Abstract

Named Entity Recognition (NER) and Relation Extraction (RE) are the core sub-tasks for information extraction. Many recent works formulate these two tasks as the span (pair) classification problem, and thus focus on investigating how to obtain a better span representation from the pre-trained encoder. However, a major limitation of existing works is that they ignore the dependencies between spans (pairs). In this work, we propose a novel span representation approach, named Packed Levitated Markers, to consider the dependencies between the spans (pairs) by strategically packing the markers in the encoder. In particular, we propose a group packing strategy to enable our model to process massive spans together to consider their dependencies with limited resources. Furthermore, for those more complicated span pair classification tasks, we design a subject-oriented packing strategy, which packs each subject and all its objects into an instance to model the dependencies between the same-subject span pairs. Our experiments show that our model with packed levitated markers outperforms the sequence labeling model by 0.4%-1.9% F1 on three flat NER tasks, beats the token concat model on six NER benchmarks, and obtains a 3.5%-3.6% strict relation F1 improvement with higher speed over previous SOTA models on ACE04 and ACE05. Code and models are publicly available at https://github.com/thunlp/PL-Marker.

Introduction

Recently, pre-trained language models (PLMs) (Devlin et al. 2019; Liu et al. 2019) have achieved significant results in Named Entity Recognition (NER, Luo, Xiao, and Zhao 2020; Fu, Huang, and Liu 2021) and Relation Extraction (RE, Wadden et al. 2019; Zhou and Chen 2021; Zhong and Chen 2021), two key sub-tasks of information extraction. As known, the essence of extracting structured information, such as the entity itself and the information between entities, is to collect the span-level information in the text. Many recent works (Wang et al. 2021a; Zhong and Chen 2021) regard these two tasks as span (paired) classification, and thus focus on extracting better span representations from the PLMs.

A straightforward approach to acquiring a given span’s representation, named Token Cat, is to concatenate the representation of its boundaries (start and end) tokens (Lee et al. 2017; Joshi et al. 2020; Jiang et al. 2020). Nevertheless, in Token Concat, a token has to capture all the contextual information for multiple spans with itself as the boundary, which would cause information confusion. Therefore, Solid Marker (Soares et al. 2019; Zhou and Chen 2021), another widely-used span representation method, inserts two markers at the left and right of the span to highlight the span in the input text, which is proved to be more effective in RE (Soares et al. 2019). However, solid markers could neither deal with the overlapping spans in the encoding procedure, nor handle multiple span pairs at the same time, for which previous works (Zhou and Chen 2021; Zhong and Chen 2021) have to use the markers independently in the training process. Thus, it cannot well consider the dependencies between spans (pairs), leading to sub-optimal representations for handling multiple entities and multiple relational facts in a sentence (Sorokin and Gurevych 2017; Luan et al. 2019; Wadden et al. 2019).

In this work, we introduce Packed Levitated Markers (PL-Marker), to model the dependencies between spans (pairs) by packing levitated markers together. As illustrated in Figure 1, a pair of Levitated Markers, emphasizing a span, consists of a start marker and an end marker which share the same position embeddings with span’s start and end tokens respectively. In addition, both levitated markers adopt a restricted attention, that is, they are visible to each other, but not to the text token and other pairs of markers. Based on the above features, the levitated marker would not affect the attended context of the

Figure 1: An illustration of the Token Concat, Solid Marker and Levitated Marker. We highlight the attention direction for the levitated marker and omit the bidirectional attention line between other token pairs. For the span David Green, Token Concat concatenates representation of boundary token, [David] and [/Green] as span representation, while Solid Marker and Levitated Marker employ the combined features of two markers, [M] and [/M].
A key challenge of packing levitated markers together is that the increasing number of inserted levitated markers would exacerbate the complexity of PLMs quadratically (Dai et al. 2020; Ye et al. 2021). Hence, to alleviate this issue, we propose a group packing strategy, which divides spans into several groups to control the length of each input sequence, equipping our method with higher speed and feasibility in practice. Additionally, we also notice another potential weakness of the levitated marker is that its feature of adopting restricted attention may confound the span concept. For example, while processing the span pair classification task, two pairs of levitated markers are mutually visible as each pair of them indicates either subject or object span. However, four markers within those two pairs will be randomly matched, which means that the correspondence between the levitated markers in a pair will be ignored, thereby confusing the span concept. Hence, we introduce a subject-oriented packing strategy to distinguish the subject span and the object span. To be specific, we emphasize the subject span with solid markers and pack all candidate object spans into a training instance by levitated markers, which helps to generate a well-considered representation of the subject span. Similarly, we apply an object-oriented packing strategy to model the reversed relation for an intact bidirectional prediction.

We examine the effect of PL-Marker on two typical span (pair) classification tasks, NER and end-to-end RE. The experimental results indicate that our model not only advances the sequences labeling model by 0.4%-1.9% on flat NER tasks (CoNLL03, Ontonotes, Few-NERD), but also beats the Token Concat model on six NER benchmarks, which demonstrates the effectiveness of our pair-wise marker feature. Moreover, compared with the previous state-of-the-art RE model, our model gains a 3.5%-3.6% strict relation F1 improvement with higher speed on ACE04 and ACE05 and also achieves comparable performance on SciERC, which shows the importance of considering the dependencies between the subject-oriented span pairs.

**Related Work**

In recent years, span representation has attracted great attention from academia, which is widely applied to extracting entities and relations from plain text, aka the end-to-end RE.

**Span Representation** To enhance the span representation, an effective approach is to introduce the concept of span by span-level pre-training tasks, which are often applied to the ordinary span in plain text (Sun et al. 2019b; Joshi et al. 2020) or the entity span associated with the knowledge graph (Zhang et al. 2019; Févr et al. 2020; Xiong et al. 2020; Yamada et al. 2020). However, this kind of method is usually resource-consuming to be re-implemented on large models (Lan et al. 2020) or domain-specific models (Gurumaran et al. 2020). In practice, a more economic approach is to extract the comprehensive span representation from a given PLM. For example, Token Cat (Jiang et al. 2020) is often used in named entity recognition (Ouchi et al. 2020), relation and event extraction (Luan et al. 2019), coreference resolution (Lee et al. 2017), semantic role labeling (He et al. 2018) and question answering (Lee et al. 2016) for span representation. As a generalized architecture, the Token Cat representation can further serve as the bridge for multi-task learning (Luan et al. 2019; Jiang et al. 2020) or for the model ensemble (Fu, Huang, and Liu 2021; Wang et al. 2021a). In addition, another span representation, Solid Marker (Soares et al. 2019), is more skilled in tasks with given span position, such as entity typing (Zhang et al. 2019), relation extraction (Soares et al. 2019), and answering re-ranking (Iyer et al. 2021). However, the markers are rarely employed on tasks that contain a large number of spans (pairs), since each span (pair) needs to be processed independently with markers, which is time-consuming and also ignores the dependencies between spans (pairs). In this work, we introduce several effective packing strategies to take advantage of the markers in the fine-tuning process.

**End-to-end RE** Jointly extracting entities and relations is considered to alleviate the error propagation issue in the pipeline models and also exploit the interrelation between NER and RE. The joint learning can be formulated in various ways, such as table filling (Miwa and Sasaki 2014; Zhang, Zhong, and Fu 2017; Wang and Lu 2020; Wang et al. 2021b), sequence tagging (Katiyar and Cardie 2017; Zheng et al. 2017), graph propagation (Sun et al. 2019a; Fu, Li, and Ma 2019; Luan et al. 2019), and memory flow (Shen et al. 2021). However, Zhong and Chen (2021) shows that, with the support of modern pre-training encoders (e.g., BERT), the combined effect of independent entity and relation model is significantly better than existing joint models. Hence, in this work, we also decompose the end-to-end RE task into a NER task and a RE task for all the recognized entity pairs.

**Method**

In this section, we first introduce the architecture of the levitated marker. Then, we present how our models apply the levitated marker to obtain the span representation and the span pair representation.

**Levitated Marker**

Levitated marker is used as an approximation of solid markers, which allows models to classify multiple pairs of entities simultaneously to accelerate the inference progress (Zhong and Chen 2021). A pair of levitated markers, associated with a span, consists of a start token marker and an end token marker. These two markers share the same position embedding with the start and end tokens of the corresponding span, while keeping the position id of original text tokens unchanged.

In order to process multiple pairs of levitated markers in parallel without interfering each other, a restricted attention direction is applied to the levitated marker. Specifically, a pair of levitated markers is invisible to the text tokens and other levitated markers. In the meantime, each levitated marker is visible to its partner marker within pair to locate their associated span.

We associate a pair of levitated markers to each required span. Then, we feed the combined sequence of the text token
**NER Model**

David Green is a doctor

- ... 4
- [O15]/[O15] 5

**Group 3**

Figure 2: An overview of our NER and RE models. In the NER model, we enumerate all possible spans and associate each span with a pair of levitated markers, where we assign a PER label to span (1, 2), i.e., the markers [O2] and [I2], and assign the non-entity type to other spans. In addition, we divide 15 pairs of markers into 3 groups and dispersedly process them in 3 runs. In the RE model, [S] and [/S] are solid markers clamping the subject entity, David Green. [O1] and [/O1] are levitated markers for the entity his. [O2] and [/O2] are for the entity wife and [O3] and [/O3] are for Dallas. For instance, we employ the concatenation of contextualized representations of [S],[/S],[O3],[/O3] to predict the relation between David Green and Dallas and apply the concatenated representations of [O3],[/O3] to predict the entity type for Dallas as an auxiliary loss.

**Span Representation**

Benefiting from the parallelism of levitated markers, we can flexibly pack a series of related spans into a training instance, which appends multiple associated levitated markers to an input sequence to conduct a comprehensive modeling on each span. For instance, we apply the levitated marker to a typical overlapping span classification task, NER, which aims to assign an entity type or a non-entity type to each possible span in a sentence. Moreover, we introduce a group packing strategy to accelerate the computation on massive spans.

**Entity Model**

For the NER task, given a sequence of text tokens, $X = \{x_1, \ldots, x_N\}$, we first enumerate possible spans in $X$ of up to length $L$ as $S(X)$ and then assign an entity label to each span. As illustrated in Figure 2, the possible spans in the sentence, “David Green is a doctor,” are $S(X) = \{(1, 1), (1, 2), (1, 3), \ldots, (4, 5), (5, 5)\}$, where $s_i = (a, b)$ consists of tokens $(x_a, \ldots, x_b)$. In these spans, the span (1, 2), David Green, is annotated as the Person type while the other spans are of non-entity type.

We associate a pair of levitated markers to each span. Then, we feed the combined sequence of the text token and the levitated marker to a pre-trained language model (e.g., BERT) to obtain the contextualized representations of text tokens $H = (h_1, \ldots, h_N)$, the contextualized representations of the start token marker $H^{(s)} = \{h_i^{(s)}\}$ and that of the end token marker $H^{(e)} = \{h_i^{(e)}\}$. Here, $h_a^{(s)}$ and $h_b^{(e)}$ are associated with the span $s_i = (a, b)$, for which we further adopt two kinds of span representations:

$$E_{\text{span}}(s_i) = [h_a^{(s)}; h_b^{(e)}], \quad \text{Token Concat} \quad (1)$$

$$E_{\text{marker}}(s_i) = [h_a^{(s)}; h_b^{(e)}], \quad \text{PL-Marker} \quad (2)$$

where $[A; B]$ denotes the concatenation operation on the vector $A$ and $B$. Benefiting from the compatibility of span prediction framework [Fu, Huang, and Liu 2021], our NER model concatenates the features from Token Concat and PL-Marker to obtain a better performance.

Moreover, to alleviate the inference cost, it is flexible to apply PL-Marker as a post-processing module of a two-stage model, in which PL-Marker is used to identify entities from a small number of candidate entities proposed by a simpler and faster NER model.

**Efficient Group Packing**

In the early stage, dominated by the large feed-forward network, the computation of PLM rises almost linearly with the increase in sequence length [Dai et al. 2020; Ye et al. 2021]. Gradually, as the sequence length continues to grow, the computation dilates quadratically due to the Self-Attention module [Vaswani et al. 2017]. Obviously, the insertion of levitated markers extends the length of input sequence, especially for the NER task, which has to deal with massive overlap candidate spans. Under the circumstance, to control the sequence length within the interval where the complexity is close to linear increases, we group the neighboring markers into several batches. Formally, we first sort the levitated markers by the left position as the first keyword and the right position as the second keyword. After that, we...
split them into groups of size \( K \). Each time, we process the input text with a group of neighboring levitated markers instead of all of them to disperse the total computation into several lightweight runs.

**Span Pair Representation**

Our span pair model adopts a fusion subject-oriented packing scheme that applies the solid markers to the subject entity and employs the levitated markers to all its candidate object entities. For instance, we evaluate our model on a typical span pair classification task, end-to-end RE, which concentrates on identifying whether all span pairs are related and their relation types.

**Relation Model**

Following Zhong and Chen (2021), we first use a NER model to narrow the candidate spans to the predicted entity spans, and then acquire the span pair representation of these entities. As illustrated in Figure 2, we insert a pair of solid markers [S] and [/S] into the left and right of the subject entity. After that, we apply levitated markers to all candidate object entities, such as his, wife and Dallas, and then pack them into a training instance, which offers an integral modeling for the subject entity.

Formally, to predict the relation between the subject entity span \( s_i = (a, b) \) and the object entity span \( s_j = (c, d) \), we apply a linear layer on the contextualized representation of their associated markers:

\[
P(r | S=s_i, O=s_j) = \text{Softmax}(W_r[h_{a-1}; h_{b+1}; h_{e}^{(s)}; h_{d}^{(r)}]),
\]

where \([A; B; C; D]\) denotes the concatenation operation on the vector \( A, B, C \) and \( D \), \( W_r \) is a trainable parameter of the relation classifier, \( S \) and \( O \) are abbreviations of subject and object respectively, \( h_{a-1} \) and \( h_{b+1} \) denote the contextualized representation of inserted solid markers for \( s_i \), \( h_{e}^{(s)} \) and \( h_{d}^{(r)} \) are the contextualized representation of the inserted levitated markers for \( s_j \).

Compared to the method that using two pairs of solid markers for the subject and object entities respectively (Zhong and Chen 2021), our fusion marker scheme adopts levitated markers to replace solid markers for the object entity, which would impair the emphasis on the object entity to some extent. To provide the supplementary information, we introduce the relation \( r^{-1} \) from the object entity to the subject entity for each relation \( r \), based on which, we employ a bidirectional prediction (Wu et al. 2020) on the entity pair \((s_i, s_j)\). The final relation prediction probability \( P \) can be compared by:

\[
\hat{P}(r | S=s_i, O=s_j)^2 \propto P(r | S=s_i, O=s_j)P(r^{-1} | S=s_j, O=s_i).
\]

In particular, the forward and inverse relation of symmetric labels is consistent. For example, we set \( r = r^{-1} \) for the PER-SOC relation in the ACE04 and ACE05 datasets and for the Compare and Conjunction relation in the SciERC dataset.

Moreover, entity types of the subject and object entities could usually reduce the search space of their relation (Han et al. 2021; Lyu and Chen 2021). Prior works (Luan et al. 2019; Wang and Lu 2020) also demonstrates that NER and RE are complementary in many scenarios. To build the connection between entity type and relation type, we add an auxiliary loss for predicting the type of object entity in our RE model. The entity type prediction from the RE model can be used to refine the prediction from the NER model.

**Experiment**

**Experimental Setup**

**Dataset**

For the NER task, we conduct experiments on both flat and nested benchmarks. For the flat NER, we adopt CoNLL03 (Sang and Meulen 2003), OntoNotes 5.0 (Pradhan et al. 2013) and Few-NERD (Ding et al. 2021). For the nested NER, we use ACE04 (Doddington et al. 2004), ACE05 (Walker et al. 2006) and SciERC (Luan et al. 2018). The three nested NER datasets are also used to evaluate the end-to-end RE. Table 1 shows the statistics of each dataset.

We follow Luan et al. (2019) to split ACE04 into 5 folds and split ACE05 into train, development, and test sets. For other datasets, we adopt the official split. For all the benchmarks, we report the average scores and standard deviation of 5 runs across different random seeds.

**Evaluation Metrics**

We follow a span-level evaluation for NER, where a predicted entity is considered as a correct prediction if the predicted span boundary and type both match the annotated entity. We report the micro precision, recall and F1 for all the NER datasets. For the end-to-end RE, we report two evaluation metrics: (1) **Boundaries evaluation** (Rel) requires the model to correctly predict the boundaries of the subject entity and the object entity, and the relation between them; (2) **Strict evaluation** (Rel+) further requires the model to predict correct entity types on the basis of the requirement of the boundaries evaluation. Moreover, following Wang et al. (2019), we regard each symmetric relational instance as two directed relational instances.

**Implementation Details**

For fair comparison with previous works, we employ bert-base-uncased (Devlin et al. 2019) and albert-xxlarge-v2 (Lan et al. 2020) as the encoders for ACE04 and ACE05. For SciERC, we use the in-domain scibert-scivocab-uncased (Beltagy, Lo, and Cohan 2019) as the encoder, whose size is similar to BERT. To increase the stability of the results, we run 5 times with the roberta-large encoder (Liu et al. 2019) for the flat NER model and report the average scores. We also introduce the cross-sentence context text (Luan et al. 2019; Luoma and Pyysalo 2020), which extends each sentence by its context and ensures that the original sentence locates in the middle of the expanded sentence as much as possible.

For entity model, we set the maximum length of expanded sentence \( C \) as 512. For relation model, we set \( C \) as 256 for ACE05 and SciERC and set \( C \) as 384 for ACE04, whose original sentence might exceed 256 tokens. For enumerating possible spans, we set the maximum span length \( L \) as 16 for OntoNote 5.0 and Few-NERD and 8 for the other datasets. We adopt a batch size of 8 for all the models, a learning rate of 2e-5 for the model with \( \text{L} \) and \( \text{L} \) and a learning rate of 1e-5 for the model with \( \text{L} \) or \( \text{L} \). In the training process, we employ a group size of 256 to batch
process the candidate spans for the NER task. And we show the detailed training configuration in the Appendix.

Moreover, inspired by the success of prompt tuning (Brown et al. 2020, Schick and Schütte 2021, Han et al. 2021), we initialize the embedding of markers with the embedding of meaningful words instead of randomness, denoted as prompt init. For NER, we initialize the pair of markers for a span with the words [MASK] and entity. For RE, we initialize the pair of solid markers for subject with the words [MASK] and subject and we initialize that for object with the words [MASK] and object.

## Named Entity Recognition

**Baselines** We compare our NER model, PL-Marker, with two common NER models: (1) **SeqTagger** (Devlin et al. 2019) regards NER as a sequence tagging task, which uses the representation of the first sub-token as the input to the token-level classifier over the IOB2 labels (Sang and Veenstra 1999). However, due to ambiguity token labels from overlap entities, SeqTagger cannot deal with the nested NER; (2) **Token Concat** (Jiang et al. 2020) assigns an entity type or a non-entity type for each span according to the Token Concat span representation, which is available for both the flat NER and the nested NER.

Furthermore, we adopt several representative flat NER baselines, such as BiLSTM-CRF (Ma and Hovy 2016), BERT-Tagger (Devlin et al. 2019), BERT-MRC (Li et al. 2020) and BioNer-NER (Yu, Bohnet, and Poesio 2020). For the nested NER, we compare our model with a series of end-to-end RE baselines, which will be detailed in next section.

**Results** We show the flat NER results in Table 2 and the nested NER results in Table 3 and Table 9. As follow, some observations are summarized from the experimental results: (1) The simple SeqTagger with the RoBERTa-LARGE encoder outperforms most of the existing BERT-based NER models, which demonstrates that the quality and selection of pre-trained encoder is crucial for the NER task; (2) With the same pre-trained encoder, PL-Marker achieves an absolute F1 improvement of +0.1% to 1.1% over Token Concat on all six NER benchmarks, which shows the advantage of levitated markers in aggregating span-wise representation for the entity type prediction; (3) PL-Marker outperforms SeqTagger by an absolute F1 of +0.4%, +0.7%, +1.9% in CoNLL03, OntoNote 5.0 and Few-NERD respectively, where CoNLL03, OntoNote 5.0 and Few-NERD contain 4, 18 and 66 entity types respectively. Such improvements prove the effectiveness of levitated markers in recognizing fine-grained named entities, which is considered to be more challenging. (4) Our separate NER model performs better than joint model for entity and relation extraction, such as DyGIE++ (Wadden et al. 2019) and UniRE (Wang et al. 2021b), which consistently demonstrates that the contextual representations for the entity and relation models essentially capture distinct information.

## Relation Extraction

**Baselines** For the end-to-end RE, we compare our model, PL-Marker, with a series of state-of-the-art models and we introduce two of the most representative works with Token Cat and Solid Markers span representation: (1) **DyGIE++** (Wadden et al. 2019) first acquires the Token Cat span representation, and then iteratively propagates coreference and relation type confidences through a span graph to refine the representation; (2) **PURE** (Zhong and Chen 2021) adopts independent NER and RE models, where the RE model processes each possible entity pair with solid markers in one pass.

**Results** As shown in Table 9, with the same BERT BASE encoder, our approach outperforms previous methods by strict F1 of +1.5% on ACE05 and +2.1% on ACE04. With the SciBERT encoder, our approach also achieves almost the best performance on SciERC. Using a larger encoder, ALBERT XXLARGE, both of our NER and RE models are further improved. Compared to the previous state-of-the-art model, PURE (Zhong and Chen 2021), our model gains +0.2% and +0.1% entity F1 improvement on ACE05 and ACE04 respectively, and a substantially +3.5% and +3.6% strict relation F1 improvement on ACE05 and ACE04 respectively. Such improvements over PURE indicate the effectiveness of modeling the interaction between the same-subject or the same-object entity pairs in the training process.

## Inference Speed

In this section, we evaluate and compare the models’ inference speed on a NVIDIA A100 GPU with a batch size of 32. We use RoBERTa-LARGE for the flat NER models, BERT BASE for ACE05 and SciBERT for SciERC.

**Entity Model** Our NER model, PL-Marker, applies an efficient group computation to speed up the processing of massive levitated markers, which packs every K neighboring levitated markers into a group. To further accelerate the inference process, we employ a cascade Two-stage Model, which first uses a small and fast NER model to filter candidate spans, and then adopts the PL-Marker to further recognize entities from the small number of proposed spans. For convenience, we select a Token Cat model with the RoBERTa-LARGE encoder for the filtering process.

We evaluate the inference speed of PL-Marker with different group size K on CoNLL03 and Few-NERD. As shown in Table 9, PL-Marker achieves 0.4 F1 improvement on CoNLL03 but also sacrifices 60% speed compared to the SeqTagger model. When we increase the enumerating span length from 8 to 16, PL-Marker further drops its efficiency in Few-NERD. At this time, the Two-stage model achieves similar performance as PL-Marker with 3.1× speedup on Few-NERD, which shows it is more efficient to use PL-Marker.
Table 2: Micro precision, recall and F1 on the test set for the flat NER. We report averaged across five random seeds, with standard deviations as subscripts.

Table 3: Micro precision, recall and F1 on test set for nested NER. Models on ACE04 and ACE05 use the ALBERT\textsubscript{XXLARGE} encoder, and models on SciERC employ the SciBERT encoder. We report averaged scores across five random seeds, with standard deviations as subscripts. The detailed comparison with other baselines is shown in the Ent column of Table 3.

Table 4: Overall entity and relation F1 scores on the test set of ACE04, ACE05 and SciERC. TriMF, UniRE, PURE and PL-Marker apply BERT\textsubscript{BASE} and ALBERT\textsubscript{XXLARGE} for ACE04 and ACE05 and adopt SciBERT for SciERC. $^\circ$ denotes that the model leverages the cross-sentence information. We report averaged scores across five random seeds. And we show the standard deviation in the Appendix.

as a post-processing module to elaborate the coarse prediction from a simple model. We also observe that when the group size grows to 512, PL-Marker slows down due to the increased complexity of the Transformer, which suggests that dividing the candidates into several proper-size groups to run is suitable to deal with massive spans in the training phase.

**Relation Model** We apply the subject-oriented and the object-oriented packing strategies on levitated markers for RE. Here, we compare our packing strategy with the other two usages of markers. Firstly, PURE (Full) (Zhong and Chen 2021) applies solid markers to process each entity pair independently. Then, PURE (Approx.) also independently employs the levitated marker in the training process. In the inference phase, PURE (Approx.) packs the levitated markers for all entity pairs into an instance for batch computation.

Since the performance and the running time of the above methods rely on the quality and the number of predicted entities, for a fair comparison, we adopt the same entity input from the entity model of PURE for all the RE models. Table 3 shows the relation F1 scores and the inference speed of the above three methods. On both datasets, our RE model, PL-Marker, achieves the best performance and PURE (Ap-
In this work, we present a novel packed levitated markers, with a group packing and a subject-oriented packing strategy, to obtain the span (pair) representation. With the comprehensive span (pair) representation, we achieve the state-of-the-art F1 scores and a promising efficiency for both NER and RE tasks across six standard benchmarks. In future, we will further investigate how the marker-based span representation can be generalized to more NLP tasks.

Appendix

Training Configuration

We train all the models with Adam optimizer [Kingma and Ba 2015] and 10% warming-up steps. And we adopt a learning rate of 2e-5 for models with BASE size and a learning rate of 1e-5 for models with LARGE or XXLARGE size. We run all the experiments with 5 different seeds (42, 43, 44, 45, 46). For the NER of CoNLL03 and the RE of ACE05, we search the batch size in [4, 8, 16, 32] and observe the model with a batch size of 8 achieves a slightly better performance. Hence, we choose a batch size of 8 for all the datasets. We search the number of epochs in [3, 5, 8, 10, 15, 50] for all the datasets and finally choose 8 for CoNLL03, 5 for OntoNote 5.0, 3 for Few-NERD, 10 for ACE05-NER, 15 for ACE04-NER, 50 for SciERC-NER and 10 for all the RE models.

RE Results with standard deviations

We show the averaged scores of PL-Marker on RE with standard deviations in Table 9.

<table>
<thead>
<tr>
<th>Dataset</th>
<th>Encoder</th>
<th>Ent</th>
<th>Rel</th>
<th>Rel+</th>
</tr>
</thead>
<tbody>
<tr>
<td>ACE05</td>
<td>BERTBASE</td>
<td>89.7 ± 0.27</td>
<td>68.8 ± 0.50</td>
<td>66.3 ± 0.45</td>
</tr>
<tr>
<td></td>
<td>ALBERT</td>
<td>91.1 ± 0.29</td>
<td>72.3 ± 0.88</td>
<td>70.5 ± 0.69</td>
</tr>
<tr>
<td>ACE04</td>
<td>BERTBASE</td>
<td>88.9 ± 0.70</td>
<td>65.7 ± 1.98</td>
<td>62.2 ± 1.67</td>
</tr>
<tr>
<td></td>
<td>ALBERT</td>
<td>91.1 ± 0.45</td>
<td>72.3 ± 2.02</td>
<td>70.5 ± 1.58</td>
</tr>
<tr>
<td>SciERC</td>
<td>SciBERT</td>
<td>69.9 ± 0.71</td>
<td>52.0 ± 0.61</td>
<td>40.6 ± 0.56</td>
</tr>
</tbody>
</table>

Table 9: Overall entity and relation F1 scores of PL-Marker on the test set of ACE04, ACE05 and SciERC. ALBERT denotes ALBERTXXLARGE. We report averaged scores across five random seeds, with standard deviations as subscripts.

Prompt Initialization for NER

As shown in Table 10, using prompt to initialize the markers can bring a slight improvement to all six NER benchmarks.

<table>
<thead>
<tr>
<th>Init Strategy</th>
<th>CoNLL03</th>
<th>OntoNote 5.0</th>
<th>Few-NERD</th>
</tr>
</thead>
<tbody>
<tr>
<td>Random</td>
<td>93.9 ± 0.12</td>
<td>91.8 ± 0.12</td>
<td>70.8 ± 0.11</td>
</tr>
<tr>
<td>Prompt</td>
<td>94.0 ± 0.09</td>
<td>91.9 ± 0.08</td>
<td>70.9 ± 0.05</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Init Strategy</th>
<th>ACE05</th>
<th>ACE04</th>
<th>SciERC</th>
</tr>
</thead>
<tbody>
<tr>
<td>Random</td>
<td>91.0 ± 0.28</td>
<td>90.3 ± 0.45</td>
<td>69.4 ± 0.50</td>
</tr>
<tr>
<td>Prompt</td>
<td>91.1 ± 0.29</td>
<td>90.4 ± 0.42</td>
<td>69.9 ± 0.71</td>
</tr>
</tbody>
</table>

Table 10: The entity F1 on test set of NER datasets when the PL-Marker is initialized with prompt or when it is initialized randomly. We use the RoBERTaLARGE for flat NER datasets and ALBERTXXLARGE for the nested NER datasets.
