Abstract

Human motion prediction, which plays a key role in computer vision, generally requires a past motion sequence as input. However, in real applications, a complete and correct past motion sequence can be too expensive to achieve. In this paper, we propose a novel approach to predict future human motions from a much weaker condition, i.e., a single image, with mixture density networks (MDN) modeling. Contrary to most existing deep human motion prediction approaches, the multimodal nature of MDN enables the generation of diverse future motion hypotheses, which well compensates for the strong stochastic ambiguity aggregated by the single input and human motion uncertainty. In designing the loss function, we further introduce an energy-based prior over learnable parameters of MDN to maintain motion coherence, as well as improve the prediction accuracy. Our trained model directly takes an image as input and generates multiple plausible motions that satisfy the given condition. Extensive experiments on two standard benchmark datasets demonstrate the effectiveness of our method, in terms of prediction diversity and accuracy.

1. Introduction

Human motion prediction has gained tremendous attention in recent years for increasing needs in the field of human-related future forecasting tasks, such as human tracking [12] and autonomous driving [30]. It is worth pointing out that understanding human dynamics is challenging because of complicated biochemical body motions and a high degree of inherent uncertainties. As a result, the task of human motion prediction is generally cast as a sequence-to-sequence mapping problem that requires the informative past observed human poses. By combining with powerful temporal information encoders (e.g., hierarchical convolutional filters [22]), a reliable future sequence can be thus recovered with Recurrent Neural Networks (RNN).

However, in real applications, it is usually the case that easily accessible input is not informative enough to yield accurate future motion predictions, such as a single image. A pioneering work by [7] first attempts to address this problem by recurrently regressing the 2D skeleton with a 2D sequence generator, followed by a 3D skeleton converter to generate 3D human poses. Despite its novel concept, the whole system is deterministic, which means the network is not able to capture the potentially diverse future motions. Fig. 1 illustrates an example of multiple possible future motions induced by a single image. Without past motions as reference, a standing human (Fig. 1(a)) in the image can be equally possible to turn left (Fig. 1(b)), turn right (Fig. 1(d)) or even keep still (Fig. 1(c)) in the following frames. Consequently, various challenges imposed by the inherent pose and motion stochasticity suggest that a powerful model should be capable of modeling such inner ambiguities. We thus argue that contrary to a deterministic prediction system, it is more acceptable to produce multiple plausible future motions that satisfy the given image, as shown in Fig. 1. This idea can manifest its essentiality in many safety practical applications. For example, for autonomous vehicles, it is crucial to foresee the future of a straight walking pedestrian suddenly turning left, even though he will most probably remain walking in the same direction.

In this paper, we resort to the mixture density networks (MDN) [5] to generate diverse human motion predictions.
Our network architecture is a simple composition of an image to 2D estimation block, a 2D feature extractor block, and a 3D mixture density block, which straightforwardly takes a single image as input. Based on the extracted features by the deep neural networks, the mixture density block outputs the parameters for the mixture distribution, including several sets of means, standard deviations, and mixture coefficients. Specifically, we extend the mean of each distribution to represent a motion sequence in 3D space. In order to maintain motion coherence and achieve decent prediction accuracy, we further design an energy-based function such that the involved prior loss can be flexibly imposed on the optimization objective under the MAP (Maximum A Posterior) formulation. The introduction of MDN on motion prediction tasks enjoys a considerable advantage in capturing a diverse set of motion hypotheses because of its multimodal nature, and it is difficult for conventional style of regression-based methods, which use a single distribution (e.g., Gaussian), to reach similar performance. Once trained, our model is able to predict diverse plausible 3D future motions that satisfy the input image.

In summary, this paper makes the following main contributions:

- We propose a novel perspective for addressing the inherent human motion stochasticity arising from the weakly informed conditions (i.e., a single image) by giving diverse plausible predictions, rather than treating it as a simple deterministic regression task.
- We model human motion from the image domain to 3D space together with the inner ambiguity under mixture density networks, which has been sparsely treated in 3D human motion prediction tasks, and formulate energy-based priors to improve the prediction performance.
- We quantitatively and qualitatively report extensive experimental results, as well as ablation studies, on Human3.6M [16] and MPII [3] dataset, and show the robustness of our method in terms of prediction accuracy and diversity.

2. Related Work

In this section, we first review previous human motion prediction techniques. We then introduce the mixture density networks in a few visual computing tasks, especially regarding human-related modeling. Finally, we briefly review some works on diverse human motion prediction.

**Human motion prediction.** The majority of previous human motion prediction works [11, 17, 6, 27, 13, 1, 36, 22, 26, 25, 24] rely on the past motion sequence. Since human motion is highly stochastic, the most likely future motions can be better captured with the high-dimensional features extracted from the observed motions. In [25], the temporal observed sequence is encoded in trajectory space with Discrete Cosine Transform (DCT). Li et al. [22] used a long-term hierarchical convolutional encoder to learn spatial dependencies. The valuable keys in past motions are also discovered with empirical observations. Mao et al. [24] argued that the history of human motion tends to repeat itself, and designed a motion attention module to model the similarity of past and future motions. After extracting the rich information in the past motions, a general style of generating the desired future sequence is to utilize RNN. Besides the training difficulty [31], the most prominent issue in RNN is the irreversible error accumulation over time [6], hence the predicting performance can degrade greatly with increasing iterations. Despite the efforts on the structural improvements on RNN (e.g., three-layer bio-mechanical RNN [10], structural RNN with spatio-temporal graph [17]), the frame-by-frame fashion of regression cannot guarantee the global smoothness. Our model regresses the whole future motion sequence as the mean of each distribution, which to some extent can avoid the general issues in RNN.

The second category predicts human motions under a much weaker condition, e.g., only a single image is given. Human motion prediction in such case increases its challenge because a single image contains far less prior information than a motion sequence, leading to more ambiguities. The first attempt to solve this task is by Chao et al. [7]. In this work, human poses are recurrently regressed in 2D domain with LSTM (Long Short Term Memory), then the 2D poses are lifted to the 3D domain with an extra 3D converter. Later, [18, 39] jointly trained a hallucinator while learning 3D human shapes from videos. The hallucinator aims to hallucinate a very short span of near past and future human motions conditioned on a video clip. Although these works provide some insights into discovering the weakly informed condition, they cannot model the stochasticity imposed by the single image.

**Mixture density networks (MDN).** MDN is first introduced by [5] to model ill-posed problems, by learning the parameters of a mixture distribution. This idea has recently been proven highly impressive in handling human-related multimodal modeling tasks [23, 32, 8]. Makansi et al. [23] proposed a Winner-Take-All (WTA) loss to overcome the training instability of MDN for predicting future vehicle location. Choi et al. [8] introduced uncertainty-aware learning using MDN to model noisy human behavior in autonomous driving. At the same time, MDN has also been adopted in human pose estimation tasks [34, 21, 43, 37]. [34] exploited MDN to simultaneously generate human pose and its location, by endowing each component in the mixture distribution with different meanings. [37] improved a MDN variant with hierarchical architecture to handle hand joint occlusions. Among these works, Li et al. [21] shares
the most similar motivation to ours in using MDN. They employed MDN to generate multiple possible 3D human poses from the 2D domain, to address the ambiguity from view-angle and depth. The most distinct point in which our method differs from these works is that we leverage MDN to model human motion, which is more challenging since the increase of the degree of freedom in motion sequence can further amplify ambiguity.

Diverse human motion prediction. In many recent works [2, 19, 40, 38, 4], the authors pointed out that even if a past sequence is given, the problem of motion prediction can still be highly ill-posed, and generating a diverse set of probable predictions can be a more reasonable choice. These works share one common motivation that the diversity can be promoted by feeding the deep generative model (e.g., CVAE (Conditional Variational Auto-Encoder) [2, 19, 40, 38], GAN (Generative Adversarial Networks) [4]) with different sampled noise. In particular, both the encoder and the decoder are under RNN architecture. However, as shown in [38], sampling randomly from the latent space is not ensured to produce diverse motion samples, and most of them may concentrate on one major mode. Consequently, special subsequent sampling strategies should be supplementarily learned. In addition, none of these works can take the input as a single image.

3. Method

Fig. 2 illustrates our network architecture for predicting future human motions from a single image, which consists of an image-to-2D (I2D) block, a feature extraction (FE) block and a mixture density (MD) block. We first follow the common 2D skeleton extraction policy [28] by adopting the stacked hourglass (SHG) [29] to build the I2D block. SHG involves repeated hourglass-like encoder-decoder structures and outputs 2D human pose estimations from images. Specifically, given an image \( I \), the I2D block generates the corresponding 2D human joint detection \( x \in \mathbb{R}^{2C} \), where \( C \) is the number of joints in one skeleton. Fed with the 2D poses, the FE block readily extracts the features and maps them into a higher dimensional space. The features then pass through the final MD block to output the parameters of a mixture distribution. The parameters for such distribution are learnable and are trained to hopefully achieve a probabilistic mapping from 2D poses to diverse 3D motions under the ground-truth supervision. Note that our training process detours the I2D block and relies on the provided ground-truth 2D annotations of the corresponding images to make full use of the dataset.

3.1. Mixture Modeling for Motion Generation

Given the 2D human poses \( x \), our goal is to learn a mapping function \( G(x) \) to generate 3D hypotheses from the unknown multimodal posterior \( p(y|x) \), where \( y \in \mathbb{R}^{3TC} \) indicates the 3D future human motions with the time horizon of \( T \) frames. Due to the human motion stochasticity, we propose to model \( p(y|x) \) under MDN, which can be formulated as

\[
p(y|x) = \sum_{m=1}^{M} \alpha_m(x) \phi_m(y|x),
\]

in which \( \alpha_m(x) \in \mathbb{R} \) is the mixture coefficient for the \( m \)-th component \( \phi_m(y|x) \). Each \( \phi_m(y|x) \) is the probabilistic
density for y conditioned on x, and in this paper is represented by Gaussian distribution:

$$
\phi_m(y|x) = \frac{1}{(2\pi)^{d/2}\sigma_m^2(x)} e^{-\frac{|y-m(x)|^2}{2\sigma_m^2(x)}},
$$

where $\mu_m(x) \in \mathbb{R}^{3TC}$ and $\sigma_m(x) \in \mathbb{R}$ are the mean and standard deviation for $m$-th Gaussian component, respectively. $d = 3TC$ means the output dimension of y. $\sigma_m(x)$ is implemented as isotropic for simplicity. Note that the mixture model can also be selected as other forms of distributions (e.g., Laplacian), and we utilize Gaussian mainly because of its convenient mathematical properties. Under such formulation, $p(y|x)$ is expressed as a Gaussian mixture, with the parameters $\alpha = \{\alpha_1, ..., \alpha_M\}$, $\mu = \{\mu_1, ..., \mu_m, ..., \mu_M\}$, and $\sigma = \{\sigma_1, ..., \sigma_m, ..., \sigma_M\}$. Each $\mu_m$ indicates a possible 3D future motion hypothesis with the length of $T$ frames conditioned on $x$. It is worth mentioning that the conventional prediction in a regression fashion can be viewed as a degeneration case of our model, by forcing all the Gaussian components to be similar, i.e., $\phi_1 \approx \phi_2 \approx ... \approx \phi_M$. The model thus reduces to a single Gaussian, and can only capture one possible hypothesis among potentially diverse modes.

### 3.2. Optimization

In essence, the target mapping $G(x)$ can be regarded as a triplet mappings of $\Theta(x) = \{\alpha(x), \mu(x), \sigma(x)\}$, which are the outputs of the MD block in our network. Particularly, by denoting the network parameters for the mapping $G(x)$ as $\psi$, the whole deep neural network in the function form can be written as

$$
\Theta(x, \psi) = G(x, \psi).
$$

Our goal is then switched to find the optimized parameters $\psi$ that form the ideal mapping $G$. Given a training set of ground-truth 3D and 2D pairs $\{Y, X\} = \{\{y_k, x_k\} | k = 1, ..., K\}$, the posterior of $\psi$ can be attained by employing the Maximum A Posterior (MAP) strategy:

$$
p(\psi|Y, X, \Omega) \propto p(\psi|\Omega)p(Y|\psi)p(X|Y, \psi)
$$

in which $\Omega$ is a newly introduced parameter to characterize the prior knowledge on $\psi$. Furthermore, by assuming the training samples being i.i.d., we obtain

$$
p(\psi|X, Y, \Omega) \propto p(\psi|X, \Omega) \prod_{k=1}^{K} \prod_{m=1}^{M} \alpha_m(x_k, \psi)\phi_m(y_k|x_k, \psi)
$$

where the parameters for mixture density network are rewritten to show dependency on $\psi$ (i.e., $\Theta(x, \psi) = \{\alpha(x, \psi), \mu(x, \psi), \sigma(x, \psi)\}$).

The optimization of $\psi$ can be thus realized by minimizing the negative log-posterior, which is equivalent to the loss function we use to train our network:

$$
L = -\log p(\psi|X, Y, \Omega)
$$

$$
\propto -\sum_{k=1}^{K} \log p(y_k|x_k, \psi) - \log p(\psi|X, \Omega)
$$

$$
= -\sum_{k=1}^{K} \sum_{m=1}^{M} \log \alpha_m(x_k, \psi)\phi_m(y_k|x_k, \psi) - \log p(\psi|X, \Omega)
$$

$$
= L_{MD} + L_{pr}
$$

It can be observed that term $L_{MD}$ stands for the likelihood, which is the general choice of objective for optimizing MDN. Differently, the MAP formulation is more beneficial as the convenient prior mechanism can play target-specific roles by flexibly designing $\Omega$. Specifically, $L_{pr}$ can be further evaluated as:

$$
L_{pr} = -\log p(\psi|X, \Omega)
$$

$$
= -\log p(\psi|X|\Omega) + \log p(X|\Omega).
$$

By substituting $\psi, X$ with its function form $\Theta(\psi, X)$, and dropping the $\psi$-independent $\log(X|\Omega)$ term, we obtain

$$
L_{pr} \propto -\log p(\Theta(\psi, X)|\Omega)
$$

$$
= -\log p(\mu(\psi, X|\omega_1)) - \log p(\alpha(\psi, X|\omega_2)) - \log p(\sigma(\psi, X|\omega_3)),
$$

where $\mu, \alpha$ and $\sigma$ are assumed to be mutually independent. $\Omega$ is further divided into $\{\omega_1, \omega_2, \omega_3\}$ to represent prior knowledge on different parameters of MDN. We next need to determine how to build such $\Omega$.

### 3.3. Energy-based Prior Loss

To enable each mean of MDN (i.e., $\mu_m$) representing the whole motion sequence, the prior $\omega_1$ for it should be elaborately defined. Although our model does not suffer from the error accumulation issue in RNN, it also does not benefit
from the feature passed from the past outputs that drives the generated sequence to be coherent. Therefore, the prior \( \omega_k \) needs to be capable of being coherence-maintaining. We draw inspiration from [38], and derive an energy function \( E_v \) by defining

\[
p(\mu) = e^{-E_v(\mu)/S},
\]

in which \( S \) is a normalizing constant, and can be dropped in the optimization. The notation of \( p(\mu(\psi, X|\omega_1) \) is simplified as \( p(\mu) \) for brevity. The corresponding loss with respect to \( \mu \) in Eq. 8 is thus given by

\[
\log p(\mu) = -E_v(\mu).
\]

We use frame-wise velocity between the ground-truth and the predicted sequence to measure the degree of motion consistency, and introduce \( f_m^t(x_k) \in \mathbb{R}^{3C} \) to denote the pose at \( t \)-th frame in the \( m \)-th motion hypothesis \( \mu_m(x_k) \). \( f_m^t(x_k) \) can also be considered as a direct mapping that outputs a 3D skeleton given the \( k \)-th training sample \( x_k \), and \( f_m^t(x) \) refers to the 3D pose of the 2D joints \( x_k \) for \( m = 1, ..., M \). Given training input \( x_k \), the velocity vector for the \( m \)-th motion hypothesis can be computed as

\[
\mathbf{v}_m^k = [f_m^T(x_k), ..., f_m^T(x_k)] - [f_m^{t-1}(x_k), ..., f_m^{t-1}(x_k)].
\]

We hence form the energy function \( E_v \) based on the pair-wise Euclidean distance \( D \) between predicted velocity \( \mathbf{v}_m^k \) and the corresponding ground-truth velocity \( \mathbf{v}^k \),

\[
E_v = \frac{1}{M(T-1)} \sum_{k=1}^{K} \sum_{m=1}^{M} (D(\mathbf{v}_m^k, \mathbf{v}^k))^2.
\]

Eventually, minimizing \( E_v \) guides the generated prediction towards a low-energy configuration such that coherent motions can be pursued.

Although our model produces diverse motion predictions, we also expect a decent prediction accuracy. To this end, we modify the energy term in Eq. 9 by adding an accuracy term

\[
E_a = \sum_{k=1}^{K} \min_{m}(D(\mu_m(x_k), y_k))^2,
\]

\( \sum_{k=1}^{K} \min_{m}(D(\mu_m(x_k), y_k))^2 \),

\( (12) \)

to hopefully ensure that at least one of the generated prediction \( \mu_m \) can precisely characterize the ground-truth \( y_k \).

### 3.4. Dirichlet Conjugate Prior Loss

The mixture coefficient \( \alpha \) of MDN can be regarded as the probability of the prediction \( y \) to be generated from the \( m \)-th Gaussian component. As an auxiliary degeneration-preventing training assistant, we adopt the strategy in [21, 14] by applying a Dirichlet conjugate loss as a regularization term to preserve the multimodality of MDN. The Dirichlet conjugate prior over mixture coefficient \( \alpha \) is computed by:

\[
p(\alpha_1, ..., \alpha_M|\Lambda) = \text{Dir}(\alpha_1, ..., \alpha_M|\lambda_1, ..., \lambda_M)
\]

\[
= \frac{\Gamma[\sum_{m=1}^{M} \lambda_m]}{\prod_{m=1}^{M} \Gamma[\lambda_m]} \prod_{m=1}^{M} \alpha_m^{(\lambda_m-1)}, \tag{13}
\]

in which \( \Gamma[\cdot] \) denotes the Gamma function, and \( \Lambda = \{\lambda_1, ..., \lambda_M\} \) represents the parameters for Dirichlet distribution.

The final Dirichlet conjugate loss is thus defined by

\[
L_d = -\log(p(\alpha)|\Lambda)
\]

\[
= -\sum_{k=1}^{K} \sum_{m=1}^{M} (\lambda_m - 1) \log \alpha_m(x_k), \tag{14}
\]

in which the \( \frac{\Gamma[\sum_{m=1}^{M} \lambda_m]}{\prod_{m=1}^{M} \Gamma[\lambda_m]} \) part is dropped since it is independent of \( \alpha_m \). Generally, \( \lambda_m = 1 \) for \( m = 1, ..., M \) implies that there is no prior knowledge over \( \alpha \). We set \( \lambda_1 = ... = \lambda_M = 2 \) as suggested in [21]. Even though our method does not trigger noticeable degeneration, we observe including \( L_d \) works well for refining prediction performance (see Sec. 4.3).

### 3.5. Training Technique

Up to this point, we have explained the proposed diverse motion prediction method, and introduced different prior terms \( \Omega \) over \( \mu \) and \( \alpha \). The remaining prior for \( \sigma \) is simply assumed to be uniform. By substituting Eq. 6 for Eq. 11, Eq. 12, and Eq. 13, the overall loss we use to train our model is given by

\[
L = L_{MD} + w_v \ast L_v + w_a \ast L_a + w_d \ast L_d, \tag{15}
\]

where

\[
L_{MD} = -\sum_{k=1}^{K} \log \sum_{m=1}^{M} \alpha_m(x_k, \psi) \phi_m(y_k|x_k, \psi),
\]

\[
L_v = E_v,
\]

\[
L_a = E_a,
\]

and \( w_v, w_a \) and \( w_d \) are the weights for the corresponding loss, respectively.

We next introduce a training technique in terms of \( L_{MD} \). Formally, given an arbitrary training sample \( x \), \( L_{MD} \) can be calculated as

\[
L_{MD} = -\log \sum_{m=1}^{M} \frac{\alpha_m(x)}{(2\pi)^{d/2} \sigma_m^2} e^{-\frac{|y - \mu_m(x)|^2}{2\sigma_m^2}}. \tag{17}
\]

In the training process, the right-most exponential term in Eq. 17 is highly likely to be excessively small, and the outside logarithm operation can induce the underflow issue. To
mum within the exponential to the outside:

\[ \log \sum_{j=1}^{J} e^{q_j} = \max_j(q_j) + \log \sum_{j=1}^{J} e^{(q_j - \max_j(q_j))}. \] (18)

By extending the exponential inside the logarithm:

\[ L_{MD} = - \log \sum_{m=1}^{M} e^{\alpha_m(x) - \frac{1}{2} \log(2\pi\sigma_m^2(x)) - \frac{|y - \mu_m(x)|^2}{2\sigma_m^2(x)}}, \] (19)

the scheme in Eq. 18 can then be easily applied.

4. Experiment

Datasets. We assess our method on the following two human pose estimation benchmarks: Human3.6M [16] and MPII [3]. Human3.6M is till today the largest and the most widely used dataset which provides accurate 2D and 3D joint annotations on videos recorded by the Vicon MoCap system. It contains 15 daily activity scenarios performed by seven professional actors under four camera views. We conduct both qualitative and quantitative evaluations on this dataset. MPII is a more challenging benchmark for 2D human pose estimation because of various types of background and severe occlusion collected from YouTube videos. We only qualitatively evaluate our method on this dataset as 3D annotations are not provided.

Network and implementation details. Similar to [41, 28], the 2D block is pretrained on MPII and finetuned with Human3.6M to directly estimate 2D poses from images in the test stage. To completely show the power of our MDN modeling, we simply adopt the architecture in [28] as the backbone to construct the FE block. As shown in Fig. 2, the FE block takes as input a 2D skeleton and lifts it to a 1024 dimensional feature space as pre-processing. The features are then passed into a two-layer residual module, in which batch normalization, dropout (with a rate of 0.5), and ReLU activation are involved after each fully connected (FC) layer. The residual module is repeated for 4 rounds to deepen the structure. The output of the FE block is fed into the proposed MD block to produce mixture distribution parameters. We use ELU [9] as the activation for \( \sigma \). We add a softmax function after FC layer for \( \alpha \) to constrain it with \( \sum_{m=1}^{M} \alpha_m = 1 \). No further treatment besides FC layer upon \( \mu \) is applied.

Our model is trained for 100 epochs on RTX 3090, and the ADAM optimizer [20] is utilized based on an exponentially decay learning rate with the initial value of 1e-4. The weights \( (w_v, w_\alpha, w_d) \) are empirically set to (0.1, 0.05, 1.0). To avoid training failure that the \( L_{MD} \) deteriorates to NaN, we clip the value of \( \sigma_m \) to [1e-10, 1e10], and \( \alpha_m \) to [1e-8, 1] for \( m = 1, \ldots, M \), respectively. For all experiments, we predict the future 15 frames (3 seconds) based on the single input image. To be consistent with the previous literature [28, 42, 33], we use S1, S5, S6, S7 and S8 for training, and testing on S9 and S11, which is commonly referred to as Protocol #1 [41].

Data pre-processing. Following the settings from previous works [35, 42], we align every 3D pose in the Human3.6M dataset with the provided ground-truth 2D joint locations by applying the camera calibration transformation. The transformation including a scale, rotation, and translation, is attained from Procrustes analysis on the hip and shoulder joints. We then zero-center both the 2D and 3D poses around the root joint (pelvis). All the sequences are downsampled to five frames per second to reduce redundancy.

4.1. Quantitative Evaluation

We first report the quantitative results in terms of prediction accuracy on Human3.6M. The evaluation metric is via the Mean Per Joint Position Error (MPJPE) in millimeters between the ground-truth and the predicted 3D motions. We follow previous works [38, 21] by measuring MPJPE between the ground-truth motion and the best generated motion prediction (i.e., the closest one to the ground-truth). Because human motion prediction via a single image is sparsely studied until today\(^1\), we devise our original baseline for comparison: We re-train two 3D pose estimation approaches [28, 41], which also take a single image as input, by extending the output to be a 3D motion sequence. The results are summarized in Tab. 1. Note that it is however not a fair comparison because these two methods are not originally designed for predicting motions from a single image, and the comparative results are only aimed to show superiority of the MDN modeling.

It can be verified from Tab. 1 that our method outperforms [28, 41] by a large margin in MPJPE, and both of the two baselines encounter the bottleneck in capturing the

\(^1\)As the motion prediction module in [7] mainly learns 2D poses and does not involve 3D supervision, we can hardly make a fair comparison as our method is trained with 3D data.
accurate future motions from the weakly-informed single image. Moreover, deterministic systems can be confused by the structurally similar 2D poses followed by distinct future motions, which can be viewed as the main reason for the low MPJPE reflected in Tab. 1. On contrary, the multimodality of MDN equipped with the accuracy-aware prior energy demonstrates the effectiveness in accurately predicting motions from a single image.

4.2. Qualitative Evaluation

We hereby show some qualitative human motion prediction results on Human3.6M in Fig. 3 ∼ Fig. 6. It can be found that our method can generate the visually accurate (or fairly close) prediction among diverse hypotheses, for both standing and sitting actions. Also, we observe that action with more ambiguity in the image results in more variations among future motion hypotheses. For example, the half squat pose in Fig. 4 can naturally evolve to many possibilities such as squat deeper (Fig. 4(g,e)), rise up (Fig. 4(f,j)), sitting down (Fig. 4(l,h)), keep still (Fig. 4(m)), etc. Similar results can be seen in Fig. 5, where the following hand motions can be lowered (Fig. 5(d,e,f,i,k,l,m)) or kept horizontally raised (Fig. 5(g,h,i)). In contrast, once the given condition is less ambiguous, like the walking pose in Fig. 3, most outputs by our model can be standing-based motions. We suspect the reason can be that a large proportion of the standing poses in Human3.6M gives rise to the dataset bias towards standing motions. Nevertheless, even in this case, we can still notice that the model attempts to yield diverse predictions, by varying walking direction or adjusting walking velocity. We also show a challenging case in terms of unexpected change in human motions in Fig. 6. In Fig. 6(c), the last two frames suddenly changed while the first 13 frames almost remain still. None of the ten motion hypotheses generated by our model give the correct changing time of arm movement in the 14th frame. Exposed to such a huge stochasticity, our model comprises to give several plausible motion hypotheses (Fig. 6(d,f,h,i)) to cover lots of probable motion combinations in elbows and wrists. From the above analysis, we can confirm that our proposed MDN in motion prediction holds the strength to disambiguate the uncertainty imposed by the single input image, and produces visually natural movements that satisfy the given condition.

We next investigate the generalization capability of our approach by using our trained model on Human3.6M to directly examine the prediction power on MPII. Challenges in transferring our model to MPII mainly lies in: (i) MPII widely includes images from both indoor and outdoor, while all the scenes in Human3.6M are recorded indoor within a fixed space; (ii) MPII contains various types of 2D poses comparing to Human3.6M, with more potential possibilities in the future motions. As illustrated in Fig. 7 ∼ Fig. 9, we can see that our method generally produces reasonable future motions on the given image. It is interesting to point out that in Fig. 7, our model generates visually convincing future motions which appear similar to be the tennis player hitting back the tennis ball (Fig. 7(g)), even if such sports-related scenes do not exist in the training data. Consequently, the qualitative results in Fig. 7 ∼ Fig. 9 demonstrate the robust generalization of our model in handling different types of datasets.

We also show a failure case of our method in Fig. 10, in which some of the generated motion hypotheses (Fig. 10(g,h)) seem in violation of body kinetics. Also, the first frame (i.e., the corresponding 3D pose for Fig. 10(b)) of all the generated motion hypotheses are visually inconsistent with the image (Fig. 10(a)). The reason can be concluded to the significantly wrong 2D pose returned by the I2D block, and our model therefore cannot recover motions correctly from the wrong input.

4.3. Ablation Studies

To provide a deeper understanding of our method, we conduct ablation studies to analyze the prediction performance with respect to the following two aspects:

Number of Gaussian components $M$. We evaluate the prediction performance under different $M$ to gain more insights into its impact, in terms of prediction accuracy and diversity. The diversity is measured via the Average Pairwise Distance (APD) metric [38], which is calculated as

### Table 2: Evaluation in terms of MPJPE on the regularizing power of $L_d$, $L_v$, and $L_a$. The best results are in bold. The final row refers to our model with all three types of prior losses involved.

\]

APD averages the L2 distance between all the pairs of generated motion hypotheses, and a higher APD indicates a richer diversity within motions. The results on changes of MPJPE (accuracy) / APD (diversity) with different \(M\) are reported in the 2nd ~ 4th columns in Tab. 3. It can be observed that the relationship between accuracy and diversity is a trade-off. A larger \(M\) leads our model to better characterizing accurate predictions while sacrificing the diversity and additional computational consumption. Also, a small \(M\) contributes less to both accuracy and diversity. Suggested by the observation, we empirically set \(M\) to 10 in all experiments to ensure decent prediction performance.

Impact of \(L_d\), \(L_v\) and \(L_a\). We introduce the energy-based formulation to maintain motion coherence (\(L_v\)) and boost prediction accuracy (\(L_a\)). Tab. 2 shows the MPJPE by including different losses. It can be observed from the 4th row in Tab. 2 that the prediction performance generally improves by adding \(L_v\), including the two challenging cases of actions in “Sitting” and “SittingDown”. In particular, for “Sitting” and “SittingDown”, since most of the actions in Human3.6M are standing-based poses, \(L_v\) is empowered to regularize inter-pose velocity such that motion coherence in large global movements (e.g., from standing to sitting) can also be retained. Besides, it is worth mentioning that further adding \(L_a\) (last row in Tab. 2) contributes to the best performance of our method.

The adoption of \(L_d\) is to regularize the mixture coefficients to alleviate the degeneration. We can see in Tab. 2 (3rd row) that training with \(L_d\) improves the MPJPE specifically on the action “Discussion” and “Purchase”. We further investigate the APD and MPJPE without \(L_d\) (i.e., only using \(L_{MD}, L_v\) and \(L_a\) in Eq. 15), and display the result in the last column in Tab. 3. It can be confirmed that using \(L_d\) also slightly refines both MPJPE and APD. The above analysis validates that \(L_v, L_a\) and \(L_d\) respectively possess the power in positively promoting the prediction performance.

5. Conclusion

In this paper, we proposed a novel human motion prediction strategy by resorting to MDN modeling. Our model takes an image as input and handles the inner ambiguities in the weakly informed condition by generating diverse plausible future motion hypotheses. We also formulated
an energy-based prior loss to boost the prediction performance. Extensive experiments on two standard datasets qualitatively and quantitatively demonstrated the generalization and capability of our approach in characterizing both accurate and diverse predictions.

Our method involves a major limitation in its dependency on the 2D motion extraction module. If the stacked hourglass network cannot guarantee a reasonable 2D pose, our model will fail to predict. In the future, we would like to explore the possibilities of either adopting a more powerful 2D estimator or developing an end-to-end manner of training policy.
