Abstract

Variational AutoEncoder (VAE) has been extended as a representative nonlinear method for collaborative filtering. However, the bottleneck of VAE lies in the softmax computation over all items, such that it takes linear costs in the number of items to compute the loss and gradient for optimization. This hinders the practical use due to millions of items in real-world scenarios. Importance sampling is an effective approximation method, based on which the sampled softmax has been derived. However, existing methods usually exploit the uniform or popularity sampler as proposal distributions, leading to a large bias of gradient estimation. To this end, we propose to decompose the inner-product-based softmax probability based on the inverted multi-index, leading to sublinear-time and highly accurate sampling. Based on the proposed proposals, we develop a fast Variational AutoEncoder (FastVAE) for collaborative filtering. FastVAE can outperform the state-of-the-art baselines in terms of both sampling quality and efficiency according to the experiments on three real-world datasets.

1 Introduction

Recommendation techniques play a role in information filtering to address the information overload in the era of big data. After decades of development, recommendation techniques have shifted from the latent linear models to deep non-linear models for modeling side features and feature interactions among sparse features. Variational AutoEncoder [17] has been extended as a representative nonlinear method (Mult-VAE) for recommendation [19], and received much attention among the recommender system community in recent years [29, 33, 34, 39, 44]. Mult-VAE encodes each user’s observed data with a Gaussian-distributed latent factor and decodes it to a probability distribution over all items, which is assumed a softmax of the inner-product-based logits. Mult-VAE then exploits multinomial likelihood as the objective function for optimization, which has been proved to be more tailored for implicit feedback than the Gaussian and logistic likelihood.

However, the bottleneck of Mult-VAE lies in the log-partition function over the logits of all items in the multinomial likelihood. The time to compute the loss and gradient in each training step grows linearly with the number of items. When there are an extremely large number of items, the training of Mult-VAE is time-consuming, making it impractical in real recommendation scenarios. To address this problem, self-normalized importance sampling is used for approximation [5, 13] since the exact gradient involves computing expectation with respect to the softmax distribution. The approximation of the exact gradient leads to the efficient sampled softmax, but it does not converge to the same loss as the softmax. The only way to eliminate the bias is to treat the softmax distribution as the proposal distribution, but it is not efficient to sample from it.
In spite of the well-known importance of a good proposal, many existing methods still often use simple and static distributions, like uniform or popularity-based distribution [20]. The problem of these proposals lies in large divergence from the softmax distribution, so that they need a large number of samples to achieve a low bias of gradient. The recent important method is to use quadratic kernel-based distributions [6] as the proposal, which are not only closer to the softmax distribution, but also efficient to sample from. However, the quadratic kernel is not always a good approximation of the softmax distribution, and it suffers from a large memory footprint due to the feature mapping of the quadratic kernel.

Recently maximum inner product search (MIPs) algorithms have been widely used for fast top-k recommendation with low accuracy degradation [24, 30, 35], but they always return the same results to the same query so that they can not be directly applied for item sampling. On this account, the MIPs indexes have been constructed over the randomly perturbed database for probabilistic inference in log-linear models and become a feasible solution to sample from the softmax distribution [25]. However, this not only increases both data dimension and sample size, but also makes the samples correlated. Moreover, this may also require to rebuild the MIPs index from scratch once the model gets updated, which has a significant impact on the training efficiency. Therefore, instead of using MIPs as a black box, it is necessary to design sampling algorithms tailored for the MIPs indexes.

To this end, based on the popular MIPs index – inverted multi-index [3], we propose a series of proposal distributions, from which items can be efficiently yet independently sampled, to approximate the softmax distribution. The basic idea is to decompose item sampling into multiple stages. In each except the last stage, only a cluster index is sampled given the previously sampled clusters. In the last stage, items being simultaneously assigned to these sampled clusters are sampled according to uniform, popularity, or residual softmax distribution. Since there are a few items left, items are sampled from these approximated distributions in sublinear or even constant time. In some cases, the decomposed sampling is as exact as sampling from softmax, such that the quality of sampled items can be guaranteed. These samplers are then adopted to efficiently train Variational AutoEncoder for collaborative filtering (FastVAE for short). FastVAE is then evaluated extensively on three real-world datasets, demonstrating that FastVAE outperforms the state-of-the-art baselines in terms of sampling quality and efficiency.

2 Related Work

In this paper, we propose a new series of approximate softmax distributions based on the inverted multi-index. These samplers are used for efficiently training VAE. Therefore, we mainly survey related work about efficient softmax, negative sampling and maximum inner product search. Please refer to the survey [45] for more progress about deep learning-based recommender systems, and the survey [1] for classical recommendation algorithms.

2.1 Efficient Softmax Training

Sampled softmax improves training based on self-normalized importance sampling [5] with a mixture proposal of unigram, bigram and trigrams. Hierarchical softmax [23] uses the tree structure and lightRNN [13] uses the table to decompose the softmax probability such that the probability can be quickly computed. Noise-Contrastive Estimation [12] uses nonlinear logistic regression to distinguish the observed data from some artificially generated noise, and has been successfully used for language modeling by treating the unigram distribution as the noise distribution [22]. Sphere softmax [8, 40] replaces the exponential function with a quadratic function, allowing exact yet efficient gradient computation.

2.2 Negative Sampling in RS

Dynamic negative sampling (DNS) [47] draws a set of negative samples from the uniform distribution and then picks the item with the largest prediction score. Similar to DNS, the self-adversarial negative sampling [38] draws negative samples from the uniform distribution but treats the sampling probability as their weights. Kernel-based sampling [6] picks samples proportionally to a quadratic kernel, making it fast to compute the partition function in the kernel space and to sample entries in a divide and conquer way. Locality Sensitive Hashing (LSH) over randomly perturbed databases enable
sublinear time sampling [25] and LSH itself can generate correlated and unnormalized samples [27], which allows efficient estimation of the partition function. Self-Contrast Estimator [9] copied the model and used it as the noise distribution after every step of learning. Generative Adversarial Networks [42] directly learn the noise distribution via the generator networks. These two methods are still based on the softmax distribution, from which it is time-consuming to sample.

2.3 Maximum Inner Product Search

The MIPS problem is challenging since the inner product violates the basic axioms of a metric, such as a triangle inequality and non-negative. Some methods try to transform MIPS to nearest neighbor search (NNS) approximately [35] or exactly [4, 26]. The key idea of the transformation lies in augmenting database vectors to ensure them an (nearly) identical norm, since MIPS is equivalent to NNS when the database vectors are of the same norm. After the transformation, a bulk of algorithms can be applied for ANN search, such as Euclidean Locality-Sensitive Hashing [7], Signed Random Projection [36] and PCA-Tree [4]. Several existing work also studies quantization-based MIPS by exploiting additive nature of inner product, such as additive quantization [6], composite quantization [46] and even extends PQ from the Euclidean distance to the inner product [10]. Similarly, the graph-based index has been extended to MIPS [24], achieving remarkable performance.

3 Preliminaries

3.1 Multi-VAE

Assuming recommender models operate on N users’ implicit behavior (e.g. click or view) over M items, where each user u is represented by the observed data $y_u$ of dimension M. Each entry $y_{ui}$ indicates an interaction record to the item i, where $y_{ui} = 0$ indicates no interaction. Multi-VAE [19] is a representative nonlinear recommender method for modeling such implicit data. It particularly encodes $y_u$ with a Gaussian-distributed latent factor $z_u$ and then decodes it to $\hat{y}_u$, a probability distribution over all items. The objective is to maximize the evidence lower bound (ELBO):

$$
\mathcal{L}(u) = \mathbb{E}_{z_u \sim q_{\theta}(\cdot|y_u)}[\log p_{\theta}(y_u|z_u)] - KL(q_{\theta}(z_u|y_u)||p(z_u)),
$$

where $q_{\theta}(z_u|y_u)$ is the variational posterior with parameters $\phi$ to approximate the true posterior $p(z_u|y_u)$. $q_{\theta}(z_u|y_u)$ is generally assumed to follow the Gaussian-distribution whose mean and variance are estimated by the encoder of Multi-VAE. That is, $z_u \sim \mathcal{N}(\text{MLP}_\mu(y_u; \phi), \text{diag}(\text{MLP}_{\sigma^2}(y_u; \phi)))$, where $\text{MLP}_\mu$ and $\text{MLP}_{\sigma^2}$ denote multilayer perceptrons (MLPs). $p(z_u)$ is the prior Gaussian distribution $\mathcal{N}(0, I)$. $p_\theta(y_u|z_u)$ is the generative distribution conditioned on $z_u$. The observed data $y_u$ is assumed to be drawn from the multinomial distribution, which motivates the widely-used multinomial log-likelihood in Eq. (1):

$$
\log p_{\theta}(y_u|z_u) = \sum_{i \in I} y_{ui} \log p_{\theta}(\hat{y}_{ui}|z_u) = \sum_{i \in I} y_{ui} \log \frac{\exp(z_u^\top \theta_i)}{\sum_{j \in I} \exp(z_u^\top \theta_j)},
$$

where $I$ is the set of all items, $z_u$ and $\theta_i$ is the latent representation of user u and item i, respectively.

3.2 Sampled Softmax

Optimizing the multinomial log-likelihood of Multi-VAE is time-consuming due to the log-partition function over the logits of all items. Given one user’s inner-product logit $o_i$ for item i, the preference probability for the item i is calculated by $P(i) = \frac{\exp(o_i)}{\sum_{j \in I} \exp(o_j)}$. Denoting model parameters by $\theta$, the gradient of the log-likelihood loss is computed as $\nabla_{\theta} \log P(i) = \nabla_{\theta} o_i - \mathbb{E}_{j \sim p} \nabla_{\theta} o_j$. Therefore, it take linear costs in the number of items to compute the loss and gradient. This hinders the multinomial likelihood from the practical use in the real-world scenario with millions of items.

Sampled softmax is one popular approximation approach for log-softmax based on the self-normalized importance sampling. Since the second term of $\nabla_{\theta} \log P(i)$ involves an expectation, it can be approximated by sampling a small set of candidate samples $Q$ from a proposal $\Phi$. This can be equivalently achieved by adjusting $o'_j = o_j - \log Q(j), \forall j \in \{i\} \cup \Phi$ and computing the softmax over $\{i\} \cup \Phi$ (i.e. sampled softmax). Obviously, the computational cost for loss and gradient is
significantly reduced. However, to guarantee the gradient of the sampled softmax unbiased, Bengio and Senécal [5] showed that the proposal $Q$ should be equivalent to the softmax distribution $P$. Since it is computationally expensive to sample from the softmax distribution, many existing methods simply use the uniform or popularity-based proposal. One recent important method [6] proposed to adopt quadratic kernel-based distributions as the proposal. However, it is not always a good approximation of the softmax distribution and suffers from a large memory footprint. Thus, it is necessary to seek a more accurate and flexible sampler.

4 Exact Sampling with Inverted Multi-Index

As demonstrated, to guarantee the gradient of the sampled softmax unbiased, it is necessary to draw candidate items from the softmax probability with the inner-product logits:

$$Q(y_i|z_u) = \frac{\exp(z_u^\top q_i)}{\sum_{j \in \Omega} \exp(z_u^\top q_j)}. \tag{3}$$

To achieve this goal, inspired by the popular inverted multi-index [3, 16, 11] for the approximate maximum inner product search (MIPS) and nearest neighbor search (ANNs), we provide a new way for sampling items from multiple multinomial distributions in order. Technical details will be elaborated below.

![Figure 1: An illustration of the sampling procedure. Firstly, draw a codeword index ($k_1 = 2$) in the first codebook, and then draw another codeword index ($k_2 = 4$). Finally, item $i_3$ is sampled from $\Omega_{2,4}$, which is the set of items assigned to $k_1$ and $k_2$.](image)

The inverted multi-index [3] generalizes the inverted index with multiple codebook quantization, such as product quantization [15] and additive quantization [2]. Below we demonstrate with product quantization, whose basic idea is to independently quantize multiple subvectors of indexed vectors. Formally, suppose $q \in \mathbb{R}^D$ is an item vector, we first evenly split it into $m$ distinct subvectors (i.e., $q = q^1 \oplus q^2 \oplus \cdots \oplus q^m$ where $\oplus$ is the concatenation). Then, each sub-vector $q^l$ is mapped to an element of a fixed-size vector set by a quantizer $f_l : f_l(q^l) \in C_l = \{c^1_k | k \in \{1, \ldots, K\}\}$, where $C_l$ is the vector set (i.e. codebook) of size $K$ in the $l$-th subspace and the element $c^1_k$ is called a codeword. Therefore, the vector $q$ is mapped as follows:

$$q \rightarrow f_1(q^1) \oplus f_2(q^2) \oplus \cdots \oplus f_m(q^m) = c^1_{k_1} \oplus c^2_{k_2} \oplus \cdots \oplus c^m_{k_m}. \tag{4}$$

where $k_l (1 \leq l \leq m)$ is the index of the mapped codeword from $q^l$. The codewords of each codebook can be simply determined by the K-means clustering [15], where the $l$-th subvectors of all items’ vectors are grouped into $K$ clusters. In the following, we demonstrate sampling with 2 codebooks for simplicity (i.e. $m = 2$), which is the default option of inverted multi-index.

With the quantization, each item vector is only approximated by the concatenation of codewords. To eliminate the difference between item vector and its approximation, we add a residual vector $\tilde{q} = q - c^1_{k_1} \oplus c^2_{k_2}$ to the approximation. It is well-known that the inverted multi-index only assigns each item to a unique codeword in each subspace, making it possible to develop sublinear-time sampling methods from the softmax distribution. The following theorem lays the foundation.

**Theorem 4.1.** Assume $z_u = z_u^1 \oplus z_u^2$ is a vector of a user $u$, $q_i = c^1_{k_1} \oplus c^2_{k_2} + \tilde{q}_i$ is a vector of an item $i$, $\Omega_{k_1, k_2}$ is the set of items which are assigned to $c^1_{k_1}$ in the first subspace and $c^2_{k_2}$ in the second subspace. The softmax probability $Q(y_i|z_u)$ can be decomposed as follows:

$$Q(y_i|z_u) = P^1_u(k_1) \cdot P^2_u(k_2|k_1) \cdot P^3_u(y_i|k_1, k_2), \quad P^1_u(k_1) = \frac{\psi_{k_1} \exp(z_u^\top c^1_{k_1})}{\sum_{k_1=1}^K \psi_{k_1} \exp(z_u^\top c^1_{k_1})}, \quad P^2_u(k_2|k_1) = \frac{\omega_{k_1, k_2} \exp(z_u^\top c^2_{k_2})}{\sum_{k_1, k_2} \omega_{k_1, k_2} \exp(z_u^\top c^2_{k_2})}, \quad P^3_u(y_i|k_1, k_2) = \frac{\exp(z_u^\top \tilde{q}_i)}{\sum_{j \in \Omega_{k_1, k_2}} \exp(z_u^\top \tilde{q}_j)}. \tag{5}$$
The proof is attached in the Appendix. Theorem 4.1 can be straightforwardly extended to the case where \( m > 2 \). Surprisingly, this theorem provides a new perspective to exactly sample a candidate item from the softmax probability in Eq. (3), which is called MIDX sampler. First of all, we should construct three multinomial distributions in Eq. (5). Second, we sample an index \( k_1 \) from \( P_{u1}^i(\cdot) \), indicating to select the codeword from the first codebook \( C^1 \). Third, we sample another index \( k_2 \) from the conditional probability \( P_{u2}^i(\cdot|k_1) \), indicating to select the codeword from the second codebook \( C^2 \) given the first index. Finally, a candidate item can be sampled from the residual softmax in \( P_{u3}^i(\cdot|k_1, k_2) \). An important observation is that \( \omega_{k_1, k_2} \) is absolutely not empty, such that each time an item can be sampled out in the last step. Figure 1 illustrates the sampling procedure and Algorithm 1 details the sampling workflow.

**Time complexity analysis.** From Algorithm 1, we see the overall procedure can be split into three parts. Lines 1-3 describe the initialization part to obtain codebooks, lines 4-8 describe the preprocessing part to construct three multinomials, and lines 9-13 show the sampling part. Being independent to users, the initialization part is only executed once in \( \mathcal{O}(KMDt) \), where \( M \) is the number of items and \( t \) is the number of iterations in K-means. Thanks to the Vose-Alias method sampling techniques, the sampling part only takes \( \mathcal{O}(1) \) time to sample an item. The bottleneck lies in the preprocessing part. Unfortunately, it is necessary to compute the inner-product logits over all items, which takes \( \mathcal{O}(MD) \) time. This indicates that it is no more efficient than sampling an item from the softmax distribution directly.

**5 Approximate Sampling with Inverted Multi-Index**

The reason why MIDX spends much time on preprocessing is that it involves computing inner-product logits over all items when preparing \( P_1(\cdot), P_2(\cdot|k_1) \) and \( P_3(\cdot|k_1, k_2) \) in Eq. (5). To address this issue, we design three variants of MIDX sampling by reducing the time for computing \( P_1(\cdot), P_2(\cdot|k_1) \) and \( P_3(\cdot|k_1, k_2) \). Although these samplers only approximate the softmax distribution, the empirical study shows that the divergence between them is small.

**5.1 MIDX with Uniform**

If replacing the multinomial distribution \( P_3(\cdot|k_1, k_2) \) with a non-personalized and static distribution, it will be efficient to prepare \( P_1(\cdot) \) and \( P_2(\cdot|k_1) \), since they only involve computing the inner product between user vector and codewords. A straightforward choice is the uniform distribution. The resultant variant is called **MIDX Uni**, whose distribution is derived based on the following theorem.
Theorem 5.1. Suppose $P_1(\cdot)$ and $P_2(\cdot|k_1)$ remain the same as in Theorem 4.1, $P_3(\cdot|k_1, k_2)$ is replaced with a uniform distribution, i.e. $P_3(y_j|k_1, k_2) = \frac{1}{|\Omega_{k_1,k_2}|}$ where $|\Omega_{k_1,k_2}|$ denotes the number of items in the set. Then, the proposal distribution is equivalent to:

$$Q_{unl}(y_j | z_u) = \frac{\exp(z_u^T c_i) \exp(z_u^T c_j)}{\sum_{k_1, k_2} |\Omega_{k_1,k_2}| \exp(z_u^T c_i) \exp(z_u^T c_j)} = \frac{\exp(z_u^T (q_i - \tilde{q}_i))}{\sum_{j \in \mathbb{Z}} \exp(z_u^T (q_j - \tilde{q}_j))}.$$  

(6)

The proof is attached in the Appendix. Theorem 5.1 shows that each time the codeword with the large inner product and with more items are more likely to be sampled. The divergence of the proposal from Eq. (3) depends on $\exp(z_u^T \tilde{q}_i)$. Therefore, when $\|\tilde{q}_i\|, \forall 1 \leq i \leq M$ (i.e., distortion of product quantization) is small, the divergence between them is small.

Time complexity analysis. In the preprocessing part, the computation only involves the inner product between the user vector and all codewords, which takes $O(KD)$ to compute. In addition, it takes $O(K^2)$ since it should calculate the normalization constant in $P_2(\cdot|k_1)$ for each $k_1$. Overall, the time complexity of the preprocessing part is $O(KD + K^2)$. Since the codebook size $K$ is much smaller than the number of items $M$, MIDX Uni sampling is much more efficient than the MIDX sampling.

5.2 MIDX with Popularity

Besides the uniform distribution, another widely-used static distribution is derived from popularity. If a user does not interact with a popular item, she may be truly uninterested in it since the item is highly likely to be exposed to the user. Therefore, by introducing the popularity, we design the second variant, MIDX Pop, whose distribution is derived by the following theorem.

Theorem 5.2. Suppose $P_1(\cdot)$ and $P_2(\cdot|k_1)$ remain the same as in Theorem 4.1, $P_3(\cdot|k_1, k_2)$ is replaced with a distribution derived from the popularity, i.e. $P_3(y_j|k_1, k_2) = \frac{1}{|\Omega_{k_1,k_2}|} \text{pop}(i)$ where pop(i) can be any metric of the popularity. Then, the proposal distribution is equivalent to:

$$Q_{pop}(y_j | z_u) = \frac{\exp(z_u^T (q_i - \tilde{q}_i) + \log \text{pop}(i))}{\sum_{j \in \mathbb{Z}} \exp(z_u^T (q_j - \tilde{q}_j) + \log \text{pop}(j))}. $$

(7)

The proof is attached in the Appendix. Generally, let $c_i$ be occurring frequency of item $i$, pop(i) can be set to $c_i$, log(1 + $c_i$) or $c_i^{1/4}$ [24]. We empirically find that $c_i$ achieves comparatively better performance. Theorem 5.2 shows that the sampling probability of an item is additionally affected by the popularity, such that the more popular items are more likely to be sampled. Regarding the time complexity, it takes $O(KD + K^2)$ time in the preprocessing part, which is the same as MIDX Uni.

5.3 MIDX with Residual

The main idea of both MIDX Uni and MIDX Pop is to reduce the computational cost by approximating the residual softmax in $P_3(\cdot|k_1, k_2)$. However, as shown in the preceding theorems, the divergence of proposals results from residual vectors. Therefore, to reduce the divergence, it may be necessary to keep the residual softmax for item sampling. In this case, we have to approximate $P_1(\cdot)$ and $P_2(\cdot|k_1)$ for efficient computation. Inspired by their efficient computation in MIDX Uni, we directly set $\omega_{k_1,k_2}$ in $P_2(\cdot|k_1)$ to $|\Omega_{k_1,k_2}|$. This variant is dubbed as MIDX Res, whose distribution is derived with the following theorem.

Theorem 5.3. Suppose $P_3(\cdot|k_1, k_2)$ remains the same as in Theorem 4.1, $\omega_{k_1,k_2}$ in $P_2(\cdot|k_1)$ is set to $|\Omega_{k_1,k_2}|$. Then, the proposal distribution is equivalent to:

$$Q_{res}(y_j | z_u) = \frac{P(k_1, k_2) \exp(z_u^T \tilde{q}_i)}{\sum_{j \in \Omega_{k_1,k_2}} \exp(z_u^T \tilde{q}_j)}, \quad P(k_1, k_2) = \frac{|\Omega_{k_1,k_2}|}{|\Omega_{k_1,k_2}|} \frac{\exp(z_u^T (c_{k_1} \oplus c_{k_2}))}{\exp(z_u^T (c_{k_1} \oplus c_{k_2}))}. $$

(8)

The proof is attached in the Appendix. Theorem 5.3 shows that MIDX Res sampling consists of two steps. First, it samples a pair of codeword indexes in the same way as MIDX Uni. Second, it draws an item in $\Omega_{k_1,k_2}$ from the residual softmax.

Time complexity analysis. The time complexity of the first step is the same as MIDX Uni and MIDX Pop (i.e. $O(KD + K^2)$). The time complexity of the second step depends on $|\Omega_{k_1,k_2}|$. By
Table 1: Time and space complexity of sampling $T$ items from different proposals. Denote by $M$ the number of items, $D$ the representation dimension, and $K$ the codebook size, $t$ the number of iterations in K-means, $B$ the sample size of DNS’s uniform sampling. ($K, D \ll M$)

simply assuming there are $M/K^2$ items in $\Omega_{k,k'}$, $\forall 1 \leq k,k' \leq K$ (which may be roughly achieved by balanced K-means), sampling an item takes $\mathcal{O}(MD/K^2)$ to dynamically calculate the residual softmax. Overall, the time complexity is $\mathcal{O}(KD+K^2+MDT/K^2)$ when sampling $T$ items.

Table 1 summarizes the time and space complexity for item sampling from different proposals, which demonstrates the superiority of MIDX_Uni and MIDX_Pop in space and time cost. Note that the initialization time refers to constructing indexes, such as alias tables, inverted multi-index or tree.

6 FastVAE

We train Multi-VAE with sampled softmax, where we use the proposed proposals for item sampling (FastVAE for short). As shown in Section 3.1, the objective function in Eq. 1 consists of two terms.

Regarding the first term, the expectation can be efficiently approximated by drawing a set of user vectors $\{z_u^{(1)}, z_u^{(2)}, \ldots, z_u^{(S)}\}$ from the variational posterior $q_{\phi}(\cdot | y_u)$. By incorporating the sampled softmax, we draw a small set of candidate items $\Phi_u$ from one of our proposed samplers (i.e., MIDX, MIDX_Uni, MIDX_Pop and MIDX_Res) and then the first term becomes:

$$
\mathbb{E}_{z_u \sim q_{\phi}(\cdot | y_u)}[\log p_{\theta}(y_u | z_u)] = \frac{1}{S} \sum_{s=1}^{S} \sum_{i \in I} y_{ui} \log \frac{\exp \left( (z_u^{(s)})^T q_i - \log Q(y_i | z_u^{(s)}) \right)}{\sum_{j \in \{1, \ldots, Q\} \setminus \Phi_u} \exp \left( (z_u^{(s)})^T q_j - \log Q(y_j | z_u^{(s)}) \right)},
$$

For the second term, both the variational posterior $q_{\phi}(z_u | y_u)$ and the prior distribution $p(z_u)$ follow Gaussian distributions, so that the KL divergence has a closed-form solution. Suppose $q_{\phi}(z_u | y_u) = N(\mu, \sigma^2)$ and $p(z_u) = N(0, 1)$, the KL divergence is computed as follows:

$$
-KL(q_{\phi}(z_u | y_u) || p(z_u)) = \frac{1}{2} \left( \log \sigma^2 - \mu^2 - \sigma^2 + 1 \right)^T 1.
$$

By maximizing the objective function, all parameters can be jointly optimized.

7 Experiments

We evaluate FastVAE with the MovieLens100k, MovieLens10M and Gowalla dataset. In the evaluation, the following three research questions are addressed. First, does FastVAE outperform the state-of-the-art baselines in terms of recommendation quality (i.e., NDCG and Recall)? The competing baselines include WRMF $^{[13, 23]}$, BPR $^{[31]}$, AOBPR $^{[22]}$, SLIM $^{[27]}$, Self-Adversarial (SA) $^{[35]}$, WARP $^{[43]}$ and Multi-VAE $^{[19]}$. Second, how accurately do the proposal distributions approximate the softmax distribution? The proposals includes Uniform, Popularity, DNS $^{[47]}$ and Kernel $^{[6]}$. Third, how efficiently are items sampled from the proposals? More details about the datasets, baselines, metrics and experimental settings are referred to in the Appendix.

7.1 Comparisons with Baselines

The comparisons of recommendation quality (i.e., Recall@50 and NDCG@50) with baselines is reported in Table 2, which are based on 5-time independent trials. We have the following findings.

Finding 1: By using the MIDX-like proposals, FastVAE with sampled softmax could perform better than Multi-VAE with full softmax. Surprisingly, the averaged relative improvements are even up to 2.72% and 2.06% on
Finding 2: FastVAE outperforms all state-of-the-art baselines on all datasets. The averaged relative improvements over the best baseline are up to 6.28% and 5.29% in terms of NDCG@50 and Recall@50, respectively. This indirectly implies the effectiveness of the proposed samplers at sampling high-informative items. Note that WRMF usually works better than static-sampling-based baselines, as WRMF treats all unobserved data as negative. However, the lack of differentiation among them leads to sub-optimal solutions compared to Multi-VAE, whose objective function (i.e. full softmax) also takes all items into account.

### 7.2 Divergence between Proposals and the Softmax Distribution

In order to understand how accurately the proposal distributions approximate the softmax distribution, we investigate the divergence between the proposals and the softmax distribution on the MovieLens10M dataset. In particular, we randomly select a user, and compute her/his softmax distribution with a randomly-initialized model and well-trained model, respectively. Regarding the proposals, we sample 100,000 items from each of them and then plot the cumulative probability distribution. Regarding MIDX-like proposals in both cases, 64 clusters in each quantization will be used. The results of these two cases are reported in Figure 2, where items are sorted by popularity for better comparison. Note that since we have observed similar results from multiple users, only one user’s result is reported for illustration. From them, we have the following findings.

Finding 1: The MIDX sampler is as accurate as softmax, based on full coincidence between softmax and MIDX in both cases. This is because the decomposition of the softmax distribution is fully exact, as shown in Section 7. However, since the item should be sampled from the residual softmax distribution, the time cost is so high that the MIDX sampler is not directly used in practice.

Finding 2: When the model is well-trained, the MIDX-variant samplers are much closer to the softmax distribution than Kernel and DNS. This implies that MIDX-variant samplers reduce the bias of sampled softmax. Though Kernel-based sampling also directly approximates the softmax distribution, it is almost as close as DNS to the softmax. Moreover, the Kernel-based sampling approximates the probability of long-tailed items less accurately. This is consistent with the fact that the Kernel-based sampler oversamples items with negative logits since long-tailed items are more likely to yield negative logits.

Finding 3: The MIDX_Uni sampler approximates the softmax distribution a little less accurately than MIDX_Pop and MIDX_Res while MIDX_Pop is almost as close as MIDX_Res. These samplers mainly vary in item sampling in the last stage, but all depend on item vector quantization. This implies the effect of inverted multi-index at approximate sampling. Moreover, compared to the softmax distribution, these approximate samplers are more likely to sample less popular items, as evidenced by that their curves are slightly above the softmax.

Finding 4: The MIDX-variant samplers can capture the dynamic update of the model. In particular, when the model is well-trained, the MIDX-variant samplers well approximate the softmax; when the model is only randomly initialized, most dynamic samplers are similar to the static samplers as expected. The latter observation is reasonable since randomized representations do not have cluster structures. This indicates that along with the training course of the model, the MIDX-variant samplers can be more and more informative.

### 7.3 Efficiency Study of Samplers

Though MIDX-variant samplers could produce a good approximation to the softmax, it is still unclear how efficiently items are sampled. Therefore, we randomly select 20 users in the MovieLens10M dataset and sample items for them from different proposals. The sample size varies from 200 to 5000. The overall running time

Figure 2: Cumulative probability distribution of different samplers. Items are sorted by popularity. (including prepossessing and sampling) of sampling a given size of items for each user is recorded. This procedure is repeated 10 times, and the average time is reported in Figure 3.

From this figure, we have the following findings: MIDX_Uni and MIDX_Pop are much more efficient than MIDX_Res and Kernel-based samplers, but a little less efficient than static samplers. Their extra cost over static samplers lies in the prepossessing step, being independent of the number of items according to Table 1. Similar to static samplers, the efficiency of MIDX_Uni and MIDX_Pop is almost not affected by sample size, which accords with their $O(1)$ sampling time complexity. To sample an item, Kernel-based sampler takes logarithmic costs in the number of items yet quadratic costs in feature dimension (i.e., $O(D^2 \log M)$). This explains its more time consumption than other proposals. The low efficiency of MIDX_Res lies in the high cost of item sampling from the residual softmax in the last stage. However, DNS takes more time to sample more items due to selecting the item with the maximal logit. Combining the preceding results, we can conclude that MIDX_Uni and MIDX_Pop strike a better balance in improving sampling efficiency and reducing sampling bias than other proposals.

8 Conclusion

In this paper, we discover the high-quality approximation of the softmax distribution by decomposing the softmax probability with the inverted multi-index, and design efficient sampling procedures, from which items can be independently sampled in sublinear or even constant time. These approximate samplers are exploited for fast training the variational autoencoder for collaborative filtering. The experiments on the three public real-world datasets demonstrate that the FastVAE outperforms the state-of-the-art baselines in terms of sampling quality and efficiency.

References

Appendix

In the appendix, we start from the proofs of theorem 4.1, theorem 5.1, theorem 5.2 and theorem 5.3 in section A. Then, we give the experimental details about the datasets, baselines, evaluation metrics and experiment settings in section B. In addition, we also illustrate some model analysis from two perspectives. On one hand, we show the divergence between the proposals and the softmax distribution. On the other hand, we conduct experiments to demonstrate the sensitivity w.r.t. the number of clusters and the number of samples.

A Proof of Theorems

For better illustration, we review some important notations here. In the following, denote by I the set of items, $z_u$ a vector of the user $u$, $q_i$ a vector of the item $i$. The softmax probability with the inner-product logits can be computed by:

$$Q(y_i | z_u) = \frac{\exp(z_u^T q_i)}{\sum_{j \in I} \exp(z_u^T q_j)}. \quad (11)$$

Particularly, $q_i$ can be decomposed based on the codebooks. It is formulated as $q_i = c^1_k \oplus c^2_k + \tilde{q}_i$ where $c^k_i$ is the $k_{th}$ codeword index of $i_{th}$ codebook and $\tilde{q}_i$ is the residual vector.

**Theorem A.1 (Theorem 4.1).** Assume $z_u = z^1_u \oplus z^2_u$ is a vector of a user $u$, $q_i = c^1_k \oplus c^2_k + \tilde{q}_i$ is a vector of an item $i$, $\Omega_{k_1, k_2}$ is the sets of items which are assigned to $c^1_k$ in the first subspace and $c^2_k$ in the second subspace. The softmax probability $Q(y_i | z_u)$ can be decomposed as follows:

$$Q(y_i | z_u) = P^1_u(k_1) \cdot P^2_u(k_2|k_1) \cdot P^3_u(y_i | k_1, k_2), \quad P^1_u(k_1) = \frac{\psi_{k_1} \exp(z_u^T c^1_{k_1})}{\sum_{k=1}^{K} \psi_k \exp(z_u^T c^1_k)}, \quad P^2_u(k_2|k_1) = \frac{\sum_{k=1}^{K} \omega_{k_1,k_2} \exp(z_u^T c^2_{k_2})}{\sum_{k_1=1}^{K} \sum_{k_2=1}^{K} \omega_{k_1,k_2} \exp(z_u^T c^2_{k_2})}, \quad P^3_u(y_i | k_1, k_2) = \frac{\sum_{k_1=1}^{K} \omega_{k_1,k_2} \exp(z_u^T c^2_{k_2}) \exp(\tilde{q}_i)}{\sum_{k=1}^{K} \sum_{k_1=1}^{K} \sum_{k_2=1}^{K} \omega_{k_1,k_2} \exp(z_u^T c^2_{k_2}) \exp(\tilde{q}_i)}. \quad \Box$$

**Proof.**

$$Q(y_i | z_u) = \frac{\exp(z_u^T q_i)}{\sum_{j \in I} \exp(z_u^T q_j)} = \frac{\exp(z_u^T c^1_{k_1}) \exp(z_u^T c^2_{k_2}) \exp(\tilde{q}_i)}{\sum_{k_1=1}^{K} \sum_{k_2=1}^{K} \omega_{k_1,k_2} \exp(z_u^T c^2_{k_2}) \exp(\tilde{q}_i)} = P^1_u(k_1) \cdot P^2_u(k_2|k_1) \cdot P^3_u(y_i | k_1, k_2).$$

**Theorem A.2 (Theorem 5.1).** Suppose $P_1(\cdot)$ and $P_2(\cdot | k_1)$ remain the same as in Theorem 4.1, $P_3(\cdot | k_1, k_2)$ is replaced with a uniform distribution, i.e. $P_3(y_i | k_1, k_2) = \frac{1}{|\Omega_{k_1,k_2}|}$ where $|\Omega_{k_1,k_2}|$ denotes the number of items in the set. Then, the proposal distribution is equivalent to:

$$Q_{uw}(y_i | z_u) = \frac{\exp(z_u^T c^1_{k_1}) \exp(z_u^T c^2_{k_2}) \exp(\tilde{q}_i)}{\sum_{k_1, k_2} \sum_{|\Omega_{k_1,k_2}|} \exp(z_u^T c^1_{k_1}) \exp(z_u^T c^2_{k_2}) \exp(\tilde{q}_i)} = \frac{\exp(z_u^T (q_i - \tilde{q}_i))}{\sum_{j \in I} \exp(z_u^T (q_j - \tilde{q}_i))}. \quad \Box$$
Proof.  

\[ Q_{\text{uni}}(y_i|z_u) = P_1(k_1) \cdot P_2(k_2|k_2) \cdot P_3(y_i|k_1, k_2) \]

\[ = \frac{\Psi'_{k_1} \exp(z_u^\top c_{k_1})}{\sum_{k=1}^{K} \Psi'_k \exp(z_u^\top c_{k_1})} \cdot \frac{\omega'_{k_1,k_2} \exp(z_{u}^{\top} c_{k_2})}{\sum_{k'=1}^{K} \omega'_{k_1,k_2} \exp(z_{u}^{\top} c_{k_2})} \cdot \frac{1}{[\Omega_{k_1,k_2}]} \]

\[ = \sum_{j \in \mathbb{Z}} \exp(z_u^\top (q_j - \tilde{q}_j)) . \]

\[ \Box \]

**Theorem A.3 (Theorem 5.2).** Suppose \( P_1(\cdot) \) and \( P_2(\cdot|k_1) \) remain the same as that in Theorem 4.1, \( P_3(\cdot|k_1, k_2) \) is replaced with a distribution derived from the popularity, i.e. \( P_3(y_i|k_1, k_2) = \frac{\text{pop}(i)}{\sum_{j \in \mathbb{Z}} \text{pop}(j)} \) where \( \text{pop}(i) \) can be any metric of the popularity. Then, the proposal distribution is equivalent to:

\[ Q_{\text{pop}}(y_i|z_u) = \frac{\exp(z_u^\top (q_i - \tilde{q}_i) + \log \text{pop}(i))}{\sum_{j \in \mathbb{Z}} \exp(z_u^\top (q_j - \tilde{q}_j) + \log \text{pop}(j))} . \]

Proof.  

\[ Q_{\text{pop}}(y_i|z_u) = P_1(k_1) \cdot P_2(k_2|k_2) \cdot P_3(y_i|k_1, k_2) \]

\[ = \frac{\Psi'_{k_1} \exp(z_u^\top c_{k_1})}{\sum_{k=1}^{K} \Psi'_k \exp(z_u^\top c_{k_1})} \cdot \frac{\omega'_{k_1,k_2} \exp(z_{u}^{\top} c_{k_2})}{\sum_{k'=1}^{K} \omega'_{k_1,k_2} \exp(z_{u}^{\top} c_{k_2})} \cdot \frac{\text{pop}(i)}{\sum_{j \in \mathbb{Z}} \text{pop}(j)} \]

\[ = \sum_{j \in \mathbb{Z}} \exp(z_u^\top (q_i - \tilde{q}_i) + \log \text{pop}(i)) \cdot \sum_{j \in \mathbb{Z}} \exp(z_u^\top (q_j - \tilde{q}_j) + \log \text{pop}(j)) . \]

\[ \Box \]

**Theorem A.4 (Theorem 5.3).** Suppose \( P_3(\cdot|k_1, k_2) \) remains the same as that in Theorem 4.1, \( \omega_{k,k'} \) in \( P_2(\cdot|k_1) \) is set to \( [\Omega_{k,k'}] \). Then, the proposal distribution is equivalent to:

\[ Q_{\text{cs}}(y_i|z_u) = P(k_1, k_2) \frac{\text{exp}(z_u^\top \tilde{q}_i)}{\sum_{j \in \Omega_{k_1,k_2}} \text{exp}(z_u^\top \tilde{q}_j)}, \quad P(k_1, k_2) = \frac{[\Omega_{k_1,k_2}] \text{exp}(z_u^{\top} (c^{\top}_{k_1} \oplus c^{\top}_{k_2}))}{\sum_{k,k'} [\Omega_{k,k'}] \text{exp}(z_u^{\top} (c^{\top}_{k} \oplus c^{\top}_{k'})))} . \]

Proof.  

\[ Q_{\text{cs}}(y_i|z_u) = P_1(k_1) \cdot P_2(k_2|k_2) \cdot P_3(y_i|k_1, k_2) \]

\[ = \frac{\Psi'_{k_1} \exp(z_u^\top c_{k_1})}{\sum_{k=1}^{K} \Psi'_k \exp(z_u^\top c_{k_1})} \cdot \frac{|\Omega_{k_1,k_2}| \exp(z_{u}^{\top} c_{k_2})}{\sum_{k'=1}^{K} |\Omega_{k_1,k_2}| \exp(z_{u}^{\top} c_{k_2})} \cdot \frac{\exp(z_{u}^{\top} \tilde{q}_i)}{\sum_{j \in \Omega_{k_1,k_2}} \exp(z_{u}^{\top} \tilde{q}_j)} \]

\[ = \frac{|\Omega_{k_1,k_2}| \exp(z_u^\top (c_{k_1} \oplus c_{k_2})))}{\sum_{k=1}^{K} |\Omega_{k_1,k_2}| \exp(z_u^\top (c_{k_1} \oplus c_{k_2})))} \cdot \frac{\exp(z_{u}^{\top} \tilde{q}_i)}{\sum_{j \in \Omega_{k_1,k_2}} \exp(z_{u}^{\top} \tilde{q}_j)} . \]

\[ \Box \]

**B Experimental Details**

**B.1 Datasets**

Experiments are conducted on the three public datasets for evaluation. The MovieLens dataset is a classic movie rating dataset, whose ratings range from 0.5 to 5. We convert them into 0/1 indicating whether the user has rated the movie. We choose the versions of MovieLens100k and MovieLens10M to evaluate the performance of our methods. For MovieLens100k, we filter out users and movies with less than 20 ratings and finally obtain 917 users and 939 movies for learning. For MovieLens10M, we ensure that each user has rated at least 5 movies and we obtain the final version with 60,655 users and 8,939 movies. The Gowalla dataset includes users’ check-ins
at locations in a location-based social network and is much sparser than the MovieLens dataset. We filter out users and locations with less than 10 interactions and finally obtain the collection of 29,858 users and 40,988 locations. The sparsity of the three datasets is 10.97%, 3.88%, 0.08% respectively.

For each user, we randomly sample 80% of interacted items to construct the history vector. We fit the models to the training items. For evaluation, we take the user history to learn the necessary representations from the well-trained model and then compute metrics by looking at how well the model ranks the unseen history.

### B.2 Baselines

We compare our FastVAE with the following competing collaborative filtering models. The dimension of latent factors for users and items is set to 32 by default.

- **WRMF** [13, 28], weighted regularized matrix factorization, is a famous collaborative filtering method for implicit feedback. It sets a prior on uninteracted items associated with the confidence level of being negative. We tune the parameter of the regularizer of uninteracted items within \{1, 5, 10, 20, 50, 100, 200, 500\} on the test dataset. The coefficient of L2 regularization is fixed to 0.01.

- **BPR** [31], Bayesian personalized ranking from implicit feedback, utilizes the pair-wise logit ranking loss between positive and negative samples. For each pair of interacted user and item, BPR randomly samples several uninteracted items of the user for training and applies stochastic gradient descent for optimization. We set the number of sampled negative items as 5 and tune the coefficient of regularization with \{2, 1, 0.5\}.

- **SLIM** [27], sparse linear method, learns the sparse aggregation coefficient matrix to capture the similarity between users and items to solve the L1-norm and L2-norm regularization optimization. The coefficients for the regularization are tuned within \{0.01, 0.05, 0.1, 0.5, 1\}. We use the version with high efficiency\(^1\).

- **WARP** [43] uses the weighted approximate-rank pair-wise loss function for collaborative filtering. Given a positive item, it uniformly samples negative items until the rating of the sampled item is higher. The rank is estimated based on the sampling trials. We use the implementation in the lightFM\(^2\). The maximal number of trails is set to 50. The coefficient of the regularization is tuned within \{0.05, 0.01, 0.005, 0.001\} and the learning rate is tuned within \{10^{-3}, 10^{-4}, 10^{-5}, 10^{-6}\}.

- **AOBPR** [32] improves the BPR with adaptive sampling method. We use the version implemented in LibRec\(^3\). The parameter for the geometric distribution is set to 500 and the learning rate is set to 0.05. We tune the coefficient of the regularization within \{0.005, 0.01, 0.02\}.

- **SA** [38], a self-supervised method for negative sampling, is recently proposed for the recommendation. It utilizes uniform sampling and assigns the sampling weight for the negative item depending on the current model.

- **Mult-VAE** [19], variational autoencoders for collaborative filtering, is the work of learning user representations with variational autoencoders in recommendation systems. It learns the user representation by aiming at maximizing the likelihood of user click history. We mainly focus on the comparison with VAE and we will introduce the parameter setting in the following part.

In addition to these recommendation algorithms, we conduct experiments with the following samplers.

- **Uniform** sampler is a common sampling strategy that randomly draws negatives from the set of items for optimization.

- **Popularity** sampler is correlated with the popularity of items, where the items with higher popularity have a greater probability of being sampled. The popularity is computed as \(\log(f_i + 1)\) where \(f_i\) is the occurring frequency of item \(i\). We normalize the popularity of all items for sampling.

- **DNS** sampler [47] dynamically chooses items according to the predicted ranking list. Specifically, the dynamic sampler first draws samples uniformly from the item set and the item with the maximum rating is selected.

- **Kernel** based sampler [6] is a recent method for adaptively sampled softmax, which lowers the bias by the non-negative quadratic kernel. Furthermore, the kernel-based sampler is implemented with divide and conquer depending on the tree structure.

### B.3 Evaluation Metrics

Two standard metrics are utilized for evaluating the quality of recommendation, Normalized Discounted Cumulative Gain (NDCG) and Recall. We conduct a cutoff \(k\) for the top \(k\) recommended item list. A higher

---

\(^1\)https://github.com/KarypisLab/SLIM
\(^2\)https://github.com/lyst/lightfm
\(^3\)https://github.com/guoguibing/librec
NDCG@$k$ represents the positive items in the test data are ranked higher in the ranking list. Recall@$k$ measures the fraction of the positive items in the test data. All algorithms are fine-tuned based on NDCG@50. After that, we run 5 times cross-validation.

B.4 Experiment Settings

We develop the proposed algorithms FastVAE with Pytorch in a Linux system (2.10 GHz Intel Xeon Gold 6230 CPUs and a Tesla V100 GPU). We utilize the Adam algorithm with a weight decay of 0.01 for optimization. We implement the variational autoencoder with one hidden layer and the generative module would be $[M \rightarrow 200 \rightarrow 32]$. The active function between layers is ReLu by default. The input of user history is dropout with a probability of 0.5 before the linear layers. The batch size is set to 16 for the MovieLens100k dataset and 256 for both the MovieLens10M and Gowalla datasets. The learning rate is tuned over $\{0.1, 0.01, 0.001, 0.0001\}$. We finally choose the fixed learning rate of 0.001 on all datasets for comparison. We train the models within 200 epochs.

For the FastVAE, the number of samples is set to 200, 500, 2000 for three datasets respectively. The number of clusters is set to 16 by default. Regarding the popularity based strategy, we follow the same popularity function $\log(f_i + 1)$. The sample-based methods utilize fewer items for learning so that we train the sample-based methods with more epochs.

B.5 The divergence between Proposals and the Softmax Distribution

We carry out experiments on multiple users to validate the deviation from the softmax distribution. We randomly choose 1,000 users for experiments, where 10,000 items are sampled for each user to calculate the approximated proposal distribution. We then obtain the Kullback-Leibler divergence ($KL(q||p)$) of the softmax distribution ($p$) and the proposal distribution for each sampler ($q$), where a smaller KL divergence indicates a better approximation of the softmax distribution. The kernel density estimation (KDE) is then reported for comparison, as shown in Figure 4.

Finding: The MIDX based samplers well approximate the softmax distribution. Compared with the Uniform and Popularity samplers, our MIDX based samplers have smaller KL divergence, indicating the more accurate approximation of the softmax distribution. The MIDX and MIDX_Res perform better than MIDX-Uni and MIDX_Pop, since they keep more information by utilizing the residual vectors of items. This observation is corresponding with the aforementioned theorems.

B.6 Sensitivity Analysis

B.6.1 Sensitivity w.r.t. Number of Clusters

The number of clusters can greatly influence the performance of the approximation. To take a deep insight, we compare the performance on the approximation error and running time respectively. We sample 100,000 items for a randomly selected user from the MovieLens10M dataset. Then, we calculate the KL divergence between the proposals and the original softmax distribution. Figure 5(a) shows the performance with the change of cluster numbers. The KL divergences of the Uniform and Pop do not change with the number of clusters and are kept around 8. Regarding the running time of the experiments, the average running time of each sampler is reported based on 10-time independent trials in Figure 5(b).

Finding 1: The MIDX_Res sampler consistently maintains small errors of the approximation. When the cluster number is relatively small, the value of the KL divergence for the MIDX based samplers would be large, apart from the accurate MIDX sampler. But the bias of MIDX_Res is lower than that of MIDX_Uni and MIDX_Pop. The reason may lie in that the residual vectors contribute a lot to make the approximate distribution closer to the softmax distribution, while MIDX_Uni and MIDX_Pop do not utilize this important information.

Finding 2: The best number of the cluster numbers is around the square root of the item numbers. We perform the experiments on the MovieLens10M dataset, which includes 8,939 items. When we have two codebooks with $K$ codewords, there would be $K^2$ union clusters for sampling. When the item number is much larger than $K^2$, each union cluster has many items for sampling, which is not friendly to conduct the multinomial sampling. On
Finding 3: The running time of MIDX based samplers is significantly affected by the number of clusters. The running time of the Uniform and Popularity samplers is almost unchanged as both samplers are independent of the number of clusters. When the number of clusters increases, it takes more time for MIDX based samplers to compute the probabilities over the clusters. The running time of MIDX_Uni and MIDX_Pop is still smaller in the case of a larger number of clusters. Thus, we can conclude that the MIDX based samplers achieve the goal of efficiently approximating the softmax distribution.

B.6.2 Sensitivity w.r.t. Number of Samples

Following a similar experiment procedure, we vary the number of sampled items to observe the approximation of different samplers. The results are depicted in Figure 6.

Finding: Our proposed MIDX based samplers show superior performances even if the number of sampled items is small. With the increase of the sample numbers, all samplers can better approximate the softmax distribution. In addition, we can observe the dynamic samplers (i.e., DNS and Kernel) have much better performances than the trivial samplers (i.e., Uniform and Popularity). However, the KL divergence of MIDX based samplers does not exceed 2 during the change of the number of samples. The outstanding performances of MIDX based samplers reveal the strong stability and capability of approximating the softmax distribution again.
