Abstract

Chance constrained optimization problems allow to model problems where constraints involving stochastic components should only be violated with a small probability. Evolutionary algorithms have recently been applied to this scenario and shown to achieve high quality results. With this paper, we contribute to the theoretical understanding of evolutionary algorithms for chance constrained optimization. We study the scenario of stochastic components that are independent and Normally distributed. By generalizing results for the class of linear functions to the sum of transformed linear functions, we show that the (1+1) EA can optimize the chance constrained setting without additional constraints in time $O(n \log n)$. However, we show that imposing an additional uniform constraint already leads to local optima for very restricted scenarios and an exponential optimization time for the (1+1) EA. We therefore propose a multi-objective formulation of the problem which trades off the expected cost and its variance. We show that multi-objective evolutionary algorithms are highly effective when using this formulation and obtain a set of solutions that contains an optimal solution for any possible confidence level imposed on the constraint. Furthermore, we show that this approach can also be used to compute a set of optimal solutions for the chance constrained minimum spanning tree problem.

1 Introduction

Many real-world optimization problems involve solving optimization problems that contain stochastic components [3]. Chance constraints [4] allow to limit the probability of violating a constraint involving stochastic components. In contrast to limiting themselves to ruling out constraint violations completely, this allows to deal with crucial constraints in a way that allows to ensure meeting the constraints with high confidence (usually determined by a confidence level $\alpha$) while still maintaining solutions of high quality with respect to the given objective function.

Evolutionary algorithms have successfully been applied chance constrained optimization problems [25-27]. Recent studies investigated the classical knapsack problem in static [31,32] and dynamic settings [1] as well as complex stockpile blending problems [33] and the optimization of submodular functions [20]. Theoretical analyses for submodular problems with chance constraints, where each stochastic component is uniformly distributed and has the same amount of uncertainty, have shown that greedy algorithms and evolutionary Pareto optimization approaches only lose a small amount in terms of approximation quality when comparing against the corresponding deterministic problems [7,20] and that evolutionary algorithms significantly outperform the greedy approaches in practice. Other recent theoretical runtime analyses of evolutionary algorithms have produced initial results for restricted classes of instances of the knapsack problem where the weights are chosen randomly [22,54].
For our theoretical investigations, we use runtime analysis which has become the major theoretical tool for analyzing evolutionary algorithms in discrete search spaces [23] [4] [14] [9]. In order to understand the working behaviour of evolutionary algorithms on broader classes of problems with chance constraints, we consider the optimization of linear functions with respect to chance constraints where the stochastic components are independent and each component is chosen according to a Normal distribution $N(\mu_i, \sigma_i^2)$. This allows us to reformulate the problem by a deterministic equivalent non-linear formulation involving a linear combination of the expected value and the standard deviation of a given solution.

We first analyze the classical (1+1) EA on this problem formulation without additional constraints and show that it obtains an optimal solution in expected time $O(n \log n)$. In fact, our result not only holds for this specific type of class of functions, but for a wide combination of two linear functions. More precisely, our analysis applies to objective functions that can be written as a (weighted) sum of two functions that each are a monotone transformation of a linear pseudo-boolean function. While the formulation arising from the chance-constrained optimization problem requires the two linear functions to be defined on the same set of variables, our generalization allows an arbitrary overlap of the search spaces underlying the linear functions, from sharing all variables until completely disjoint search spaces. This part of our study is of particular interest as it broadens the class of functions from the class of simple linear pseudo-boolean functions widely studied in the area of runtime analysis of evolutionary algorithms to much more complex combinations of linear functions. Afterwards, we show that imposing a simple cardinality constraint for a simplified class of instances leads to local optima and exponential lower bounds for the (1+1) EA.

In order to deal with the issue of the (1+1) EA not being able to handle even simple constraints due to the non-linearity of the objective functions, we introduce a Pareto optimization approach for the chance constrained optimization problems under investigation. So far, Pareto optimization approaches that achieved provably good solutions provided a trade-off with respect to the original objective functions and given constraints. In contrast to this, our approach trades off the different components determining the uncertainty of solutions, namely the expected value and variance of a solution. A crucial property of our reformulation is that the extreme points of the Pareto front provide optimal solutions for any linear combination of the expected value and the standard deviation and solves the original chance constrained problem for any confidence level $\alpha \geq 1/2$. These insights mean that the users of the evolutionary multi-objective algorithm does not need to know the desired confidence level in advance but can pick from a set of trade-offs with respect to the expected value and variance for all possible confidence levels. We show that this approach can also be applied to the chance constrained minimum spanning tree problem where each edge cost is chosen independently according to its own Normal distribution. In terms of algorithms, we analyze the well-known GSEMO [12] which has been frequently applied in the context of Pareto optimization [23] [10] [15] [11] [35] and show that it computes such an optimal set of solutions for any confidence level of $\alpha \geq 1/2$ in expected polynomial time if the population size stays polynomial with respect to the given inputs. In order to deal with potentially exponentially many non-dominated objective vectors for the multi-objective formulation, we propose to use a convex hull based evolutionary multi-objective algorithm and show that it computes for every possible confidence level of $\alpha \geq 1/2$ an optimal solution in expected polynomial time even if the number of trade-offs with respect to the two objectives becomes exponential.

## 2 Chance Constrained Optimization Problems

Our basic chance-constrained setting is given as follows. Given a set of $n$ items $E = \{e_1, \ldots, e_n\}$ with weights $w_i$, $1 \leq i \leq n$, we want to solve

$$\min W \text{ subject to } Pr(w(x) \leq W) \geq \alpha,$$

where $w(x) = \sum_{i=1}^n w_i x_i$, $x \in \{0,1\}^n$, and $\alpha \in [0,1]$. Throughout this paper, we assume that the weights are independent and each $w_i$ is distributed according to a Normal distribution $N(\mu_i, \sigma_i^2)$, $1 \leq i \leq n$, where $\mu_i \geq 1$ and $\sigma_i \geq 1$, $1 \leq i \leq n$. We denote by $\nu_{\text{max}} = \max_{1 \leq i \leq n} \sigma_i^2$ and $\mu_{\text{max}} = \max_{1 \leq i \leq n} \mu_i$ the maximal variance and maximal expected value, respectively. According to [13], the problem given in Equation (1) is in this case equivalent to minimizing

$$g(x) = \sum_{i=1}^n \mu_i x_i + K_\alpha \cdot \left( \sum_{i=1}^n \sigma_i^2 x_i \right)^{1/2},$$

where $K_\alpha$ is the $\alpha$-fractile point of the standard Normal distribution. Throughout this paper, we assume $\alpha \in [1/2, 1]$ as we are interested in solutions of high confidence. Note that there is no finite value of $K_\alpha$ for $\alpha = 1$ due to the infinite tail of the Normal distribution. Our range of $\alpha$ implies $K_\alpha \geq 0$.

Our goal is to understand the working behaviour of evolutionary algorithms when optimizing chance constrained optimization problems. In particular, we want to understand how the reformulation in terms of the functions $g$ potentially in connection with additional constraints can be optimized by evolutionary algorithms. Note that the search point $0^n$ is
the optimal solution for \(g(x)\) and we first would like to understand the working behaviour of evolutionary algorithms on this problem formulation without any additional constraints. Such investigations generalize previous important analyses on the runtime behaviour of evolutionary algorithms for the class of linear functions, which has been the key vehicle for developing advanced analysis methods for evolutionary algorithms.

Afterwards, we will extend our investigations to the case where there are additional constraints. First, we consider the additional constraint \(|x|_1 \geq k\) which requires that at least \(k\) items are chosen in each feasible solution. Furthermore, we consider the formulation of the stochastic minimum spanning tree problem given in \([13]\). Given an undirected connected weighted graph \(G = (V, E)\), \(n = |V|\) and \(m = |E|\) with random weights \(w(e_i), e_i \in E\). The search space is \(\{0, 1\}^m\). For a search point \(x \in \{0, 1\}^m\), we have \(w(x) = \sum_{i=1}^{m} w(e_i)x_i\) as the weight of a solution \(x\). We investigate the problem given in Equation 1 and require for a solution \(x\) to be feasible that \(x\) encodes a connected graph. We do not require a solution to be a spanning tree in order to be feasible as removing an edge from a cycle in a connected graph automatically improves the solution quality and is being taken care of by the multi-objective algorithms we analyze in this paper. Note that the only difference compared to the previous setting involving the uniform constraint is the requirement that a feasible solution has to be a connected graph.

### 3 Analysis of (1+1) EA

The (1+1) EA (Algorithm 1) is a simple evolutionary algorithm using independent bit flips and elitist selection. It is very well studied in the theory of evolutionary computation \([5]\) and serves as a stepping stone towards the analysis of more complicated evolutionary algorithms. As common in the area of runtime analysis, we measure the run time of the (1+1) EA by the number of iterations of the repeat loop. The optimization time refers to the number of fitness evaluations until an optimal solution has been obtained for the first time, and the expected optimization time refers to the expectation of this value.

#### 3.1 Sums of Two Transformed Linear Functions without Constraints

In this subsection, we will study the (1+1) EA on the scenario given in (2), assuming no constraints on the number of one-bits. In fact, we will generalize the scenario to the sum of two transformed pseudo-Boolean linear functions which may only be partially overlapping. In (2), there is complete overlap on the domains of the two linear functions and the transformations are the identity function and the square root.

The crucial observation in our analysis is that the scenario considered here extends the linear function problem \([30]\) that is heavily investigated in the theory of evolutionary algorithms. Despite the simple structure of the problem, there is no clear fitness-distance correlation in the linear function problem, which makes the analysis of the global search operator of the (1+1) EA difficult. If only local mutations are used, leading to the well known randomized local search (RLS) algorithm \([6]\), then both the linear function problem and the generalized scenario considered here are very easy to analyze using standard coupon collector arguments \([19]\), leading to \(O(n \log n)\) expected optimization time. For the globally searching (1+1) EA, we will obtain the same bound, proving that the problem is easy to solve for it; however, we need advanced drift analysis methods to prove this.

**Set-up.** We will investigate a general optimization scenario involving two linear pseudo-Boolean functions in an unconstrained search space \(\{0, 1\}^n\). The objective function is an arbitrarily weighted sum of monotone transformations of two linear functions defined on (possibly overlapping) subspaces of \(\{0, 1\}^n\). Formally, we have

\[
\ell_1, \ell_2 : \{0, 1\}^{n/2} \to \mathbb{R}, \text{ where } \ell_1(y_1, \ldots, y_{n/2}) = \sum_{i=1}^{n/2} w^{(1)}_i y_i, \text{ and } \ell_2(z_1, \ldots, z_{n/2}) = \sum_{i=1}^{n/2} w^{(2)}_i z_i \text{ with non-negative weights } w^{(1)}_i \text{ and } w^{(2)}_i .
\]
• $B_1 \subseteq \{1, \ldots, n\}$ and $B_2 \subseteq \{1, \ldots, n\}$ of cardinality $n/2$ each, denoting the bit positions that $\ell_1$ resp.
\ $\ell_2$ are defined on in the actual objective function, and their overlap count $s := |B_1 \cap B_2|$, satisfying the
extended definitions $\ell_1^*(x_1, \ldots, x_{n-s}) = \sum_{i \in B_1} w_i r^{(1)}(i) x_i$ where $r^{(1)}(i)$ is the rank of $i$ in $B_1$; analogously
$\ell_2^*(x_1, \ldots, x_{n-s}) = \sum_{i \in B_2} w_i r^{(2)}(i) x_i$; note that $\ell_1^*$ and $\ell_2^*$ only depend essentially on $n/2$ bits.

Then the objective function $f: \{0,1\}^{n-s} \to \mathbb{R}$, which w.l.o.g. is to be minimized, is given by

$$f(x_1, \ldots, x_{n-s}) = h_1(\ell_1^*(x_1, \ldots, x_{n-s})) + h_2(\ell_2^*(x_1, \ldots, x_{n-s})). \tag{3}$$

This set-up includes the case that

$$f(x_1, \ldots, x_m) = \ell_1(x_1, \ldots, x_m) + R \sqrt{\ell_1(x_1, \ldots, x_m)}$$

for two $m$-dimensional, completely overlapping linear functions $\ell_1$ and $\ell_2$ and an arbitrary factor $R \geq 0$, as present
above in (2).

**Theorem 1.** Let $f$ be the sum of two transformed linear functions as defined in the set-up above. Then the expected
optimization time of the (1+1) EA on $f$ is $O(n \log n)$.

The proof of Theorem 1 uses drift analysis with a carefully defined potential function, explained in the following.

**Potential function.** We build upon the approach from 30 to construct a potential function $g^{(1)}$ for $\ell_1$ and a potential
function $g^{(2)}$ for $\ell_2$, resulting in a combined potential function $\phi(x) = g^{(1)}(x) + g^{(2)}(x)$. The individual potential
functions are obtained in the same way as if the (1+1) EA with mutation probability $1/n$ was only optimizing $\ell_1$ and
$\ell_2$, respectively, on an $n/2$-dimensional search space. The key idea is that accepted steps of the (1+1) EA on $g$
must improve at least one of the two functions $\ell_1$ and $\ell_2$. This event leads to a high enough drift of the respective
potential function that is still positive after pessimistically incorporating the potential loss due to flipping zero-bits that
only the other linear function depends on.

We proceed with the definition of the potential functions $g^{(1)}$ and $g^{(2)}$ (see Section 5 in 30). For the two underlying
linear functions we assume their arguments are reordered according to increasing weights. Note we cannot necessarily
sort the set of all indices $1, \ldots, n-s$ of the function $f$ so that both underlying linear functions have increasing
coefficients; however, as we analyze the underlying functions separately, we can each time use the required sorting in
these separate considerations.

**Definition 1.** Given a linear function $\sum_{i=1}^{k} w_i x_i$, where $w_1 \leq \cdots \leq w_k$, we define the potential function
$g(x_1, \ldots, x_k) = \sum_{i=1}^{k} g_i x_i$ by $g_i = \left(1 + \frac{1}{n - i}\right)^{n/2}$. In our scenario, $g^{(1)}(y)$ is the potential function
obtained from applying this construction to the $n/2$-dimensional linear function $\ell_1(y)$, and proceeding accordingly
with $g^{(2)}(z)$ and $\ell_2(y)$. Finally, we define $\phi(x) = g^{(1)}(y) + g^{(2)}(z)$.

For the proof of Theorem 1 we shall also need the following lemma, which basically establishes the non-overlapping
case $s = 0$ as worst case.

**Lemma 1.** For $n$ sufficiently large and $0 \leq s \leq n/2$ it holds that

$$\frac{1}{n-s} \left( \left(1 + \frac{1}{n-1}\right)^{n/2} - \left(1 + \frac{1}{n-1}\right)^s \right) \leq \frac{1}{n} \left( \left(1 + \frac{1}{n-1}\right)^{n/2} - 1 \right).$$

**Proof.** Writing the inequality with common denominator, we arrive at the equivalent inequality

$$\frac{s \left(1 + \frac{1}{n-1}\right)^{n/2} - n \cdot \left(1 + \frac{1}{n-1}\right)^s + n-s}{(n-s)n} \leq 0,$$

which holds for $s = 0$. The derivative of the numerator is

$$\left(1 + \frac{1}{n-1}\right)^{n/2} - n \cdot \ln(1+1/(n-1)) \left(1 + \frac{1}{n-1}\right)^s - 1,$$

which is clearly negative for all $s \geq 0$. \(\square\)
Proof of Theorem 7. Using the potential function from Definition 3, we analyze the (1+1) EA on \( f \), assume an arbitrary, non-optimal search point \( x_t \in \{0, 1\}^{n-s} \) and consider the expected change of \( g \) from time \( t \) to time \( t+1 \). We consider an accepted step where the offspring differs from the parent since this is necessary for \( g \) to change. That is, at least one 1-bit flips and \( f \) does not grow. Let \( A \) be the event that an offspring \( x' \neq x_t \) is accepted. We now condition on \( A \). Clearly, this implies that at least one of the two functions \( \ell_1 \) and \( \ell_2 \) does not grow. Since the two cases are symmetrical, we assume without loss of generality that \( \ell_1 \) does not grow and that at least one bit in \( B_1 \) is flipped from 1 to 0. Hence, we consider exactly the situation that the (1+1) EA with the linear function \( \ell_1 \) as n/2-bit fitness function produces an offspring that is accepted and different from the parent.

Let \( Y_t = g^{(1)}(y_t) \), where \( y_t \) is the restriction of \( x_t \) to the \( n/2 \) bits in \( B_1 \) that \( g^{(1)} \) depends on, assuming the indices of \( x_t \) to be reordered with respect to increasing coefficients \( w_1^{(1)} \ldots w_{n/2}^{(1)} \). To compute the drift of \( g \), we distinguish between several cases and events in a way similar to the proof of Th. 5.1 in [30]. Every of these cases first bounds the drift of \( Y_t \) precisely and then adds a pessimistic estimate of the drift of \( Z_t = g^{(2)}(z_t) \), which corresponds to the other linear function on bits from \( B_2 \), i.e., the function whose value may grow under the event \( A \), assuming the indices of \( z_t \) to be reordered with respect to increasing coefficients \( w_1^{(2)} \ldots w_{n/2}^{(2)} \). Since the estimate of the drift of \( Z_t \) is always the same, we present it first. No matter whether we condition on \( A \) or not, if we pessimistically assume that each bit in \( z_t \) (i.e., the restriction of \( x_t \) to the bits in \( B_2 \)) can flip to 1, assume the largest possible weights in the potential function and that the resulting search point is still accepted, we obtain the upper bound

\[
E(Z_{t+1} - Z_t | Z_t) \leq \frac{1}{n-s} \sum_{i=s+1}^{n/2} \left( 1 + \frac{1}{n-1} \right)^{i-1} \leq \frac{1}{n} \sum_{i=1}^{n/2} \left( 1 + \frac{1}{n-1} \right)^{i-1} \leq \frac{1 + o(1)}{n} \frac{e^{1/2} - 1}{1/(n-1)} < 0.649
\] (4)

for \( n \) large enough, where the first inequality uses Lemma 4.

We next make the detailed case analysis for the drift, assuming \( A \). To bound \( E(g(x_t) - g(x_{t+1}) | x_t) \), three different cases are considered.

Case 1: at least two one-bits in \( y_t \) flip (event \( S_1 \)). Since \( g_i \geq 1 \) for all \( i \) and every zero-bit in \( y_t \) flips to one with probability at most \( 1/(n-s) \), we can re-use the estimations from (4) and obtain

\[
E(Y_t - Y_{t+1} | Y_t; S_1) \geq 2 - \frac{1}{n-s} \sum_{i=s+1}^{n/2} \left( 1 + \frac{1}{n-1} \right)^{i-1} \geq 2 - 0.649.
\]

Along with (4), we have

\[
E(g(x_t) - g(x_{t+1}) | x_t; S_1) \geq E(Y_t - Y_{t+1} | Y_t; S_1) - E(Z_{t} - Z_{t+1} | Z_t; S_1) \geq 2 - 0.649 - 0.649 > 0.7.
\]

Case 2: exactly one one-bit in \( y_t \) flips (event \( S_2 \)). Let \( i^* \) denote the random index of the flipping one-bit in \( y_t \). Moreover, let the function \( \alpha(i) = \max\{j \leq i \mid w_{j}^{(1)} = w_{j}^{(1)} \} \) denote the largest index at most \( i \) with the same weight as \( w_i \), i.e., \( \alpha(i) - 1 \) is the largest index of a strictly smaller weight; using our assumption that the weights are monotonically increasing with their index. Recalling that we still condition on \( A \), we distinguish between two subcases according to the number of flipping zero-bits in \( y_t \).

Subcase 2.1: exactly one one-bit and no zero-bit in \( y_t \) flips (event \( S_{21} \)). By definition of \( g^{(1)} \), we have

\[
E(Y_t - Y_{t+1} | Y_t; S_{21}) \geq \left( 1 + \frac{1}{n-1} \right)^{\alpha(i^*) - 1},
\]

so along with (4), we have

\[
E(g(x_t) - g(x_{t+1}) | x_t; S_{21}) \geq \left( 1 + \frac{1}{n-1} \right)^{\alpha(i^*) - 1} - 0.649 > 1 - 0.649 > 0.351
\]

We summarize that the drift of \( g \) is non-negative both in Case 1 and in Case 2.1. Hence, we estimate the drift in these cases as 0 and focus only on the event defined in the following subcase.

Subcase 2.2: exactly one one-bit and at least one zero-bit in \( y_t \) flips (event \( S_{21} \)).

If at least one zero-bit having the same or a larger weight than bit \( i^* \) flips, neither \( \ell_1 \) nor \( g_t \) change (because the offspring has the same function value or is rejected); hence, we now assume without loss of generality that all flipping
zero-bits are right of \( \alpha(i^*) \). This corresponds to the case called Subcase 2.2.2 in the proof of Th. 5 from [30]. Redoing that piece of analysis, using \( k \) for the number of zero-bits right of \( \alpha(i^*) \), we obtain
\[
E(Y_t - Y_{t+1} \mid Y_t; S_{22}) \geq \left( 1 + \frac{1}{n-1} \right)^{\alpha(i^*)-1} - \sum_{j=1}^{k} \frac{g_{\alpha(i^*)-j}}{n(1 - (1/1/n)^k)} \geq 0
\]

Along with [4], we have
\[
E(g(x_t) - g(x_{t+1}) \mid x_t; S_{22}) \geq 0 - 0.649 = -0.649.
\]

We now compute the total drift using the law of total probability. Let \( I \) be the set of one-bits in the whole bit string \( x_t \). Since the analysis is symmetrical, when considering an index \( i \in I \), we implicitly consider the situation that \( A \) occurs if \( i \in S_1 \), i.e., \( i \) belongs to \( y_t \), and analogously with the event \( A' \), the bits \( S_2 \) and \( z_t \). Now, for \( i \in I \), let \( L_i \) denote the event that bit \( i \) is the only flipping one-bit in the considered part of the bit string and that no zero-bit left of (and including) bit \( \alpha(i) \) flips in that part. Furthermore, let \( S_i \) the subevent that no zero-bits right of \( \alpha(i) \) flip. Thanks to the analysis above, the union of the \( L_i \) are the only cases that may lead to a negative drift of the total potential \( g(x_t) - g(x_{t+1}) \). We note that \( S_i \) corresponds to the event \( S_{21} \) and \( L_i \setminus S_i \) to the event \( S_{22} \), each time with \( i \) as the flipping one-bit. We obtain
\[
E(g(x_t) - g(x_{t+1}) \mid x_t) \geq \sum_{i \in I} \left( E(g(x_t) - g(x_{t+1}) \mid S_i) \cdot \Pr(S_i) + E(g(x_t) - g(x_{t+1}) \mid L_i \setminus S_i) \cdot \Pr(L_i \setminus S_i) \right)
\]
(5)

We derive that \( \Pr(S_i) = (1/n)(1 - 1/n)^{n/2 - 1} \geq e^{-1/2}/n \) since bit \( i \) flips and the remaining \( n/2 - 1 \) bits are not allowed to flip. Moreover, \( \Pr(L_i \setminus S_i) = (1 - 1/n)^{n/2 - \alpha(i^*)-1} (1/n)(1 - 1/n)^{\alpha(i^*)} = (1/n)(1 - 1/n)^{n/2 - \alpha(i^*)-1} (1 - 1/n)^{n/2 - 1} \) since only one bit from positions \( \alpha(i^*), \ldots, n/2 \) flips and at least one bit from positions \( 1, \ldots, \alpha(i^*) \). Plugging these probability bounds and the bounds on conditional drifts into (5), we have
\[
E(g(x_t) - g(x_{t+1}) \mid x_t) \geq \sum_{i \in I} \left( \left( 1 + \frac{1}{n-1} \right)^{\alpha(i^*)-1} - 0.649 \right) \frac{1}{n} \left( 1 - \frac{1}{n} \right)^{n/2 - 1} - 0.649 \frac{1}{n} \left( 1 - \frac{1}{n} \right)^{n/2 - \alpha(i^*)-1} - \left( 1 - \frac{1}{n} \right)^{n/2 - 1} \right)
\]
\[
= \frac{1}{n} \sum_{i \in I} \left( 1 - \frac{1}{n} \right)^{n/2 - \alpha(i^*)-1} - 0.649 \left( \left( 1 - \frac{1}{n} \right)^{n/2 - 1} + \left( 1 - \frac{1}{n} \right)^{n/2 - \alpha(i^*)-1} - \left( 1 - \frac{1}{n} \right)^{n/2 - 1} \right)
\]
\[
\geq \frac{1}{n} \sum_{i \in I} \left( 0.351 \left( 1 - \frac{1}{n} \right)^{n/2 - \alpha(i^*)-1} \right) \geq \frac{1}{n} \sum_{i \in I} 0.351 e^{-1/2} \geq 0.351 e^{-1/2} \frac{g(x_t)}{n},
\]
where the last inequality follows from the fact that \( g_i \leq e^{-1/2} \) for all \( i \in I \). This concludes the case analysis.

Altogether, we have established a multiplicative drift of the potential \( g \) with a factor \( \delta = 0.351 e^{-1/2}/n \) so that we obtain the claimed \( O(n \log n) \) bound on the expected optimization time via the multiplicative drift theorem [8].

3.2 Lower bound for (1+1) EA and uniform constraint

We now consider the problem stated in Equation 11 with an additional uniform constraint that requires that each feasible solution contains at least \( k \) elements, i.e., \( |x_1| \geq k \) holds. We show that the (1+1) EA has an exponential optimization time on an even very restrictive class of instances involving only two different weight distributions.

We use the following fitness function, which should be minimized in the (1+1) EA:
\[
f(x) = \begin{cases} g(x) \\ (k - |x_1|) \cdot L \end{cases} \quad |x_1| \geq k,
\]
where \( L = (1 + \sum_{i=1}^{n} \mu_i + K \alpha(\sum_{i=1}^{n} \sigma_i^2)^{1/2}) \). This gives a large penalty to each unit of constraint violation. This implies that any feasible solution is better than any infeasible solution and that \( f(x) > f(y) \) holds iff both \( x \) and \( y \) are infeasible and \( |x_1| > |y_1| \). Furthermore, the fitness value of an infeasible solution only depends on the number of its elements.
We now show a lower bound on the optimization time of the (1+1) EA for a specific instance class \( I \) containing only two types of elements. Type \( a \) elements have weights chosen according to \( N(n^2 + \delta, 1) \) and type \( b \) elements have weights chosen according to \( N(n^2, 2) \). We set \( \delta = \frac{2k}{k+1.48} \). The instance \( I \) has exactly \( n/2 \) elements of type \( a \) and \( n/2 \) elements of type \( b \). We consider \( K_\alpha = 1 \) which matches \( \alpha = 0.84134 \), and set \( k = 0.51n \). Using the fitness function \( f \), we have the additional property for two feasible solutions \( x \) and \( y \) that \( f(x) < f(y) \) if \( |x_1| < |y_1| \) due to an expected weight of at least \( n^2 \) for any additional element in a feasible solution. This also implies that an optimal solution has to consist of exactly \( k \) elements. The quality of a solution with \( k \) elements only depends on the number of type \( a \) and type \( b \) elements it contains. An optimal solution includes \( n/2 \) elements of type \( a \) whereas a locally optimal solution includes \( n/2 \) elements of type \( b \). The (1+1) EA produces with high probability the locally optimal solution before the global optimum which leads to the following result.

**Theorem 2.** The optimization time of the (1+1) EA on the instance \( I \) using the fitness function \( f \) is \( e^{\Omega(n)} \) with probability \( 1 - e^{-\Omega(n^{1/4})} \).

**Proof.** We first analyze the quality of solutions with exactly \( k \) elements and show that \( x^* \) is an optimal solution if it contains exactly \( n/2 \) elements of type \( a \). Consider a solution \( x \) with \( \ell \) elements of type \( b \) and \( k \) elements in total.

We have

\[
f(x) = (k - \ell)(n^2 + \delta) + \ell \cdot n^2 + \sqrt{k + \ell} = k(n^2 + \delta) - \delta \ell + \sqrt{k + \ell}
\]

Let \( \ell \in [\max\{0, k - n/2\}, \min\{k, n/2\}] \) and consider the first derivative of the corresponding continuous function

\[
p(\ell) = k(n^2 + \delta) - \delta \ell + \sqrt{k + \ell}.
\]

We have \( p'(\ell) = -\delta + \frac{1}{2\sqrt{k + \ell}} = -\frac{1}{2\sqrt{1.48}} + \frac{1}{2\sqrt{k + \ell}}, \) and \( p'(\ell) = 0 \) for \( \ell = 0.48 \cdot k \) and \( p''(\ell) = -\frac{1}{4(k + \ell)^{3/2}} \) which is negative for all \( \ell \geq 0 \).

Therefore, \( p \) has its maximum at \( \ell = 0.48k \), is strongly monotonically increasing in \( \ell \) in the interval \( [0, 0.48 \cdot k] \), and strongly monotonically decreasing for \( \ell \in [0.48 \cdot k, k] \). We have \( k = 0.51n \) with implies that we consider integer values of \( k \in [0.01n, 0.5n] \). We have

\[
p(0.01n) < p(0.5n)
\]

\[
\iff k(n^2 + \delta) - 0.01\delta n + \sqrt{0.52n} < k(n^2 + \delta) - 0.5\delta n + \sqrt{1.01n}
\]

\[
\iff 0.49n \cdot \frac{1}{2\sqrt{0.51n \cdot 1.48}} < \sqrt{1.01n} - \sqrt{0.52n}
\]

\[
\iff \frac{0.49}{2\sqrt{0.7548}} \cdot \sqrt{n} < (\sqrt{1.01} - \sqrt{0.52}) \sqrt{n}
\]

where the last inequality holds as \( \frac{0.49}{2\sqrt{0.7548}} < 0.2821 \) and \( \sqrt{1.01} - \sqrt{0.52} > 0.2838 \).

Hence, among the all solutions consisting of exactly \( k \) elements, solutions are optimal if they contain exactly \( n/2 \) elements of type \( a \) and are locally optimal if they contain exactly \( n/2 \) elements of type \( b \).

Any search point with \( r + 1 \) elements is worse than any search point with \( r \) elements, \( k \leq r \leq n \), as the expected weight of an element is in \( \{n^2, n^2 + \delta\} \) and the standard deviation of a solution is at most \( \sqrt{2n} \) and \( K_\alpha = 1 \) holds. Therefore, once a feasible solution has been obtained the number of elements can not be increased and the number of elements decreases until a solution with \( k \) elements has been obtained for the first time.

We now show that the (1+1) EA produces a locally optimal solution consisting of \( n/2 \) elements of type \( b \) within \( O(n^2) \) iterations with probability \( 1 - e^{-\Omega(n^{1/4})} \). We do this by considering different phases of the algorithm of length \( O(n^2) \) and bounding the failure probabilities by \( e^{-\Omega(n^{1/4})} \) in each phase. The initial solution \( x \) chosen uniformly at random is infeasible and we have \( 0.49n < |x_1| < 0.51n \) with probability \( 1 - e^{-\Omega(n)} \) using Chernoff bounds.

For two infeasible solutions \( x \) and \( y \) we have \( f(x) > f(y) \) iff \( |x_1| > |y_1| \). The number of elements in an infeasible solution is increased with probability at least \( (n - k)/en = \Theta(1) \) and at most \( 0.02n \) steps increasing the number of elements are necessary to obtain a feasible solution. Hence, and expected number of \( O(n) \) is required to produce a feasible solution and the probability to achieve a feasible solution within \( O(n^2) \) steps is \( 1 - e^{-\Omega(n)} \) using Markov’s inequality in combination with a restart argument consisting of \( n \) restarts.

Until a feasible solution has been found for the first time, there is no bias and the first feasible solution with \( r \geq k \) items is chosen uniformly at random among all sets containing exactly \( r \) items. When reaching the first feasible solution with \( r \geq k \) elements, it contains in expectation \( r/2 \) elements of type \( a \) and \( r/2 \) elements of type \( b \). The probability
that the number of type $a$ elements is less than $0.499r$ is $e^{-\Omega(n)}$ using the Chernoff bound for the hypergeometric distribution (see Theorem 1.10.25 in [5]). We have $r \leq k + n^{1/2}$ with probability $1 - e^{-\Omega(n^{1/2})}$ for the first feasible solution as the probability to flip at least $n^{1/2}$ in a single mutation step within $O(n^2)$ steps is $e^{-\Omega(n^{1/2})}$.

Using arguments as before, the function

$$p_r(\ell) = r(n^2 + \delta) - \delta \ell + \sqrt{r + \ell}$$

has its maximum at $0.48r$ and is strongly monotonically increasing in $\ell$ in the interval $[0, 0.48 \cdot r]$, and strongly monotonically decreasing for $\ell \in [0.48 \cdot r, r]$. Hence producing from a solution $x$ an solution $y$ with $|x|_1 = |y|_1$ with a smaller number of type $b$ elements is not accepted unless a solution with at most $0.48r$ elements of type $b$ is produced which happens with probability $e^{-\Omega(n)}$ in $O(n^2)$ steps. The only steps that may reduce the number of type $b$ elements are steps reducing the number of elements in the solution over all. A step reducing the number of elements has probability at least $r/(en) = \Theta(1)$. At most $n^{1/2}$ of such steps are required to obtain a solution with exactly $k$ elements and the expected number of steps required to produce from a solution with $r \leq k + n^{1/4}$ elements a solution with $k$ elements is $O(n^{1/4})$ and a solution with exactly $k$ elements has been produced in time $O(n^2)$ with probability $1 - e^{-\Omega(n)}$ using again Markov’s inequality in combination with $n$ restarts. In each of these $O(n^2)$ steps, there is no mutation flipping at least $n^{1/4}$ bits with probability $e^{-\Omega(n^{1/4})}$. This implies that the algorithm reaches a solution with $k$ elements where at least

$$0.499 \cdot (k + n^{1/2}) - n^{1/4} \cdot n^{1/2} \geq 0.49k$$

elements are of type $b$ with probability $1 - e^{-\Omega(n^{1/4})}$ within a phase of $O(n^2)$ steps.

Having obtained a solution with $k$ elements and at least $0.49k$ elements of type $b$, the (1+1) EA does not accept any solution with less elements of type $b$ unless a solution with at most $0.48k$ elements of type $b$ is produced. Producing a solution with at most $0.48k$ elements of type $b$ requires flipping at least $0.01k$ bits which happens with probability $e^{-\Omega(n^2)}$ in $O(n^2)$ steps. Let $x$ be a solution with $k$ elements where $\ell < n^{1/2}$ elements are of type $b$. The probability to produce from $x$ a solution with $k$ elements and at least $\ell + 1$ elements of type $b$ is at least

$$(n/2 - \ell) \cdot (k - \ell)/(en) \geq (n/2 - \ell) \cdot 0.01n/(en) = (n/2 - \ell)/(100en)$$

as $k - \ell \geq 0.01n$ and a type $a$ and a type $b$ elements need to swap. The number of type $b$ elements is increased until having achieved $\ell = n/2$ in expected time $O(n \log n)$ using fitness based partitions with respect to $\ell$ and summing up the waiting times to increase the different values of $\ell$. Using again Markov’s inequality together with the restart argument involving $n/\log n$ restarts, the probability to have not obtained the solution with $n/2$ elements of type $b$ is $e^{-\Omega(n/\log n)}$. Hence, the local optimal solution with $k$ elements among them $n/2$ of type $b$ is produced in $O(n^2)$ steps with probability $1 - e^{-\Omega(n^{1/4})}$.

The time to producing from such a locally optimal solution an optimal solution consisting of $n/2$ elements of type $a$ is $e^{\Omega(n)}$ with probability $1 - e^{-\Omega(n)}$ as the number of type $b$ elements needs to be reduced to at most $0.48k$ in order to accept an offspring with less than $n/2$ elements of type $b$. This implies that the optimization time on the instance $I$ is $e^{\Omega(n)}$ with probability $1 - e^{-\Omega(n^{1/4})}$.

A similar lower bound for a specific class of instances of the chance constrained minimum spanning tree problem having two types of edge weights can be obtained following the ideas given in the proof of Theorem 2.

## 4 Multi-Objective Evolutionary Algorithm

We now consider bi-objective formulations of the chance constrained problems with uniform and spanning tree constraints. We use a Pareto Optimisation approach for this which computes trade-offs with respect to the expected weight $\mu$ and variance $\nu$. We say that a solution $z$ dominates a solution $x$ (denoted as $z \preceq x$) iff $\mu(z) \leq \mu(x)$ and $\nu(z) \leq \nu(x)$. We say that $z$ strongly dominates $x$ (denoted as $z < x$) iff $z \preceq x$ and $\mu(z) < \mu(x)$ or $\nu(z) < \nu(x)$.

We investigate the algorithm GSEMO [16, 12] shown in Algorithm 2 which has been frequently used in theoretical studies of Pareto optimization. It starts with a solution chosen uniformly at random and keeps at each time step a set of non-dominated solutions found so far. In addition to being able to achieve strong theoretical guarantees [16, 11, 35], GSEMO using different types of multi-objective formulation has shown strong performance in practice [27, 26, 23]. We study the multi-objective evolutionary algorithms in terms of the expected time (measured in terms of iterations of the algorithm) until they have produced a population which contains an optimal solution for each $\alpha \in [1/2, 1]$. 

8
Algorithm 2: Global SEMO

1. Choose $x \in \{0, 1\}^n$ uniformly at random;
2. $P \leftarrow \{x\}$;
3. repeat
4. Choose $x \in P$ uniformly at random;
5. Create $y$ by flipping each bit $x_i$ of $x$ with probability $\frac{1}{n}$;
6. if $\exists w \in P : w \prec y$ then
   7. $S \leftarrow (P \cup \{y\}) \setminus \{z \in P \mid y \leq z\}$;
8. until stop;

4.1 Uniform Constraints

For the case of the uniform constraint $|x|_1 \geq k$, we consider the objective function $f(x) = (\mu(x), v(x))$ where

$$\mu(x) = \begin{cases} \sum_{i=1}^n \mu_i x_i & |x|_1 \geq k \\ (k - |x|_1) \cdot (1 + \sum_{i=1}^n \mu_i) & |x|_1 < k \end{cases}$$

$$v(x) = \begin{cases} \sum_{i=1}^n \sigma_i^2 x_i & |x|_1 \geq k \\ (k - |x|_1) \cdot (1 + \sum_{i=1}^n \sigma_i^2) & |x|_1 < k \end{cases}$$

Note that it gives the expected value and variance for any feasible solution, and a large penalty for any unit of constraint violation in each objective function if a solution is infeasible. This implies that the objective value of an infeasible solution is always worse than the value of a feasible solution.

As we have $\mu_i \geq 1$, and $\sigma_i \geq 1$, $1 \leq i \leq n$, each Pareto optimal solution contains exactly $k$ elements. This is due to the fact that we can remove from a solution $x$ with $|x|_1 > k$ any element to obtain a solution $y$ with $c(y) < c(x)$ and $v(y) < v(x)$. We will minimize $f_\lambda(x) = \lambda \mu(x) + (1-\lambda)v(x)$ by selecting minimal elements with respect to $f_\lambda(e_i) = \lambda \mu_i + (1-\lambda)\sigma_i^2$, $0 < \lambda < 1$. For the special cases $\lambda = 0$ and $\lambda = 1$, we minimize $f_\lambda$ by minimizing $f_0(x) = (v(x), \mu(x))$ and $f_1(x) = (\mu(x), v(x))$ with respect to the lexicographic order. Note, that we are using $f_\lambda$ both for the evaluation of a search point $x$ as well as the evaluation of an element $e_i$. For each fixed $\lambda \in [0,1]$, an optimal solution for $f_\lambda$ can be obtained by sorting the items increasing order of $f_\lambda$ and selecting the first $k$ of them.

For a given set $X$ of such points we denote by $X_\lambda \subseteq X$ the set of minimal elements with respect to $f_\lambda$. Note that all points in the sets $X_\lambda$, $0 \leq \lambda \leq 1$, are not strongly dominated in $X$ and therefore constitute Pareto optimal points when only considering the set of search points in $X$.

Definition 2 (Extreme point of set $X$). For a given set $X$, we call $f(x) = (\mu(x), v(x))$ an extreme point of $X$ if there is a $\lambda \in [0,1]$ such that $x \in X_\lambda$ and $v(x) = \max_{y \in X_\lambda} v(y)$.

We denote by $f(X)$ the set of objective vectors corresponding to a set $X \subseteq 2^E$, and by $f(2^E)$ the set of all objective vectors of the considered search space $2^E$. The extreme points of $2^E$ are given by the extreme points of the convex hull of $f(2^E)$. A crucial property of the extreme points is that they contain all objective vectors that are optimal for any $\lambda \in [0,1]$. Hence, if there is an optimal solution that can be obtained by minimizing $f_\lambda$ for a (potentially unknown) value of $\lambda$, then such a solution is contained in the set of search points corresponding to the extreme points of $2^E$.

In the following, we relate an optimal solution of

$$g(x) = \sum_{i=1}^n \mu_i x_i + K_\alpha \cdot \left(\sum_{i=1}^n \sigma_i^2 x_i\right)^{1/2}$$

subject to $|x|_1 \geq k$.

to an optimal solution of

$$g_R(x) = R \cdot \sum_{i=1}^n \mu_i x_i + K_\alpha \cdot \left(\sum_{i=1}^n \sigma_i^2 x_i\right)$$

subject to $|x|_1 \geq k$. 

9
for a given parameter $R \geq 0$ that determines the weighting of $\mu(x)$ and $\nu(x)$. Note that $g_R$ is a linear combination of the expected value and the variance and optimizing $g_R$ is equivalent to optimizing $f_X$ for $\lambda = R/(R + K_\alpha)$ as we have $g_R(x) = (R + K_\alpha) \cdot f_X(x)$ in this case. We use $g_R$ to show that there is a weighting that leads to an optimal solution for $g$ following the notation given in [13], but will work with the normalized weighting of $\lambda$ when analyzing our multi-objective approach.

Let $x^*$ be an (unknown) optimal solution for $g$ and let $D(x^*) = (\sum_{i=1}^n \sigma_i^2 x_i^*)^{1/2}$ be its standard deviation. Lemma 2 follows directly from the proof of Theorems 1–3 in [13] where it has been shown to hold for the constraint where a feasible solution has to be a spanning tree. However, the proof only uses the standard deviation of an optimal solution and relates this to the weighting of the expected value and the variance. It therefore holds for the whole search space independently of the constraint that is imposed on it. Therefore, it also holds for the uniform constraint where we require $|x|_1 \geq k$.

**Lemma 2** (follows from Theorems 1–3 in [13]). An optimal solution for $g_{2D(X^*)}$ is also optimal for $g$.

Based on Lemma 2, an optimal solution for $f_\lambda$, where $\lambda = 2D(X^*)/(2D(X^*) + K_\alpha)$, is also optimal for $g$. As we are dealing with a uniform constraint, an optimal solution for $f_\lambda$ can be obtained by greedily selecting elements according to $f_\lambda$ until $k$ elements have been included. The extreme points of the convex hull cover to all values of $\lambda$ where optimal solutions differ as they constitute the values of $\lambda$ where the optimal greedy solution might change and we bound the number of such extreme points in the following.

In order to identify the extreme points of the Pareto front, we observe that the order of two elements $e_i$ and $e_j$ with respect to a greedy approach selecting always a minimal element with respect to $f_\lambda$ can only change for one fixed value of $\lambda$. We define $\lambda_{i,j} = \frac{\sigma_i^2 - \sigma_j^2}{(\mu_i - \mu_j) + (\sigma_i^2 - \sigma_j^2)}$ for the pair of items $e_i$ and $e_j$ where $\sigma_i^2 \leq \sigma_j^2$ and $\mu_i > \mu_j$ holds, $1 \leq i < j \leq n$. Consider the set $\Lambda = \{\lambda_0, \lambda_1, \ldots, \lambda_t, \lambda_t+1\}$ where $\lambda_1, \ldots, \lambda_t$ are the values $\lambda_{i,j}$ in increasing order and $\lambda_0 = 0$ and $\lambda_t+1 = 1$. The key observation is that computing Pareto optimal solutions that are optimal solutions for $f_\lambda$ and every $\lambda \in \Lambda$ gives the extreme points of the problem.

**Lemma 3.** Each extreme point of the multi-objective formulation is Pareto optimal and optimal with respect to $f_\lambda$ for at least one $\lambda \in \Lambda$. The number of extreme points is at most $n(n-1)/2 + 2 \leq n^2$.

**Proof.** For each extreme point $f(x)$ there is a $\lambda \in [0,1]$ such that $x$ is optimal for $f_\lambda$ which implies that $x$ is Pareto optimal. Let $X^* \subseteq 2^E$ be the set of solutions corresponding to the extreme points of the convex hull of the Pareto front. For each extreme point $f(x^*) \in f(X^*)$, there exists a $\lambda^* \in [0,1]$ such that $f_{\lambda^*}(x^*) = \min_{x \in 2^E} f_{\lambda^*}(x)$ and $f_{\lambda^*}(x) > \min_{x \in 2^E} f_{\lambda^*}(x)$ for all $f(x) \neq f(x^*)$.

If an item $e_i$ dominates an item $e_j$, i.e. we have $\mu_i \leq \mu_j$ and $\sigma_i^2 \leq \sigma_j^2$, then $e_i$ can be included prior to $e_j$ in a greedy solution for any $f_\lambda$. Assume that the item $e_1, \ldots, e_n$ are sorted in increasing order of the variances $\sigma_i^2$, i.e $i \leq j$ iff $\sigma_i^2 \leq \sigma_j^2$. For two items $e_i$ and $e_j$, $i < j$, that are incomparable, i.e. where $\sigma_i^2 < \sigma_j^2$ and $\mu_i > \mu_j$ holds, the order of the items for $f_\lambda$ changes from $f_\lambda(e_i) < f_\lambda(e_j)$ to $f_\lambda(e_j) < f_\lambda(e_i)$ at exactly one particular threshold value $\lambda$.

Consider the items $e_i$ and $e_j$ with $\sigma_i^2 < \sigma_j^2$ and $\mu_i > \mu_j$. We have $f_\lambda(e_i) < f_\lambda(e_j)$ iff

\[
\lambda \mu_i + (1 - \lambda) \sigma_i^2 < \lambda \mu_j + (1 - \lambda) \sigma_j^2 \\
\iff \lambda/(1 - \lambda) < (\sigma_j^2 - \sigma_i^2)/((\mu_i - \mu_j)) \\
\iff \lambda < \frac{\sigma_j^2 - \sigma_i^2}{(\mu_i - \mu_j) + (\sigma_j^2 - \sigma_i^2)}.
\]

Moreover, we have

\[
f_\lambda(e_i) = f_\lambda(e_j) \text{ iff } \lambda = \frac{\sigma_j^2 - \sigma_i^2}{(\mu_i - \mu_j) + (\sigma_j^2 - \sigma_i^2)}
\]

and

\[
f_\lambda(e_i) > f_\lambda(e_j) \text{ iff } \lambda > \frac{\sigma_j^2 - \sigma_i^2}{(\mu_i - \mu_j) + (\sigma_j^2 - \sigma_i^2)}.
\]

We define $\lambda_{i,j} = \frac{\sigma_j^2 - \sigma_i^2}{(\mu_i - \mu_j) + (\sigma_j^2 - \sigma_i^2)}$ for the pair of items $e_i$ and $e_j$ where $\sigma_i^2 < \sigma_j^2$ and $\mu_i > \mu_j$ holds, $1 \leq i < j \leq n$. Note $\lambda_{i,j} \in [0,1]$ if $\sigma_i^2 < \sigma_j^2$ and $\mu_i > \mu_j$, $1 \leq i < j \leq n$, and that these values of $\lambda$ are the only values where the
order between the two elements according to $f_\lambda$ can change. This implies that these are the only weightenings where the greedy solution (which is an optimal solution) may change.

Consider the set $\Lambda = \{\lambda_0, \lambda_1, \ldots, \lambda_\ell, \lambda_{\ell+1}\}$ where $\lambda_0, \lambda_1, \ldots, \lambda_\ell$ are the values $\lambda_{i,j}$ in increasing order and $\lambda_0 = 0$ and $\lambda_{\ell+1} = 1$. We have $\ell \leq n(n - 1)/2$ as we only need to consider pairs of items and therefore $|\Lambda| \leq n(n - 1)/2 + 2 \leq n^2$. □

In the following, we assume that $v_{\text{max}} \leq \mu_{\text{max}}$ holds. Otherwise, the bound can be tightened by replacing $v_{\text{max}}$ by $\mu_{\text{max}}$. The following lemma gives an upper on the expected time until GSEMO has obtained Pareto optimal solution of minimal variance. Note that this solution is optimal for $f_0$.

**Lemma 4.** The expected time until GSEMO has included a Pareto optimal search point of minimal variance in the population is $O(\lambda_{\text{max}}^n n^2 (\log n + \log v_{\text{max}}))$.

**Proof.** Starting with an infeasible solution this implies that the population size is 1 until a feasible solution has been obtained for the first time. The fitness of an infeasible solution is determined by the number of elements $r = |x|_1 < k$ in the solution. It increases with probability at least $r/(en)$ in the next iteration. As no solution with less then $r$ elements is accepted until a feasible solution has been obtained for the first time, the number of elements increases to at least $k$ within $O(n \log n)$ steps using a fitness level argument [29] with respect to the number of elements in an infeasible solution.

Once a feasible solution has been obtained for the first time, only feasible solutions are accepted during the optimization process. We use multiplicative drift analysis [8] and consider in each step the search point $x$ with the smallest value of $v(x)$ in the population. Let $r = |x|_1 \geq k$. If $r > k$, then flipping any of the 1-bits is accepted and the value of $v(x)$ decreases at least by a factor of $1 - 1/(\lambda_{\max} e n)$ in expectation in the next iteration. If $r = k$, consider a Pareto optimal solution $x^*$ that has minimal variance. Assume that there are $s \geq 1$ elements contained in $x$ that are not contained in $x^*$. Then removing any of these elements from $x$ and including one of the missing $s$ elements from $x^*$ can not be a Pareto optimal solution of minimal variance. Furthermore, there are $s$ such operations that are all accepted and in total reduce the variance from $v(x)$ to $v(x^*)$. Hence, the variance of the solution having the smallest variance in the population reduces by at least $1/(\lambda_{\max} e n^2) \cdot (v(x) - v(x^*))$ in expectation in the next iteration. Note, that this reduction is less than the one in the case of $r > k$. Using the multiplicative drift theorem [8], a Pareto optimal solution of minimal variance is obtained in expected time $O(\lambda_{\max}^n n^2 (\log n + \log v_{\text{max}}))$. □

Based on a Pareto optimal solution having the minimal variance, GSEMO can construct all other extreme points and we obtain the following result.

**Theorem 3.** Considering the chance constrained problem with a uniform constraint, the expected time until GSEMO has computed a population which includes an optimal solution for any choice of $\alpha \in [1/2, 1]$ is $O(\lambda_{\max}^n n^2 \ell (\log n + \log v_{\text{max}}))$.

**Proof.** We assume that we have already included a Pareto optimal solution of minimal variance $v_{\text{min}}$ into the population. Let

$$v_{\lambda}^{\text{max}} = \max_{x \in 2^\ell} \left\{ v(x) \mid f_\lambda(x) = \min_{z \in 2^\ell} f_\lambda(z) \right\}$$

and

$$v_{\lambda}^{\text{min}} = \min_{x \in 2^\ell} \left\{ v(x) \mid f_\lambda(x) = \min_{z \in 2^\ell} f_\lambda(z) \right\}$$

be the maximal and minimal variance of any optimal solution for the linear weighting $f_\lambda$.

Note that we have $v_{\lambda}^{\text{max}} = v_{\lambda}^{\text{min}}$ for $\lambda = 0$ as the Pareto optimal objective vector of minimal variance is unique. Hence, the Pareto optimal solution of minimal variance $v_{\text{min}} = v_{\lambda_{\text{max}}}^{\text{max}}$ is a solution of maximal variance for $\lambda = 0$. Consider $\lambda_i$, $0 \leq i \leq \ell$. We have $v_{\lambda_i}^{\text{max}} = v_{\lambda_{i+1}}^{\text{min}}$ as the extremal point that is optimal for $f_{\lambda_i}$ and $f_{\lambda_{i+1}}$ has the largest variance for $f_{\lambda_i}$ and the smallest variance for $f_{\lambda_{i+1}}$ among the corresponding sets of optimal solutions.

Assume that we have already included into the population a search point $x$ that is minimal with respect to $f_{\lambda_i}$ and has maximal variance $v_{\lambda_{i+1}}^{\text{max}}$ among all these solutions. The solution $x$ is also optimal with respect to $f_{\lambda_{i+1}}$ and we have $v_{\lambda_{i+1}}^{\text{max}} = v_{\lambda_i}^{\text{min}}$. We let $r$ be the number of elements contained in $x$ but not contained in the optimal solution $y$ for $f_{\lambda_{i+1}}$ that has variance $v_{\lambda_{i+1}}^{\text{max}}$. As both solutions contain $k$ elements, differ by $r$ elements and $y$ has maximal variance with respect to $f_{\lambda_{i+1}}$, there are $r^2$ 2-bit flips that bring down the distance $d(x) = v_{\lambda_{i+1}}^{\text{max}} - v(x) \leq v_{\lambda_{i+1}}^{\text{max}} - v_{\lambda_i}^{\text{max}}$. Using the multiplicative drift theorem [8] where we always choose the solution that is optimal with respect $f_{\lambda_{i+1}}$ and has the
largest variance, the expected time to reach such as solution of variance \( v_{\lambda_{i+1}} \) is \( O(P_{\max} n^2 \log(v_{\lambda_{i+1}} - v_{\lambda_i})) = O(P_{\max} n^2 (\log n + \log v_{\lambda_{i+1}})) \). Summing up over the different values of \( i \), we get \( O(P_{\max} n^2 (\log n + \log v_{\lambda_{i+1}})) \) as an upper bound on the expected time to generate all extreme points. \( \square \)

4.2 Chance Constrained Minimum Spanning Trees

We now extend the previous results to the chance constrained minimum spanning tree problem where edge weights are independent and chosen according to a Normal distribution. Note that using the expected weight and the variance of a solution as objectives results in a bi-objective minimum spanning tree problems for which a runtime analysis of GSEMO has been provided in [21].

Let \( c(x) \) be the number of connected components of the solution \( x \). We consider the bi-objective formulation for the multi-objective minimum spanning tree problem given in [21]. Let \( w_{ub} = n^2 \cdot \max\{\mu_{\max}, v_{\max}\} \). The fitness of a search point \( x \) is given as \( f(x) = (\mu(x), v(x)) \) where \( \mu(x) = (c(x) - 1) \cdot w_{ub} + \sum_{i=1}^{\ell} \mu_i x_i \) and \( v(x) = (c(x) - 1) \cdot w_{ub} + \sum_{i=1}^{\ell} \sigma_i^2 x_i \). It gives a large penalty for each additional connected component.

We transfer the results for the multi-objective setting under the uniform constraint to the setting where a feasible solution has to be a spanning tree. The crucial observation from [21] to obtain the extreme points is that edge exchanges resulting in new spanning trees allow to construct solutions on the linear segments between two consecutive extreme points in the same way as in the case of the uniform constraint. Let \( \ell \leq m(m-1)/2 \) be the pairs of edges \( e_i \) and \( e_j \) with \( \sigma_i^2 < \sigma_j^2 \) and \( \mu_i > \mu_j \). Similar to Lemma 3 and using the arguments in [12], the number of extreme points is at most \( \ell + 2 \leq m^2 \) as an optimal solution for \( f_A = \lambda \mu(x) + (1-\lambda)v(x) \) can be obtained by Kruskal’s greedy algorithm.

We replace the expected time of \( O(n^2) \) for an item exchange in the case of the uniform constraint with the expected waiting time of \( O(m^2) \) for a specific edge exchange in the case of the multi-objective spanning tree formulation and get the following results.

**Theorem 4.** Considering the chance constrained minimum spanning tree problem, the expected time until GSEMO has computed a population which includes an optimal solution for any choice of \( \alpha \in [1/2, 1] \) is \( O(P_{\max} m^2 (\log n + \log v_{\max})) \).

5 Convex Multi-Objective Evolutionary Algorithm

The results presented in the previous section depended on \( P_{\max} \) which might be exponential with respect to the given input in the case that the expected values and variances are exponential in \( n \). We now introduce an approach which provably can obtain the set of optimal solutions in expected polynomial time.

As the extreme points are of significant importance when computing optimal solutions for the chance constrained problems studied in this paper, we consider the Convex hull ranking algorithm shown in Algorithm 3 which has originally been introduced in [13]. Our Convex \((\mu + 1)\)-EA shown in Algorithm 4 uses this approach to assign ranks to the search points in a given population and use this for survival selection. The idea here is to assign ranks to individuals by iterative computing the convex hull of a population in the objective space and assigning ranks to the individuals when they become part of the convex hull of the remaining set of elements.

More precisely, for a given set of elements \( S \), Algorithm 3 selects the element \( x \) that is minimal w. r. t. the lexicographic order of \((f_1, f_2)\) and \( y \) which is minimal with respect to the lexicographic order of \((f_2, f_1)\). Note that \( x \) and \( y \) are not strictly dominated by any solution in \( S \) and are solutions of minimal value with respect to \( f_1 \) and \( f_2 \), respectively. As
Choose a population $P$ consisting of $\mu$ individuals from $\{0, 1\}^n$ uniformly at random;

$P \leftarrow \{x\}$;

repeat

Choose $x \in P$ uniformly at random;

Create $y$ by flipping each bit $x_i$ of $x$ with probability $\frac{1}{n}$;

$P := P \cup \{y\}$;

Remove an individual $z$ from $P$ with $z = \arg \max_{x \in P} (rp(x), v(x))$

until stop;

$x$ and $y$ are such extreme points, they are part of the convex hull $C(S)$ of the given set $S$ in the objective space. The convex ranking algorithm initially sets the rank value $r$ to 1, includes $x, y$, and all other points on the convex hull into $C(S)$, assigns them the same rank $r$, and removes $C(S)$ from $S$ afterwards. It then proceeds by increasing the rank $r$ by 1 and repeating the procedure until the set $S$ is empty.

We denote by $rp(x)$ the rank of solution $x$ with respect to population $P$ using the convex hull ranking algorithm. When removing an element $z$ from $P$ in Algorithm $4$, then this element is chosen according to the lexicographic order with respect to $(rp(x), v(x))$, i.e., an element with the highest variance from the front having the largest rank is removed.

Let $\lambda^* \in [0, 1]$ and $X$ be an arbitrary set of search points. Then the element $x^* \in X^*$ with $x^* = \arg \max_{x \in X} v(x)$ is an extreme point of the convex hull of $X$ according to Definition $2$.

We consider the different values of $\lambda \in \Lambda$ where extreme points can change based on the order of pairs of edges. The following lemma shows that extreme points that are obtained with increasing $\lambda$ stay in the population.

**Lemma 5.** Assume $\mu \geq \ell + 2$ and that $P$ includes the extreme points for $\lambda_0, \ldots, \lambda_q \in \Lambda$. Then the algorithm does not remove any of these extreme points during the run of the algorithm.

**Proof.** The extreme points all have rank 1 as otherwise they won’t be extreme points for the given problem. Furthermore, all solutions of rank 1 with variance $v(x) \leq v_{\max}^{\lambda_q}$ are extreme points and we have $q + 1 \leq \ell + 2 \leq \mu$ of them. This implies that the algorithm does not remove any of these extreme points in the survival selection step. \hfill $\square$

As the Convex $(\mu + 1)$-EA does not remove the extreme points and is able to construct extreme points in the same way as GSEMO, it can produce the extreme points for values $\lambda \in \Lambda$ iteratively for increasing values of $\lambda$. We therefore get the following result for the case of a uniform constraint.

**Theorem 5.** Let $\mu \geq \ell + 2$ and consider the case of a uniform constraint. Then the expected time until the Convex $(\mu + 1)$-EA has computed a population which includes an optimal solution for any choice of $\alpha \in [1/2, 1]$ is $O(\mu n^2 (\ell \log n + \log v_{\max}^\ell))$.

Similarly, we get the following polynomial upper bound when considering the multi-objective formulation for the chance constrained minimum spanning tree problem.

**Theorem 6.** Let $\mu \geq \ell + 2$ and consider the chance constrained minimum spanning tree problem. Then the expected time until the Convex $(\mu + 1)$-EA has computed a population which includes an optimal solution for any choice of $\alpha \in [1/2, 1]$ is $O(\mu n^2 (\ell \log n + \log v_{\max}^\ell))$.

The proofs of the previous two theorems are analogous to Theorem $3$ and Theorem $4$ respectively. Note that the polynomial runtime bound for the Convex $(\mu + 1)$-EA and the computation of the extreme points holds in general for bi-objective spanning trees. It therefore improves upon the pseudo-polynomial runtime given in $[21]$ to achieve a 2-approximation for bi-objective minimum spanning trees using evolutionary algorithms.

### 6 Conclusions

With this paper, we provided the first analysis of evolutionary algorithms for chance constrained combinatorial optimization problems with Normally distributed variables. As a fundamental theoretical contribution to the area of runtime analysis, we have shown that the $(1+1)$ EA obtains an optimal solution in expected time $O(n \log n)$ for the class of two transformed linear functions which includes the chance constrained formulation without additional constraints. For the case of uniform constraints we have shown that there are simple instances where the $(1+1)$ EA has an
exponential optimization time. Based on these insights we a multi-objective formulation which allows Pareto opti-
mization approaches to compute a set of solutions containing for every possible confidence of $\alpha$ an optimal solution. To
deal with possibly exponentially many trade-offs of the objective values, we proposed to use a convex multi-objective
 evolutionary algorithm which provably obtains such a set of solutions in expected polynomial time.
