of transition probabilities \( P \) and obtain reward \( r \) and costs \( c_k, \forall \; k \in \{1, \cdots, d\} \) for each state action pair. Initially, when algorithm does not have good estimate of the model, it accumulates a regret as well as violates constraints as it does not know the optimal policy. We define reward regret \( R(T) \) as the difference between the average cumulative reward obtained vs the expected rewards from running the optimal policy \( \pi^* \) for \( T \) steps, or

\[
R(T) = f (\lambda^P_{\pi^*}) - f \left( \frac{1}{T} \sum_{t=1}^{T} r (s_t, a_t) \right)
\]

Additionally, we define constraint regret \( C(T) \) as the gap between the constraint function and incurred and constraint bounds, or

\[
C(T) = \left( g \left( \frac{1}{T} \sum_{t=1}^{T} c_1 (s_t, a_t), \cdots, \frac{1}{T} \sum_{t=1}^{T} c_1 (s_t, a_t) \right) \right)_+
\]

where \( (x)_+ = \max (0, x) \).

In the following section, we present a model-based algorithm to obtain this policy \( \pi^* \), and reward regret and the constraint regret accumulated by the algorithm.
Algorithm 1: UC-CURL

Parameters: $K$

Input: $S, A, r, d, c_i \forall i \in [d]$

1: Let $t = 1, e = 1, \epsilon_e = K\sqrt{\frac{\ln t}{t}}$

2: for $(s, a) \in S \times A$ do

3: $\nu_e(s, a) = 0, N_e(s, a) = 0, \tilde{P}(s', a, s) = 0 \forall s' \in S$

4: end for

5: Solve for policy $\pi_e$ using Eq. (23)

6: for $t \in \{1, 2, \cdots\}$ do

7: Observe $s_t$, and play $a_t \sim \pi_e(\cdot|s_t)$

8: Observe $s_{t+1}, r(s_t, a_t)$ and $c_i(s_t, a_t) \forall i \in [d]$

9: $\nu_e(s_t, a_t) = \nu_e(s_t, a_t) + 1$

10: $\tilde{P}(s_t, a_t, s_{t+1}) = \tilde{P}(s_t, a_t, s_{t+1}) + 1$

11: if $\nu_e(s, a) = \max\{1, N_e(s, a)\}$ for any $s, a$ then

12: for $(s, a) \in S \times A$ do

13: $N_{e+1}(s, a) = N_e(s, a) + \nu_e(s, a)$

14: $e = e + 1$

15: $\nu_e(s, a) = 0$

16: end for

17: $\epsilon_e = K\sqrt{\frac{\ln t}{t}}$

18: Solve for policy $\pi_e$ using Eq. (23)

19: end if

20: end for

4. Algorithm

We now present our algorithm UC-CURL and the key ideas used in designing the algorithm. Note that if the agent is aware of the true transition $P$, it can solve the following optimization problem for the optimal feasible policy.

$$\max_{\rho(s, a)} \left\{ \sum_{s, a} r(s, a) \rho(s, a) \right\}$$

with the following set of constraints,

$$\sum_{s, a} \rho(s, a) = 1, \quad \rho(s, a) \geq 0$$

$$\sum_{a \in A} \rho(s', a) = \sum_{s, a} P(s'|s, a) \rho(s, a)$$

$$g\left( \sum_{s, a} c_1(s, a) \rho(s, a), \cdots, \sum_{s, a} c_d(s, a) \rho(s, a) \right) \leq 0$$

for all $s' \in S, \forall s \in S$, and $\forall a \in A$. Equation (16) denotes the constraint on the transition structure for the underlying Markov Process. Equation (15) ensures that the solution is a valid probability distribution. Finally, Equation (17) are the constraints for the constrained MDP setup which the policy must satisfy. Using the solution for $\rho$, we can obtain the optimal policy as:

$$\pi^*(a|s) = \frac{\rho(s, a)}{\sum_{b \in A} \rho(s, b)} \forall s, a$$

However, the agent does not have the knowledge of $P$ to solve this optimization problem, and thus starts learning the transitions with an arbitrary policy. We first note that if the agent does not have complete knowledge of the transition $P$ of the true MDP $\mathcal{M}$, it should be conservative in its policy to allow room to violate
constraints. Based on this idea, we formulate the $\epsilon$-tight optimization problem by modifying the constraint in Equation (17) as.

$$g\left(\sum_{s,a} (c_1 \rho_e)(s,a), \cdots, \sum_{s,a} (c_l \rho_e)(s,a)\right) \leq -\epsilon$$  \hspace{1cm} (19)

Let $\rho_e$ be the solution of the $\epsilon$-tight optimization problem, then the optimal conservative policy becomes:

$$\pi_e^*(a|s) = \frac{\rho_e(s,a)}{\sum_{b \in A} \rho_e(s,b)} \forall s,a$$  \hspace{1cm} (20)

We are now ready to design our algorithm UC-CURL which is based on the optimism principle Jaksch et al. (2010). The UC-CURL algorithm is presented in Algorithm 1. The algorithm proceeds in epochs $e$. The algorithm maintains three key variables $\nu_e(s,a), N_e(s,a),$ and $P(s,a,s')$ for all $s,a, \nu_e(s,a)$ stores the number of times state-action pair $(s,a)$ are visited in epoch $e$. $N_e(s,a)$ stores the number of times $(s,a)$ are visited till the start of epoch $e$. $P(s,a,s')$ stores the number of times the system transitions to state $s'$ after taking action $a$ in state $s$. Another key parameter of the algorithm is $\epsilon_e = K\sqrt{\log t_e}/t_e$ where $t_e$ is the start time of the epoch $e$ and $K$ is a configurable constant. Using these variables, the agent solves for the optimal $\epsilon_e$-conservative policy for the optimistic MDP by replacing the constraints in Equation (16) by:

$$\sum_{a \in A} \rho_e(s',a) = \sum_{s,a} \tilde{P}_e(s'|s,a)\rho(s,a)$$  \hspace{1cm} (21)

$$\|\tilde{P}_e(\cdot|s,a) - \frac{P(s,a,\cdot)}{1 \vee N_e(s,a)}\|_1 \leq \sqrt{\frac{14S \log (2At)}{1 \vee N_e(s,a)}}$$  \hspace{1cm} (22)

for all $s' \in S$, $\forall s \in S$, and $\forall a \in A$. Equation (22) ensures that the agent searches for optimistic policy in the confidence intervals of the transition probability estimates.

Let $\rho_e$ be the solution for $\epsilon_e$-tight optimization equation for the optimistic MDP. Then, we obtain the optimal conservative policy for epoch $e$ as:

$$\pi_e(a|s) = \frac{\rho_e(s,a)}{\sum_{b \in A} \rho_e(s,b)} \forall s,a$$  \hspace{1cm} (23)

The agent plays the optimistic conservative policy $\pi_e$ for epoch $e$. Note that the conservative parameter $\epsilon_e$ decays with time. As the agent interacts with the environment, the system model improves and the agent does not need to be as conservative as before. This allows us to bound both constraint violations and the objective regret.

For the UC-CURL algorithm described in Algorithm 1, we choose $\{\epsilon_e\} = \{K\sqrt{\log t_e}/t_e\}$. However, if the agent has access to a lower bound $T_l$ (Assumption 4) on the time horizon $T$, the algorithm can change the $\epsilon_e$ in each epoch $e$ as follows.

$$\epsilon_e = K\sqrt{\frac{\ln(t_e \vee T_l)}{t_e \vee T_l}} \leq \delta$$  \hspace{1cm} (24)

Note that if $T_l = 0$, $\epsilon_e$ becomes as specified in Algorithm 1 and if $T_l = T$, $\epsilon_e$ becomes constant for all epochs $e$.

5. Regret Analysis

After describing UC-CURL algorithm, we now perform the regret and constraint violation analysis using Bellman error. We note that the standard analysis for infinite horizon tabular MDPs of UCRL2 Jaksch et al. (2010) cannot be directly applied as the policy $\pi_e$ is possibly stochastic for every epoch. Another peculiar
aspect of the analysis of the UCRL2 algorithm is the regret grows linearly with the number of epochs. The analysis still bounds the regret by $O(DS\sqrt{A/T})$ as the number of epochs are bounded by $O(SA\log T)$. However, the analysis is counter-intuitive as the agent is able to work with a better policy at every time-step not just for an epoch. We also note that the analysis of UCRL-CMDP Singh et al. (2020) bounds the deviations with value function instead of bias resulting in regret scaling as $O(T^{-1/4})$. Compared to these works, our analysis works with stochastic policies, obtains regret independent to number of epochs, and scales as $O(1/\sqrt{T})$. Hence, our analysis can be used as a tool to tightly analyze other learning algorithms for tabular infinite horizon MDPs.

Before diving into the details, we first define few important variables which are key to our analysis. The first variable is the standard $Q$-value function. We define $Q^\pi_{\gamma,P}$ as the long term expected reward on taking action $a$ in state $s$ and then following policy $\pi$ for the MDP with transition $P$. Mathematically, we have:

$$Q^\pi_{\gamma,P}(s,a) = r(s,a) + \gamma \sum_{s' \in S} P(s'|s,a)V^\pi_{\gamma,P}(s').$$

(25)

We also define Bellman error $B^\pi_{\gamma,P}(s,a)$ for the infinite horizon MDPs as the difference between the cumulative expected rewards obtained for deviating from the system model with transition $P$ for one step by taking action $a$ in state $s$ and then following policy $\pi$. We have:

$$B^\pi_{\gamma,P}(s,a) = \lim_{\gamma \to 1} \left( Q^\pi_{\gamma,P}(s,a) - r(s,a) - \gamma \sum_{s' \in S} P(s'|s,a)V^\pi_{\gamma,P}(s,a) \right)$$

(26)

After defining the key variables, we can now jump into bounding the objective regret $R(T)$. Intuitively, the algorithm incurs regret on three accounts. First source is following the conservative policy which we require to limit the constraint violations. Second source of regret is solving for the policy which is optimal for the optimistic MDP. Third source of regret is the stochastic behavior of the system. We also note that the constraints are violated because of the imperfect MDP knowledge and the stochastic behavior. However, the conservative behavior actually allows us to violate the constraints within some limits which we will discuss in the later part of this section.

We start by stating our first lemma which relates the regret because we solve for a conservative policy. We define $\epsilon$-tight optimization problem as optimization problem for the true MDP with transitions $P$ with $\epsilon = \epsilon_c$. We bound the gap between the value of function $f$ at the long-term expected reward of the policy for $\epsilon$-tight optimization problem and the true optimization problem (Equation (14)-(17)) in the following lemma.

**Lemma 1** Let $\lambda^P_{\pi}$ be the long-term average reward following the optimal feasible policy $\pi^*$ for the true MDP $\mathcal{M}$ and let $\lambda^P_{\epsilon_c}$ be the long-term average rewards following the optimal policy $\pi_c$ for the $\epsilon_c$ tight optimization problem for the true MDP $\mathcal{M}$, then for $\epsilon_c \leq \delta$, we have,

$$f(\lambda^P_{\pi}) - f(\lambda^P_{\epsilon_c}) \leq \frac{2L\epsilon_c}{\delta}$$

(27)

**Proof** [Proof Sketch] We construct a policy for which the steady state distribution is the weighted average of two steady state distributions. First distribution is for the optimal policy for the true optimization problem. Second distribution is for the policy which satisfies Assumption 4. Now, we show that this constructed policy satisfies the $\epsilon_c$-tight constraints. Now, using Lipschitz continuity, we convert the difference between function value into the difference between the long-term average reward to obtain the required result.

The detailed proof is provided in Appendix A.

Lemma 1 and our construction of $\epsilon_c$ sequence allows us to limit the growth of regret because of conservative policy by $O(LdDS\sqrt{A/T})$. 

8
To bound the regret from the second source, we propose a novel Bellman error based analysis. In our next lemma, we show that the difference between the performance of a policy on two different MDPs is bounded by long-term averaged Bellman error. Formally, we have:

**Lemma 2** The difference of long-term average rewards for running the optimistic policy $\pi_e$ on the optimistic MDP, $\lambda^P_{\pi_e}$, and the average long-term average rewards for running the optimistic policy $\pi_e$ on the true MDP, $\lambda^P_{\pi_e}$, is the long-term average Bellman error as

$$\lambda^P_{\pi_e} - \lambda^P_{\pi_e} = \sum_{s,a} \rho^P_{\pi_e} B^\pi_{\pi_e}(s,a)$$

(28)

**Proof** [Proof Sketch] We start by writing $Q^\pi_{\pi_e}$ in terms of the Bellman error. Now, subtracting $V^\pi_{\pi_e}$ from $V^\pi_{\pi_e}$ and using the fact that $\lambda^P_{\pi_e} = \lim_{\gamma \to 1} V^\pi_P$ and $\lambda^P_{\pi_e} = \lim_{\gamma \to 1} V^\pi_{\tilde{P}}$ we obtain the required result. A complete proof is provided in Appendix B.

After relating the gap between the long-term average rewards of policy $\pi_e$ on the two MDPs, we now want to bound the sum of Bellman error over an epoch. For this, we first bound the Bellman error for a particular state action pair $s, a$ in the form of following lemma. We have,

**Lemma 3** With probability at least $1 - 1/t^6$, the Bellman error $B^\pi_{\pi_e}(s,a)$ for state-action pair $s, a$ in epoch $e$ is upper bounded as

$$B^\pi_{\pi_e}(s,a) \leq \sqrt{\frac{14S \log(2AT)}{1 \lor N_e(s,a)}} D$$

(29)

**Proof** [Proof Sketch] We start by noting that the Bellman error essentially bounds the impact of the difference in value obtained because of the difference in transition probability to the immediate next state. We bound the difference in transition probability between the optimistic MDP and the true MDP using the result from Weissman et al. (2003). This approach gives the required result. A complete proof is provided in Appendix B.

To bound the regret because of the imperfect knowledge of the system model, we can now use Lemma 2 and Lemma 3. We now bound the expected Bellman error in epoch $e$ starting from state $s_t$, and action $a_t$, by constructing a Martingale sequence with filtration $F_t = \{s_1, a_1, \cdots, s_{t-1}, a_{t-1}\}$ and using Azuma’s inequality Bercu et al. (2015). Using the Azuma’s inequality, we can also bound the deviations because of the stochasticity of the Markov Decision Process. The result is stated in the following lemma.

**Lemma 4** With probability at least $1 - T^{-5/4}$, the regret incurred from imperfect model knowledge and process stochastics is bounded by

$$DS \sqrt{A(\log AT)/T}$$

(30)

The regret analysis framework also prepares us to bound the constraint violations as well. We again start by quantifying the reasons for constraint violations. The major reason the agent violates the constraint is because it is playing with the imperfect knowledge of the MDP and the stochasticity of the MDP which results in the deviation from the average costs. We note that the conservative policy $\pi_e$ for every epoch does not violate the constraints, but instead allows the agent to manage the constraint violations because of the imperfect model knowledge and the system dynamics.

We note that the Lipschitz continuity of the constraint function $g$ allows us to convert the function of $d$ averaged costs to the sum of $d$ averaged costs. Further, we note that we can treat the cost similar to rewards Brantley et al. (2020). This property allows us to bound the cost incurred incurred in a way similar to how we bound the gap from the optimal reward by $LdDS \sqrt{A(\log AT)/T}$. We now want that the slackness provided
Figure 1: Performance of the proposed UC-CURL algorithm on a flow and service control problem for a single queue with respect to algorithmic parameter $K$ and choice of policy update times. The algorithm does not violate the constraints for higher value of $K$ at the expense of rewards regret.

by the conservative policy should allow $LdDS\sqrt{A(\log AT)/T}$ constraint violations. This is ensured by our chosen $\epsilon_e$ sequence. We formally state that result in the following lemma proven in parts in Appendix B and Appendix C.

**Lemma 5** The cumulative sum of the $\epsilon_e$ sequence is upper and lower bounded as,

$$\sum_{e=1}^{E} (t_{e+1} - t_e)\epsilon_e = \Theta \left( LdDS\sqrt{A T \log T} \right)$$

(31)

After giving the details on bounds on the possible sources of regret and constraint violations, we can formally state the result in the form of following theorem.

**Theorem 1** For all $T$ and $K = \Theta(LdDS\sqrt{A})$, the regret $R(T)$ of UC-CURL algorithm is bounded by

$$R(T) = O \left( \frac{1}{\delta} LdDS\sqrt{A \log AT} \right)$$

(32)

and the constraints are bounded as $C(T) = O(1/T)$, with probability at least $1 - \frac{1}{T^{5/4}}$. 

10
Our Bellman error based analysis allows us to remove the dependency on bounding the number of epochs for infinite-horizon MDPs algorithms. We believe this is an important step to close the gap between the finite-horizon MDP algorithms and infinite-horizon MDP algorithms. Further, our decaying conservative parameter $\epsilon_c$ also appears in the optimality of parameter knowledge of $T$ for practical algorithms.

The agent solves the $\epsilon_c$-tight optimization problem for the optimistic MDP at every epoch which may be a computationally inefficient step. Thus, the agent can still prefer to choose a lesser number of epochs to reduce this computational cost. Thus, an agent can choose a tradeoff between sample efficiency by updating policy frequently and computational efficiency of the logarithmic number of epochs.

6. Experimental Studies

We now evaluate the empirical performance of the proposed UC-CURL algorithm using the flow and service control in a single-server queue, which is introduced in (Altman and Schwartz, 1991).

We consider a discrete-time queue with a buffer of finite size $L$. The state is the number of customers waiting in the queue with $S = L + 1$. The system has two types of actions, service and flow, to control the number of customers. At time $t$, the agent takes action $a_t = (a_t(1), a_t(2))$ from a finite subset of $[0, 1] \times [0, 1]$, where $a_t(1)$ is the service action and $a_t(2)$ is the flow action. The service action $a_t(1)$ reduces the queue length by 1 with probability $a_t(1)$, and the flow action increases the queue by 1 with probability $a_t(2)$. Also, we assume that there is no customer arriving when the queue is full. The precise environment and implementation details are provided in Appendix E.

For $a_t \sim \pi$, the optimization problem is defined as

$$
\max_\pi \lim_{T \to \infty} \frac{1}{T} \sum_{t=1}^{T} (5 - s_t)
$$

subject to

$$
\lim_{T \to \infty} \frac{1}{T} \sum_{t=1}^{T} (6 - 10a_t(1)) \geq 0
$$
$$
\lim_{T \to \infty} \frac{1}{T} \sum_{t=1}^{T} (2 - 8(1 - a_t(2))^2) \geq 0
$$

We use the length of horizon $T = 10^5$ and run 100 independent simulations of the proposed UC-CURL algorithm. The result is shown in the Figure 1. The average values of the long-term averaged reward and the constraint functions are shown in the solid lines, and the shadow region denotes the standard deviation. In order to compare this result to the optimal, we assume that the full information of the transition dynamics is known and then use Linear Programming to solve the problem. The optimal expected reward from LP is 4.08 for the true MDP. We now make the following observations based on the simulation results.

Effect of the frequency of policy updates: We compare the UC-CURL algorithm in Algorithm 1 with a modified algorithm which updates the policy after every interaction with the environment. The number of epochs in Algorithm 1 is bounded by $O(SA \log(T))$ (Jaksch et al., 2010, Proposition 18) whereas the number of epochs of the modified algorithm is $T$. Our claim that the proposed regret bounds do not depend on the number of epochs, is empirically evident in Figure 1a. The regret of the doubling epoch based algorithm 1 matches the regret guarantees of the everytime policy update strategy, however it does not match the performance empirically. However, the doubling epoch based algorithm obtains lower constraint violations as the agent plays $\epsilon_c$-conservative policy for longer duration, thus violating constraints less (Figure 1c and Figure 1b). Compared to this, the agent which updates the policy after every interaction, plays a less conservative policy and this results in empirically increased constraints violations.

Effect of the parameter $K$ in UC-CURL algorithm: We note that in practice the optimal $K = LdDS/\sqrt{A}$ may be difficult to precisely calculate. Hence, we evaluate the proposed UC-CURL algorithm for various values of $K$. If we choose the multiplication factor $K = 0$, we will not be achieving zero constraint violations but still bounding the constraint violations with $O(LdDS/\sqrt{T})$. Note that as we increase the value of $K$, the constraint violations decrease in Figure 1b and Figure 1c. However, this results in a lower reward value as observed in Figure 1a. In principle, the agent must select $K$ which allows to obtain a feasible policy and reduce the violations.
7. Conclusion

We considered the problem of constrained Markov Decision Process with concave objective and convex constraint. For this problem, we proposed UC-CURL algorithm which works on the principle of optimism. To bound the constraint violations, we solve for a conservative policy using an optimistic model for an $\epsilon$-tight optimization problem. Using a novel analysis based on Bellman error for infinite-horizon MDPs, we show the UC-CURL algorithm achieves $O(1/T)$ constraint violations with a regret bound of $\tilde{O}(LdDS\sqrt{A/T})$. A major limitation of the work in its current form is the algorithm parameter $K$. Dynamically configuring $K$ is an interesting direction for future work. Other future works include making the algorithm more computationally efficient and creating model-free algorithms.

References

Appendix A. Proof of Lemma 1

Proof Note that $\rho_{\pi^*}^P(s,a)$ denotes the stationary distribution of the optimal solution which satisfies

$$g \left( \sum_{s,a} \rho_{\pi^*}^P(s,a)c_1(s,a), \cdots, \sum_{s,a} \rho_{\pi^*}^P(s,a)c_d(s,a) \right) \leq C$$

(34)

Further, from Assumption 4, we have a feasible policy $\pi$ for which

$$g \left( \sum_{s,a} \rho_{\pi}^P(s,a)r_1(s,a), \cdots, \sum_{s,a} \rho_{\pi}^P(s,a)r_K(s,a) \right) \leq C - \delta$$

(35)

We now construct a stationary distribution $\rho^P$ obtain the corresponding $\pi'_e$ as:

$$\rho^P(s,a) = \left( 1 - \frac{\epsilon_e}{\delta} \right) \rho_{\pi^*}^P(s,a) + \frac{\epsilon_e}{\delta} \rho_{\pi}^P(s,a)$$

(36)

$$\pi'_e = \frac{\rho^P(s,a)}{\sum_{s,b} \rho^P(s,b)}$$

(37)

For this new policy, for the convex constraint $g$, we observe that,

$$g \left( \sum_{s,a} \rho_{\pi}^P(s,a)c_1(s,a), \cdots, \sum_{s,a} \rho_{\pi}^P(s,a)c_d(s,a) \right)$$

(38)

$$= g \left( \sum_{s,a} \left( \left( 1 - \frac{\epsilon_e}{\delta} \right) \rho_{\pi^*}^P(s,a) + \frac{\epsilon_e}{\delta} \rho_{\pi}^P(s,a) \right) r_1(s,a), \cdots, \sum_{s,a} \left( \left( 1 - \frac{\epsilon_e}{\delta} \right) \rho_{\pi^*}^P(s,a) + \frac{\epsilon_e}{\delta} \rho_{\pi}^P(s,a) \right) r_K(s,a) \right)$$

(39)

$$\leq \left( 1 - \frac{\epsilon_e}{\delta} \right) g \left( \sum_{s,a} \rho_{\pi^*}^P(s,a)c_1(s,a), \cdots, \sum_{s,a} \rho_{\pi^*}^P(s,a)c_d(s,a) \right)$$

$$+ \frac{\epsilon_e}{\delta} g \left( \sum_{s,a} \rho_{\pi}^P(s,a)c_1(s,a), \cdots, \sum_{s,a} \rho_{\pi}^P(s,a)c_d(s,a) \right)$$

(40)

$$\leq \left( 1 - \frac{\epsilon_e}{\delta} \right) C + \frac{\epsilon_e}{\delta} (C - \delta)$$

(41)

$$= C - \delta \leq C - \epsilon_e$$

(42)

where Equation (40) follows from the convexity of the constraints. Equation (41) follows from Equation (34) and Equation (35).

Now, note that the policy $\pi'_e$ corresponding to stationary distribution constructed in Equation (36) satisfies the $\epsilon_e$-tight constraints. Further, we find $\pi^*_e$ as the optimal solution for the $\epsilon_e$-tight optimization problem. Hence,
we have

\[
\begin{align*}
\frac{\sum_{s,a} \rho_\pi^P(s,a)r(s,a)}{f} - \frac{\sum_{s,a} \rho^P(s,a)r(s,a)}{f} & \leq \frac{\sum_{s,a} \rho_\pi^P(s,a)r(s,a)}{f} - \frac{\sum_{s,a} \rho^P(s,a)r(s,a)}{f} \\
& \leq L \left| \sum_{s,a} (\rho_\pi^P(s,a) - \rho^P(s,a)) r(s,a) \right| \quad (44) \\
& \leq L \left| \sum_{s,a} \left( \rho_\pi^P(s,a) - \frac{1 - \epsilon}{\delta} \rho_\pi^P(s,a) - \frac{\epsilon}{\delta} \rho^P(s,a) \right) r(s,a) \right| \quad (45) \\
& \leq L \frac{\epsilon}{\delta} \left| \sum_{s,a} \rho_\pi^P(s,a) - \rho^P(s,a) \right| r(s,a) \quad (46) \\
& \leq L \frac{\epsilon}{\delta} \left| \sum_{s,a} \rho_\pi^P(s,a) r(s,a) \right| + L \frac{\epsilon}{\delta} \left| \sum_{s,a} \rho^P(s,a) r(s,a) \right| \\
& \leq 2L \frac{\epsilon}{\delta} \quad (48)
\end{align*}
\]

where, Equation (44) follows from the Lipschitz assumption on the joint objective \( f \). Equation (48) follows from the fact that \( r_k(s,a) \leq 1 \) for all \( k \in [K] \) and for all \( (s,a) \in S \times A \).
Appendix B. Objective Regret Bound

To bound the regret $R(T)$, we first consider two cases. First case is where the confidence intervals in Equation (22).

For the second case now holds with probability at-least $1 - \frac{1}{T\gamma_T}$, we break the regret into multiple components. We can then bound these components individually.

**Regret breakdown**

We first break down our regret into multiple parts which will help us bound the regret.

$$R(T) = f(\lambda_t^T) - f\left(\frac{1}{T} \sum_{t=1}^{T} r_t(s_t, a_t)\right)$$

$$= f(\lambda_t^T) - \frac{1}{T} \sum_{e=1}^{E} T_e f(\lambda_t^{P_e}) - f\left(\frac{1}{T} \sum_{t=1}^{T} r_t(s_t, a_t)\right)$$

$$= \frac{1}{T} \sum_{e=1}^{E} T_e \left(f(\lambda_t^P) - f(\lambda_t^{P_e})\right) + \frac{1}{T} \sum_{e=1}^{E} T_e f(\lambda_t^{P_e}) - f\left(\frac{1}{T} \sum_{t=1}^{T} r_t(s_t, a_t)\right)$$

$$\leq \frac{1}{T} \sum_{e=1}^{E} T_e \left(f(\lambda_t^P) - f(\lambda_t^{P_e})\right) + \frac{1}{T} \sum_{e=1}^{E} T_e f(\lambda_t^{P_e}) - f\left(\frac{1}{T} \sum_{t=1}^{T} r_t(s_t, a_t)\right)$$

$$\leq \frac{1}{T} \sum_{e=1}^{E} T_e \left(f(\lambda_t^P) - f(\lambda_t^{P_e})\right) + \lambda \frac{1}{T} \sum_{e=1}^{E} \sum_{t=t_e}^{t_e+1-1} \left(\lambda_t^{P_e} - \lambda_t^P - r_t(s_t, a_t)\right)$$

$$= R_1(T) + R_2(T) + R_3(T)$$

where Equation (52) comes from the fact that the policy $\pi_e$ is for the optimistic CMDP and provides a higher value of the function $f$. Equation 53 comes from the concavity of the function $f$, and Equation 54 comes from the Lipschitz continuity of the function $f$. The three terms in Equation (57) are now defined as:

$$R_1(T) = \frac{1}{T} \sum_{e=1}^{E} T_e \left(f(\lambda_t^P) - f(\lambda_t^{P_e})\right)$$

$R_1(T)$ denotes the regret incurred from not playing the optimal policy $\pi^*$ for the true optimization problem in Equation (14) but the optimal policy $\pi_e^*$ for the $\epsilon_e$-tight optimization problem in epoch $e$.

$$R_2(T) = \frac{1}{T} \sum_{e=1}^{E} \sum_{t=t_e}^{t_e+1-1} \left(\lambda_t^{P_e} - \lambda_t^P\right)$$

$R_2(T)$ denotes the gap between expected rewards from playing the optimal policy $\pi_e$ for $\epsilon_e$-tight optimization problem on the optimistic MDP instead of the true MDP.
\[ R_3(T) = \frac{L}{T} \sum_{\epsilon=1}^{E} \sum_{t_{\epsilon}+1}^{t_{\epsilon+1}-1} (\lambda \pi^\epsilon - r_t(s_t, a_t)) \] 

(60)

\( R_3(T) \) denotes the gap between obtained rewards from playing the optimal policy \( \pi_\epsilon \) for \( \epsilon \)-tight optimization problem the true MDP and the expected per-step reward of playing the optimal policy \( \pi_\epsilon \) for \( \epsilon \)-tight optimization problem the true MDP.
Bounding $R_1(T)$

Bounding $R_1(T)$ requires using Lemma 1. We have the following set of equations:

$$R_1(T) = \frac{1}{T} \sum_{e=1}^{E} \sum_{t=t_e}^{t_{e+1}-1} \left( f(\lambda^P_e) - f(\lambda^*_{e,t}) \right)$$  \hspace{1cm} (61)

$$\leq \frac{1}{T} \sum_{e=1}^{E} \sum_{t=t_e}^{t_{e+1}-1} \frac{2Le}{t}$$  \hspace{1cm} (62)

$$= \frac{2L}{T\delta} \sum_{e=1}^{E} \sum_{t=t_e}^{t_{e+1}-1} \sqrt{\frac{\log t}{t}}$$  \hspace{1cm} (63)

$$\leq \frac{2L}{T\delta} \sum_{e=1}^{E} \sum_{s,a} \nu_e(s,a) \frac{\sqrt{\log T}}{N_e(s,a)}$$  \hspace{1cm} (64)

$$\leq \frac{2L}{T\delta} \sum_{s,a} \sum_{e=1}^{E} \nu_e(s,a) \frac{\sqrt{\log T}}{N_e(s,a)}$$  \hspace{1cm} (65)

$$\leq (\sqrt{2} + 1) \frac{2L}{T\delta} \sqrt{\log T} \frac{\sum_{s,a} N(s,a)}{T\delta}$$  \hspace{1cm} (66)

$$\leq (\sqrt{2} + 1) \frac{2L}{T\delta} \sqrt{\log T} \sqrt{\sum_{s,a} N(s,a)}$$  \hspace{1cm} (67)

$$\leq (\sqrt{2} + 1) \frac{2L}{T\delta} \sqrt{\log T} \sqrt{SAT}$$  \hspace{1cm} (68)

where Equation (64) follows from the fact that $\log t \leq \log T$ for all $t \leq T$ and $N_e(s,a) \leq t_e \leq t$ for all $t$. The bound on summation over $e$ in Equation (66) follows from (Jaksch et al., 2010, Lemma 19). Finally, equation (67) follows from the Cauchy-Schwarz inequality.
Bounding $R_2(T)$

We relate the difference between long-term average rewards for running the optimistic policy $\pi_e$ on the optimistic MDP $\lambda^P_{\pi_e}$ and the long-term average rewards for running the optimistic policy $\pi_e$ on the true MDP $(\lambda^P_e)$ with the Bellman error. Formally, we have the following lemma:

**Lemma 6** The difference of long-term average rewards for running the optimistic policy $\pi_e$ on the optimistic MDP, $\lambda^P_{\pi_e}$, and the average long-term average rewards for running the optimistic policy $\pi_e$ on the true MDP, $\lambda^P_e$, is the long-term average Bellman error as

$$\lambda^P_{\pi_e} - \lambda^P_e = \sum_{s,a} \rho^P_{\pi_e} B^\pi_e(s,a)$$

(69)

**Proof** Note that for all $s \in S$, we have:

$$V^\pi_e(s) = \mathbb{E}_{a \sim \pi_e} \left[ Q^\pi_e(s,a) \right]$$

(70)

where Equation (71) follows from the definition of the Bellman error for state action pair $s,a$.

Similarly, for the true MDP, we have,

$$V^\pi_e(s) = \mathbb{E}_{a \sim \pi_e} \left[ Q^\pi_e(s,a) \right]$$

(72)

Subtracting Equation (73) from Equation (71), we get:

$$V^\pi_e(s) - V^\pi_e(s) = \mathbb{E}_{a \sim \pi_e} \left[ B^\pi_e(s,a) + \gamma \sum_{s' \in S} P(s'|s,a) V^\pi_e(s') \right]$$

(74)

Using the vector format for the value functions, we have,

$$\tilde{V}^\pi_e(s) - \tilde{V}^\pi_e(s) = (I - \gamma P_{\pi_e})^{-1} B^\pi_e$$

(76)

Now, converting the value function to average per-step reward we have,

$$\lambda^P_{\pi_e} 1_S - \lambda^P_e 1_S = \lim_{\gamma \to 1} (1 - \gamma) \left( \tilde{V}^\pi_e(s) - \tilde{V}^\pi_e(s) \right)$$

(77)

$$= \lim_{\gamma \to 1} (1 - \gamma) (I - \gamma P_{\pi_e})^{-1} B^\pi_e$$

(78)

$$= \left( \sum_{s,a} \rho^P_{\pi_e} B^\pi_e(s,a) \right) 1_S$$

(79)

where the last equation follows from the definition of occupancy measures by Puterman (2014).

**Remark 2** Note that the Bellman error is not to be confused by Advantage function and policy improvement lemma Langford and Kakade (2002). The policy improvement lemma relates the performance of two policies on same MDP whereas we bounded the performance of one policy on two different MDPs in Lemma 6.
We now want to bound the Bellman errors to bound the gap between the average per-step reward $\lambda_{\pi,e}^B$, and $\lambda_{\pi,e}^P$. From the definition of Bellman error and the confidence intervals on the estimated transition probabilities, we obtain the following lemma:

**Lemma 7** With probability at least $1 - 1/\ell_e^3$, the Bellman error $B^{\pi,e,\hat{P}_e}(s,a)$ for state-action pair $s,a$ in epoch $e$ is upper bounded as

$$B^{\pi,e,\hat{P}_e}(s,a) \leq \sqrt{\frac{14S \log(2AT)}{1 \lor N_e(s,a)}} D$$

**Proof** Starting with the definition of Bellman error in Equation (26), we get

$$B^{\pi,e,\hat{P}_e}(s,a) = \lim_{\gamma \rightarrow 1} \left( Q^{\pi,e,P}_{\gamma}(s,a) - \left( r(s,a) + \gamma \sum_{s' \in S} P(s'|s,a) V_{\gamma,e}^{\pi,e,\hat{P}_e}(s') \right) \right)$$

$$= \lim_{\gamma \rightarrow 1} \left( r(s,a) + \gamma \sum_{s' \in S} \hat{P}_e(s'|s,a) V_{\gamma,e}^{\pi,e,\hat{P}_e}(s') - \left( r(s,a) + \gamma \sum_{s' \in S} P(s'|s,a) V_{\gamma,e}^{\pi,e,\hat{P}_e}(s') \right) \right)$$

$$= \lim_{\gamma \rightarrow 1} \gamma \sum_{s' \in S} \left( \hat{P}_e(s'|s,a) - P(s'|s,a) \right) V_{\gamma,e}^{\pi,e,\hat{P}_e}(s')$$

$$= \lim_{\gamma \rightarrow 1} \gamma \sum_{s' \in S} \left( \hat{P}_e(s'|s,a) - P(s'|s,a) \right) V_{\gamma,e}^{\pi,e,\hat{P}_e}(s') + V_{\gamma,e}^{\pi,e,\hat{P}_e}(s) - V_{\gamma,e}^{\pi,e,\hat{P}_e}(s)$$

$$= \lim_{\gamma \rightarrow 1} \gamma \sum_{s' \in S} \left( \hat{P}_e(s'|s,a) - P(s'|s,a) \right) V_{\gamma,e}^{\pi,e,\hat{P}_e}(s') - \sum_{s' \in S} \hat{P}_e(s'|s,a) V_{\gamma,e}^{\pi,e,\hat{P}_e}(s) + \sum_{s' \in S} P(s'|s,a) V_{\gamma,e}^{\pi,e,\hat{P}_e}(s)$$

$$= \lim_{\gamma \rightarrow 1} \gamma \sum_{s' \in S} \left( \hat{P}_e(s'|s,a) - P(s'|s,a) \right) \left( V_{\gamma,e}^{\pi,e,\hat{P}_e}(s') - V_{\gamma,e}^{\pi,e,\hat{P}_e}(s) \right)$$

$$\leq \left\| \hat{P}_e(\cdot|s,a) - P(\cdot|s,a) \right\| \| h(\cdot) \|_{\infty}$$

$$\leq \sqrt{\frac{14S \log(2AT)}{1 \lor N_e(s,a)}} D$$

where Equation (83) comes from the assumption that the rewards are known to the agent. Equation (87) follows from the fact that the difference between value function at two states is bounded. Equation (88) comes from the definition of bias term Puterman (2014). Equation (89) follows from Hölder’s inequality. In Equation (90), $\| h(\cdot) \|_{\infty}$ is bounded by the diameter $D$ Jaksch et al. (2010). Also, the $\ell_1$ norm of probability vector is bounded using Lemma 10 for start time $t_e$ of epoch $e$. 

Additionally, note that the $\ell_1$ norm in Equation (89) is bounded by 2. Thus the Bellman error is loose upper bounded by $2D$ for all state-action pairs.
Note that we have converted the difference of average rewards into the average Bellman error. Also, we have bounded the Bellman error of a state-action pair. We now want to bound the average Bellman error of an epoch using the realizations of Bellman error at state-action pairs visited in an epoch. For this, we present the following lemma.

**Lemma 8** With probability at least $1 - 1/T^6$, the cumulative expected bellman error is bounded as:

$$
\sum_{e=1}^{E} (t_{e+1} - t_e) \mathbb{E}_{\pi_e, P_e} \left[ B^{\pi_e, \tilde{P}_e} (s, a) \right] \leq \sum_{e=1}^{E} \sum_{t=t_e}^{t_{e+1} - 1} B^{\pi_e, \tilde{P}_e} (s_t, a_t) + 4D \sqrt{tT \log(T)} \quad (92)
$$

**Proof** Let $\mathcal{F}_t = \{s_1, a_1, \ldots, s_t, a_t\}$ be the filtration generated by the running the algorithm for $t$ time-steps. Now, for all $E' \in \{1, \ldots, E\}$ and $T' \in \{t'_{E'}, \ldots, t_{E' + 1} - 1\}$, we observe that the sequence

$$
S(E', T') = \sum_{e=1}^{E' - t_{E' + 1} - 1} \sum_{t=t_e}^{t_{e+1} - 1} B^{\pi_e, \tilde{P}_e} (s_t, a_t) + \sum_{t=t_{E'}}^{T'} B^{\pi_e, \tilde{P}_e} (s_t, a_t) - \mathbb{E} \left[ S(E', T') | \mathcal{F}_{T' - 1} \right] \quad (93)
$$

is a zero-mean Martingale sequence. Moreover, the fact that Bellman error is upper bounded by $2D$ for all state action pairs, we also observe that

$$
\max \mathbb{E} \left[ S(E', T') | \mathcal{F}_{T' - 1} \right] - \min \mathbb{E} \left[ S(E', T') | \mathcal{F}_{T' - 1} \right] \leq 4D \quad (94)
$$

Further, we have

$$
\mathbb{E} \left[ S(E', T_{E' + 1} - 1) - S(E' - 1, T_{E' - 1}) | \mathcal{F}_{T_{E' + 1} - 1} \right] = \mathbb{E}_{\pi_e, P_e} \left[ B^{\pi_e, \tilde{P}_e} (s, a) | \mathcal{F}_{T_{E' + 1} - 1} \right] \quad (95)
$$

as the policy $\pi_e$ and transitions $\tilde{P}_e$ for the optimistic MDP in epoch $E' \in \{1, \ldots, E\}$ are $\mathcal{F}_{T_{E' + 1}}$ measurable.

Now, using Azuma’s inequality for Martingale concentration bound, we have

$$
\left| \sum_{e=1}^{E} \sum_{t=t_e}^{t_{e+1} - 1} B^{\pi_e, \tilde{P}_e} (s_t, a_t) - \sum_{e=1}^{E} (t_{e+1} - t_e) \mathbb{E}_{\pi_e, P_e} \left[ B^{\pi_e, \tilde{P}_e} (s, a) \right] \right| \leq 4D \sqrt{T \log(2T)} \quad (96)
$$

$$
\leq 4D \sqrt{T \log(2T)} \quad (97)
$$

Now, using the required sign after removing the modulo operator, we get the required result. \qed

22
We are now ready to bound \( R_2(T) \) using Lemma 6, Lemma 7, and Lemma 8. We have the following set of equations:

\[
R_2(T) = \frac{L}{T} \sum_{e=1}^{E} \sum_{t=t_e}^{t_{e+1}-1} \left( \lambda^{\pi_e} - \lambda^{P_e} \right)
\]

(98)

\[
= \frac{L}{T} \sum_{e=1}^{E} \sum_{t=t_e}^{t_{e+1}-1} \sum_{s,a} \rho_e P^{\pi_e} B_e^{\pi_e} (s, a)
\]

(99)

\[
\leq \frac{L}{T} \sum_{e=1}^{E} \sum_{t=t_e}^{t_{e+1}-1} B^{\pi_e}(s_t, a_t) + 2D \sqrt{\frac{T \log(2T)}{1 \vee N_e(s, a)}}
\]

(100)

\[
\leq \frac{L}{T} \sum_{e=1}^{E} \sum_{t=t_e}^{t_{e+1}-1} D \sqrt{\frac{14S \log(2AT)}{1 \vee N_e(s, a)}} + 2D \sqrt{T \log(2T)}
\]

(101)

\[
\leq \frac{L}{T} \sum_{e=1}^{E} \sum_{s,a} \nu_e(s,a) D \sqrt{\frac{14S \log(2AT)}{1 \vee N_e(s, a)}} + 2D \sqrt{T \log(2T)}
\]

(102)

\[
\leq \frac{L}{T} \sum_{s,a} D (\sqrt{2} + 1) \sqrt{14S A \log(2AT) \nu(s, a) 1 \vee N_e(s, a)} + 2D \sqrt{T \log(2T)}
\]

(103)

\[
\leq \frac{L}{T} \sum_{s,a} D (\sqrt{2} + 1) \sqrt{14SA \log(2AT) \sqrt{N(s, a)} + 2D \sqrt{T \log(2T)}
\]

(104)

\[
\leq \frac{L}{T} D (\sqrt{2} + 1) \sqrt{14SA \log(2AT) \sqrt{N(s, a)}} + 2D \sqrt{T \log(2T)}
\]

(105)

\[
\leq \frac{L}{T} D (\sqrt{2} + 1) \sqrt{14SA \log(2AT) \sqrt{SAT} + 2D \sqrt{T \log(2T)}
\]

(106)

where Equation (99) follows from Lemma 6, Equation (100) follows from Lemma 8, and Equation (101) follows from Lemma 8. Equation (104) follows from (Jaksch et al., 2010, Lemma 19) and Equation (105) follows from Cauchy-Schwarz inequality.
Bounding $R_3(T)$

Bounding $R_3(T)$ follows mostly similar to Lemma 8. At each epoch, the agent visits states according to the occupancy measure $\rho^P_{\pi_e}$ and obtains the rewards. We bound the deviation of the observed visitations to the expected visitations to each state action pair in each epoch.

**Lemma 9** With probability at least $1 - 1/T^6$, the difference between the observed rewards and the expected rewards is bounded as:

$$\left| \sum_{e=1}^{E} (t_{e+1} - t_e) E_{\pi_e, P} [r(s, a)] - \sum_{e=1}^{E} \sum_{t=t_e}^{t_{e+1}-1} r(s_t, a_t) \right| \leq 2 \sqrt{7T \log(T)}$$

(107)

**Proof** Let $\mathcal{F}_t = \{s_1, a_1, \cdots, s_t, a_t\}$ be the filtration generated by the running the algorithm for $t$ time-steps. Now, for all $E' \in \{1, \cdots, E\}$ and $T' \in \{t'_{E'}, \cdots, t_{E'+1} - 1\}$, we observe that the sequence

$$S(E', T') = \sum_{e=1}^{E'-1} \sum_{t=t_e}^{t_{e+1}-1} r(s_t, a_t) + \sum_{t=t_{E'}}^{T'} r(s_t, a_t) - E [S(E', T') | \mathcal{F}_{T'-1}]$$

(108)

is a zero-mean Martingale sequence. Moreover, using the fact that reward is upper bounded by 1 for all state action pairs, we also observe that

$$\max E \left[ S(E', T') | \mathcal{F}_{T'-1} \right] - \min E \left[ S(E', T') | \mathcal{F}_{T'-1} \right] \leq 2$$

(109)

Further, we have

$$E \left[ S(E', T_{E'+1} - 1) - S(E' - 1, T_{E'} - 1) | \mathcal{F}_{T_{E'+1}-1} \right] = E_{\pi_e, P} [r(s, a) | \mathcal{F}_{T_{E'}-1}]$$

(110)

as the policy $\pi_e$ and transitions $\tilde{P}_e$ for the optimistic MDP in epoch $E' \in \{1, \cdots, E\}$ are $\mathcal{F}_{T_{E'}}$ measurable.

Now, using Azuma’s inequality for Martingale concentration bound, we have

$$\left| \sum_{e=1}^{E} \sum_{t=t_e}^{t_{e+1}-1} r(s_t, a_t) - \sum_{e=1}^{E} (t_{e+1} - t_e) \lambda_{\pi_e, P} \right| \leq 2 \sqrt{7T \log(2T)}$$

(111)

and

$$2 \sqrt{7T \log(2T)}$$

(112)
Appendix C. Bounding Constraint Violations

To bound the constraint violations \(C(T)\), we break it into multiple components. We can then bound these components individually.

**Constraint breakdown**

We first break down our regret into multiple parts which will help us bound the regret.

\[
C(T) = \left( g \left( \frac{1}{T} \sum_{t=1}^{T} c_1(s_t, a_t), \cdots, \frac{1}{T} \sum_{t=1}^{T} c_d(s_t, a_t) \right) \right) + \sum_{i=1}^{d} T \sum_{e=1}^{E} \sum_{t=t_e}^{t_e+1-1} \left( c_i(s_t, a_t) - \zeta_{\pi_e}^P (i) \right) \leq \frac{1}{T} \sum_{e=1}^{E} T_e \epsilon_e \tag{113}
\]

\[
\leq \left( \frac{1}{T} \sum_{t=1}^{T} c_1(s_t, a_t), \cdots, \frac{1}{T} \sum_{t=1}^{T} c_d(s_t, a_t) \right) - \frac{1}{T} \sum_{e=1}^{E} T_e \epsilon_e \tag{114}
\]

\[
\leq \left( g \left( \frac{1}{T} \sum_{t=1}^{T} c_1(s_t, a_t), \cdots, \frac{1}{T} \sum_{t=1}^{T} c_d(s_t, a_t) \right) - g \left( \frac{1}{T} \sum_{e=1}^{E} T_e \zeta_{\pi_e}^P (1), \cdots, \frac{1}{T} \sum_{e=1}^{E} T_e \zeta_{\pi_e}^P (d) \right) - \frac{1}{T} \sum_{e=1}^{E} T_e \epsilon_e \right) \tag{115}
\]

\[
\leq \left( \frac{1}{T} \sum_{i=1}^{d} \sum_{e=1}^{E} \sum_{t=t_e}^{t_e+1-1} \left( c_i(s_t, a_t) - \zeta_{\pi_e}^P (i) \right) \right) - \frac{1}{T} \sum_{e=1}^{E} T_e \epsilon_e \tag{116}
\]

\[
\leq \left( L \sum_{i=1}^{d} \sum_{e=1}^{E} \sum_{t=t_e}^{t_e+1-1} \left( c_i(s_t, a_t) - \zeta_{\pi_e}^P (i) \right) \right) - \frac{1}{T} \sum_{e=1}^{E} T_e \epsilon_e \tag{117}
\]

\[
\leq \left( \frac{1}{T} \sum_{i=1}^{d} \sum_{e=1}^{E} \sum_{t=t_e}^{t_e+1-1} \left( c_i(s_t, a_t) - \zeta_{\pi_e}^P (i) + \zeta_{\pi_e}^P (i) - \zeta_{\pi_e}^P (i) \right) \right) - \frac{1}{T} \sum_{e=1}^{E} T_e \epsilon_e \tag{118}
\]

\[
\leq \left( \frac{L}{T} \sum_{i=1}^{d} \sum_{e=1}^{E} \sum_{t=t_e}^{t_e+1-1} \left( c_i(s_t, a_t) - \zeta_{\pi_e}^P (i) \right) \right) + \frac{L}{T} \sum_{i=1}^{d} \sum_{e=1}^{E} \sum_{t=t_e}^{t_e+1-1} \left( \zeta_{\pi_e}^P (i) - \zeta_{\pi_e}^P (i) \right) - \frac{1}{T} \sum_{e=1}^{E} T_e \epsilon_e \tag{119}
\]

\[
\leq (C_3(T) + C_2(T) - C_1(T))_+ \tag{120}
\]

where Equation (52) comes from the fact that the policy \(\pi_e\) is for the optimistic CMDP and provides a higher value of the function \(f\). Equation 53 comes from the concavity of the function \(f\), and Equation 54 comes from the Lipschitz continuity of the function \(f\). The three terms in Equation (57) are now defined as:

\[
C_1(T) = \frac{1}{T} \sum_{e=1}^{E} T_e \epsilon_e \tag{121}
\]

\(C_1(T)\) denotes the gap left by playing the policy for \(\epsilon_e\)-tight optimization problem on the optimistic MDP.

\[
C_2(T) = \frac{L}{T} \sum_{i=1}^{d} \sum_{e=1}^{E} \sum_{t=t_e}^{t_e+1-1} \left( \zeta_{\pi_e}^P (i) - \zeta_{\pi_e}^P (i) \right) \tag{122}
\]

\(C_2(T)\) denotes the difference between long-term average costs incurred by playing the policy \(\pi_e\) on the true MDP with transitions \(P\) and the optimistic MDP with transitions \(\tilde{P}\). This term is bounded similar to the bound of \(R_2(T)\).
\[ C_3(T) = \frac{1}{T} \sum_{t=1}^{d} \left( \sum_{e=1}^{E} \sum_{t=t_e}^{t_{e+1}-1} (c_t(s_t, a_t) - \zeta_{\pi_e}(i)) \right) \]  

(123)

\( C_3(T) \) denotes the difference between long-term average costs incurred by playing the policy \( \pi_e \) on the true MDP with transitions \( P \) and the realized costs. This term is bounded similar to the bound of \( R_3(T) \).
Bounding $C_1(T)$

Note that $C_1(T)$ allows us to violate constraints by not having the knowledge of the true MDP and allowing deviations of incurred costs from the expected costs. We now want to lower bound $C_1$ to allow us sufficient slackness. With this idea, we have the following set of equations.

\[
C_1(T) = \frac{1}{T} \sum_{e=1}^{E} \sum_{t=t_e}^{t_e+1-1} \epsilon_e
\]

\[
= \frac{1}{T} \sum_{e=1}^{E} \sum_{t=t_e}^{t_e+1-1} K \frac{\log t_e}{t_e}
\]

\[
\geq K \frac{1}{T} \sum_{e=1}^{E} \sum_{t=t_e}^{t_e+1-1} \frac{\log(T/4)}{t_e}
\]

\[
\geq K \frac{1}{T} \sum_{e=1}^{E} \sum_{t=t_e}^{t_e+1-1} \frac{\log(T/4)}{T}
\]

\[
= K \frac{1}{T} (T - t_{E'}) \frac{\log(T/4)}{T}
\]

\[
\geq K \frac{1}{2} \sqrt{\frac{\log(T/4)}{T}}
\]

\[
\geq K \frac{1}{4} \sqrt{\frac{\log T}{T}}
\]

where $E'$ is some epoch for which $T/4 \leq t_{E'} < T/2$.

Bounding $C_2(T)$, and $C_3(T)$

We note that costs incurred in $C_2(T)$, and $C_3(T)$ follows the same bound as $R_2(T)$ and $R_3(T)$ respectively.

Summing the three terms gives the required bound and choosing $K = \Theta(LdDS\sqrt{A})$. 

27
Appendix D. Concentration bound results

We want to bound the deviation of the estimates of the estimated transition probabilities of the Markov Decision Processes $\mathcal{M}$. For that we use $\ell_1$ deviation bounds from (Weissman et al., 2003). Consider, the following event,

$$\mathcal{E}_t = \left\{ \| \hat{P}(\cdot|s,a) - P(\cdot|s,a) \|_1 \leq \sqrt{\frac{14S \log(2AT)}{\max\{1,n(s,a)\}}} \forall (s,a) \in \mathcal{S} \times \mathcal{A} \right\}$$  \hspace{1cm} (131)

where $n = \sum_{t' = 1}^{t} 1_{\{s_{t'} = s, a_{t'} = a\}}$. Then we have, the following lemma:

**Lemma 10** The probability that the event $\mathcal{E}_t$ fails to occur is upper bounded by $\frac{1}{20A^5}$.

**Proof** From the result of (Weissman et al., 2003), the $\ell_1$ distance of a probability distribution over $S$ events with $n$ samples is bounded as:

$$P \left( \| P(\cdot|s,a) - \hat{P}(\cdot|s,a) \|_1 \geq \epsilon \right) \leq (2S - 2) \exp \left( -\frac{n\epsilon^2}{2} \right) \leq (2S) \exp \left( -\frac{n\epsilon^2}{2} \right)$$  \hspace{1cm} (132)

This, for $\epsilon = \sqrt{\frac{2}{n(s,a) \log(2SA^5)}} \leq \sqrt{\frac{14S}{n(s,a) \log(2AT)}} \leq \sqrt{\frac{14S}{n(s,a) \log(2AT)}}$ gives,

$$P \left( \| P(\cdot|s,a) - \hat{P}(\cdot|s,a) \|_1 \geq \sqrt{\frac{14S}{n(s,a) \log(2AT)}} \right) \leq (2S) \exp \left( -\frac{n(s,a)}{2} \frac{2}{n(s,a) \log(2S20SA^5)} \right)$$  \hspace{1cm} (133)

$$= \frac{2S}{2S20SA^5} \leq \frac{1}{20A^5}$$  \hspace{1cm} (134)

Finally, summing over all the possible values of $n(s,a)$ till $t$ time-step to bound the probability that the event $\mathcal{E}_t$ does not occur as:

$$\sum_{n(s,a) = 1}^{t} \frac{1}{20A^5} \leq \frac{1}{20A^5}$$  \hspace{1cm} (136)

The second lemma is the Azuma-Hoeffding’s inequality, which we use to bound Martingale difference sequences.

**Lemma 11 (Azuma-Hoeffding’s Inequality)** Let $X_1, \cdots, X_n$ be a Martingale difference sequence such that $|X_i| \leq c$ for all $i \in \{1, 2, \cdots, n\}$, then,

$$P \left( \left| \sum_{i=1}^{n} X_i \right| \geq \epsilon \right) \leq 2 \exp \left( -\frac{\epsilon^2}{2nc^2} \right)$$  \hspace{1cm} (138)
Corollary 2 Let \( X_1, \cdots, X_n \) be a Martingale difference sequence such that \( |X_i| \leq c \) for all \( i \in \{1, 2, \cdots, n\} \), then,

\[
\mathbb{E} \left( \left| \sum_{i=1}^{n} X_i \right| \right) \leq O(c \sqrt{n \log n}) \tag{139}
\]

We can now use the Azuma-Hoeffding’s inequality to upper bound the expected value of the expected value of the absolute value of the sum of the \( n \) terms of the Martingale difference sequence \( \{X_i\}_{i=1}^{n} \).

**Proof**

\[
\mathbb{E} \left( \left| \sum_{i=1}^{n} X_i \right| \right) \leq c \sqrt{n \log n} \mathbb{P} \left( \left| \sum_{i=1}^{n} X_i \right| \leq c \sqrt{n \log n} \right) + cn \mathbb{P} \left( \left| \sum_{i=1}^{n} X_i \right| \geq c \sqrt{n \log n} \right) \tag{140}
\]

\[
\leq c \sqrt{n \log n} + cn \left( 2 \exp \left( -\frac{c^2 n \log n}{2nc^2} \right) \right) \tag{141}
\]

\[
= c \sqrt{n \log n} + cn \left( 2 \exp \left( -\frac{\log n}{2} \right) \right) \tag{142}
\]

\[
= c \sqrt{n \log n} + \frac{2}{\sqrt{n}} \tag{143}
\]

\[
= 3c \sqrt{n \log n} \tag{144}
\]

where Equation (141) follows by putting \( \epsilon = c \sqrt{n \log n} \) in Equation (138).  \( \blacksquare \)
Appendix E. Simulation Details

To validate the performance proposed UC-CURL algorithm and the understanding of our analysis, we run the simulation on the flow and service control in a single-serve queue, which is introduced in (Altman and Schwartz, 1991). A discrete-time single-server queue with a buffer of finite size \( L \) is considered in this case. The number of the customer waiting in the queue is considered as the state in this problem and thus \(|S| = L + 1\). Two kinds of the actions, service and flow, are considered in the problem and control the number of customers together. The action space for service is a finite subset \( A \) in \([a_{\text{min}}, a_{\text{max}}]\), where \(0 < a_{\text{min}} \leq a_{\text{max}} < 1\). A given specific service action \( a \), the service a customer is successfully finished with the probability \( b \). If the service is successful, the length of the queue will reduce by 1. Similarly, the space for flow is also a finite subsection \( B \) in \([b_{\text{min}}, b_{\text{max}}]\). In contrast to the service action, flow action will increase the queue by 1 with probability \( b \) if the specific flow action \( b \) is given. Also, we assume that there is no customer arriving when the queue is full. The overall action space is the Cartesian product of the \( A \) and \( B \). According to the service and flow probability, the transition probability can be computed and is given in the Table 2.

### Table 2: Transition probability of the queue system

Define the reward function as \( r(s, a, b) \) and the constraints for service and flow as \( c^1(s, a, b) \) and \( c^2(s, a, b) \), respectively. Define the stationary policy for service and flow as \( \pi_a \) and \( \pi_b \), respectively. Then, the problem can be defined as

\[
\max_{\pi_a, \pi_b} \lim_{T \to \infty} \frac{1}{T} \sum_{t=1}^{T} r(s_t, \pi_a(s_t), \pi_b(s_t))
\]

s.t.

\[
\lim_{T \to \infty} \frac{1}{T} \sum_{t=1}^{T} c^1(s_t, \pi_a(s_t), \pi_b(s_t)) \geq 0 \tag{146}
\]

\[
\lim_{T \to \infty} \frac{1}{T} \sum_{t=1}^{T} c^2(s_t, \pi_a(s_t), \pi_b(s_t)) \geq 0
\]

According to the discussion in (Altman and Schwartz, 1991), we define the reward function as \( r(s, a, b) = 5 - s \), which is an decreasing function only dependent on the state. It is reasonable to give higher reward when the number of customer waiting in the queue is small. For the constraint function, we define \( c^1(s, a, b) = -10a + 6 \) and \( c^2 = -8(1 - b)^2 + 2 \), which are dependent only on service and flow action, respectively. Higher constraint value is given if the probability for the service and flow are low and high, respectively.

In the simulation, the length of the buffer is set as \( L = 5 \). The service action space is set as \([0.2, 0.4, 0.6, 0.8]\) and the flow action space is set as \([0.5, 0.6, 0.7, 0.8]\). We use the length of horizon \( T = 10^3 \) and run 100 independent simulations of the proposed UC-CURL algorithm. The result is shown in the Figure 1. The average values of the cumulative reward and the constraint functions are shown in the solid lines. Also, we plot the standard deviation around the mean value in the shadow to show the random error. It is found that the cumulative reward convergences to about 4. The service and flow constraints converge to 0 as expected. In order to compare this result to the optimal, we assume that the full information of the transition dynamics is known and then use Linear Programming to solve the problem. The optimal cumulative reward from LP is shown to be 4.08. We note that the reward of the proposed UC-CURL algorithm becomes closer the optimal reward as the algorithm proceeds.
Figure 2: Performance of the proposed UC-CURL algorithm on a flow and service control problem for a single queue with respect to algorithmic parameter $K$ and choice of policy update times.
