Abstract. Optical coherence tomography angiography (OCTA) is a novel noninvasive imaging modality for visualization of retinal blood flow in the human retina. Using specific OCTA imaging biomarkers for the identification of pathologies, automated image segmentations of the blood vessels can improve subsequent analysis and diagnosis. We present a novel method for the vessel identification based on frequency representations of the image, in particular, using so-called Gabor filter banks. The algorithm is evaluated on an OCTA image data set from 10 eyes acquired by a Cirrus HD-OCT device. The segmentation outcomes received very good qualitative visual evaluation feedback and coincide well with device-specific values concerning vessel density. Concerning locality our segmentations are even more reliable and accurate. Therefore, we suggest the computation of adaptive local vessel density maps that allow straightforward analysis of retinal blood flow.

1 Introduction

Optical coherence tomography angiography (OCTA) is a novel technique for noninvasive, rapid imaging and quantification of retinal blood flow and has expanded the diagnostic toolbox in ophthalmology. OCTA enables the visualization of the retinal and choroidal vascular networks (by creating a 3D angiogram) based on detection of red blood cell movement. These vascular networks and their specific biomarkers can be investigated individually by creating a 2D top view image (called enface image) of the chosen slab. OCTA en face images are mostly 8-bit grayscale images with very small greyish-dark vessels and large whitish-bright retinal vessels. Dark pixels correspond to no retinal blood flow. For subsequent automated analysis of some biomarkers it is important to transform these grayscale en-face images into segmented binary images, where black pixels correspond to the absence of blood flow and white pixels indicate blood flow. Several studies have demonstrated the importance of OCTA imaging biomarkers, e.g. vessel density or the foveal avascular zone (FAZ), for early detection and monitoring of several retinal diseases but also systemic diseases like diabetes.

* corresponding author
Acute renal injury, cardiovascular disease and arterial hypertension. A correct segmentation of the retinal capillary networks is critical for the computation of such markers and its subsequent clinical applicability. It is not feasible to manually annotate the vessel architecture in a bigger amount of OCTA en-face images and therefore a tool for automated segmentation is needed. Moreover, consistent segmentations of OCTA data sets can subsequently be evaluated more easily by humans and machines, improving diagnosis and therapy of patients. One main challenge therein is to obtain a representation of the vessel architecture that still maintains the actual vascular network.

Finding good, and especially generalizable (across devices), automated segmentation tools for retinal vessels in OCTA scans remains an open problem in clinical routine and research (see e.g. [17, 18]). Some OCTA manufacturers provide their own binarization algorithms for an expanded OCTA analysis but these are device and platform dependent and have their own limitations in particular regarding vessel density.

Deep learning is nowadays widely used for diverse medical imaging problems. The huge drawback is the need for a big amount of annotated data in order to yield accurate results, and especially, to avoid overfitting and allowing generalization to new data. E.g. in [13] an automated vessel segmentation algorithm has been proposed based on deep learning with annotated OCTA data. They use patches derived from 11 OCTA scans to train convolutional neural networks.

We will present an algorithm that is independent from annotated data, segmenting OCTA en-face images based on frequency representations. In particular, we use so-called Gabor filters that are known to be closely connected to the perception of mammalian brains, and have been successfully applied in texture analysis and denoising. Moreover, they have been successfully used in medical applications, and in particular in segmentation tasks of OCT images. Beyond that, in a novel Gabor OCTA imaging algorithm was proposed, suggesting to include Gabor filters in the OCTA processing to receive the en face vascular images.

Here, we use a comprehensive Gabor filter bank that allows enhancement of selected frequency ranges in the new image representations. These preprocessed images enable successful local and global thresholding for the identification of small and big vessels. The last step of the algorithm is the segmentation of the FAZ and is approached by variational energy minimization, the so-called Potts problem, yielding a piecewise constant representation of the image that enables direct identification of the area.

The algorithm is evaluated quantitatively and qualitatively on OCTA data from 10 eyes with various retinal diseases. Our segmentations received positive qualitative visual evaluation feedback by expert clinicians. In the quantitative comparison concerning vessel density with the in-built values of the device, our segmentations are also more reliable and accurate. Moreover, we provide local vessel density maps, which allow a direct interpretation of the blood flow in regions of any desired size.
2 Methods

The first important step is the preprocessing of the data with filters derived from a so-called Gabor filter bank.

A continuous Gabor filter can be written as

\[
g_{\theta, \omega}(x_1, x_2) := \frac{\omega^2}{\pi \sigma_1 \sigma_2} e^{-\frac{\omega^2}{\sigma_1^2} \left( \frac{(x_1 \cos \theta + x_2 \sin \theta)^2}{\sigma_1^2} + \frac{(-x_1 \sin \theta + x_2 \cos \theta)^2}{\sigma_2^2} \right)} e^{2\pi i \omega (x_1 \cos \theta + x_2 \sin \theta)},
\]

for some chosen frequency \(\omega\), orientation \(\theta\) and \(\sigma_1, \sigma_2\) correspond to the spatial widths of the filter, which is then applied to an image. Here, we choose the parameters as suggested in [19] and use 3 frequency scalings \(\{\omega_i\}_{i=1}^3\) and 6 orientations \(\{\theta_j\}_{j=1}^6\) to create our Gabor filter bank. The \(3 \cdot 6 = 18\) computed Gabor filters are then convolved with the original image \(I \in \mathbb{R}^{m \times n}\) to derive the new image representations in \(\mathbb{R}^{m \times n}\). Next, for fixed \(\omega_i\), we take the pixel-wise maximum in the images corresponding to the 6 orientations \(\{\theta_j\}_{j=1}^6\), leading to 3 images \(I_1, I_2, I_3\) with different emphasized frequency ranges, see Figure 1. These new representations are our basis for the further processing.

![Figure 1](image1.png)

**Fig. 1.** New image representations are obtained by the convolution of the original image \(I\) with Gabor filters. The images \(I_1, I_2, I_3\) correspond to the 3 chosen frequency ranges defined by \(\{\omega_i\}_{i=1}^3\).

Our image segmentation is divided into three subtasks: the identification of small and big vessel and the FAZ. The final result, see Figure 2(b), is obtained by uniting the binary images with the small and big vessels and subsequently using the FAZ segmentation as a mask that excludes that area.

2.1 Identification of small and big vessels

For the image processing steps that focus on the identification of the small and big vessels, we will use the image representation \(I_2\) that emphasizes the medium frequencies. These frequencies correspond best to the vessels we aim
to identify and therefore the new representation reveals a more clear structure of the relevant characteristics. We smooth the image $I_2$ by convolution with a Gaussian filter

$$h(x_1, x_2) := \frac{1}{2\pi\sigma^2} \exp\left(\frac{-x_1^2 + x_2^2}{2\sigma^2}\right),$$

(2)

with standard deviation $\sigma = 1$, in the following referring to this smoothed version as $I_2$.

In order to identify the smaller vessels, we compute a threshold from local and global statistics of the preprocessed image. In particular, we apply two order-statistic filters to the image: the local one takes the maximum of a $3 \times 3$ neighborhood, the global one the median of a $30 \times 30$ neighborhood. After the filters are applied to $I_2$, we obtain two new images. Finally, we threshold the image $I_2$ pixel-wise by the pixel-wise mean of the two images, yielding a binary segmentation of the small vessels.

To identify the big vessels, we apply the well known thresholding method by Otsu (cf. [21]) to $I_2$.

![Original image](image1.png) ![Final segmentation](image2.png)

Fig. 2. The combined substeps described in Sections 2.1 and 2.2 yield the final image.

### 2.2 Identification of the FAZ

For the identification of the FAZ, we will use the image that is obtained by taking the pixel-wise maximum over all frequency ranges $\{\omega_i\}^3_{i=1}$ and orientations $\{\theta_k\}^9_{k=1}$, i.e. the pixel-wise maximum of the images $I_1, I_2$ and $I_3$, followed by a Gaussian filter (2) with $\sigma = 2$. In this task particular frequencies do not play a substantial role since there are no vessels to be identified in the FAZ. To segment
the FAZ region, we use a variational energy minimization problem to obtain a piecewise constant representation of the image. We employ the so-called Potts model, which can be formulated as follows: For a given initial image $z : \Omega \rightarrow \mathbb{R}^r$ on a continuous region $\Omega \subset \mathbb{R}^2$ and $\gamma > 0$, find the piecewise constant minimizer of

$$\arg \min_u \gamma \cdot \|\nabla u\|_0 + \int_\Omega (u(x) - z(x))^2 \, dx,$$

where $u : \Omega \rightarrow \mathbb{R}^r$ denotes a bounded piecewise constant function and $\|\nabla u\|_0$ the total boundary length of its partitioning, cf. \cite{20, 8, 24} for details. The second term provides approximation to the original data and the first term enforces the partitioning, where the parameter $\gamma$ controls the balance between the two penalties. We use the fast strategy and code presented in \cite{24} for solving a discretization of (3) to receive the piecewise constant image representation. The FAZ is then identified by choosing the darkest segment in the central part of the image.

3 Data, Results and Discussion

OCTA examinations were performed with a Cirrus HD-OCT (Angioplex) by an experienced ophthalmologist according to a standardized protocol as part of an OCTA device comparison study in 2020 at the Department of Ophthalmology and Optometry at the Medical University of Vienna. The study was approved by its ethics committee (EK#1437/2019) and was conducted in accordance with the Declaration of Helsinki. $3 \times 3$ mm OCTA scans with various retinal diseases were recorded and en-face images for the superficial vascular network were exported for this investigation. All enrolled patients provided written informed consent for analysis and publication of their OCTA images. For the evaluation we chose 10 eyes with varying diseases and similar image quality, where 5 patients were used to fine-tune the parameters of the algorithm.

3.1 Qualitative results

Vessel Density The visual results of the segmentation are very good: small vessels are identified accurately, branches are preserved and the ratio of the vessel diameter is pictured realistically. Furthermore, small non-perfusion areas around larger vessel and vascular angles are also depicted truthfully. See Figure 3 for a visualisation of some details.

FAZ identification In Figure 4 we can see the FAZ annotated manually by one expert grader, from the device and the result from our algorithm. We observe that the manual annotation and the automated one from the device differ in their main characteristics and that our segmentation contains characteristics of both.

3.2 Quantitative results

Vessel Density has been identified as an important marker for vascular diseases in OCTA \[1, 16, 12\]. To allow quantitative evaluation of our segmentations, we compare the VD of our results with in-built values from the OCTA device itself. The VD is returned in defined areas, i.e. the number of pixels containing blood flow (all pixels $> 0$) divided by the number of all pixels in that area. The typical areas of interest are defined by the inner areas of an ETDRS grid, see Figure 5(a).

The grid for the 3x3mm scans divides the retina into five large regions bound by two rings: a central foveal circle with 1mm diameter and an inner parafoveal ring around it with 3mm diameter divided into four quadrants; temporal, superior, nasal and inferior. For these areas the VD values are provided by the OCTA device. We observed that the vessel identification of the device is quite inaccurate concerning particular vessels, i.e. more local areas, see Figure 5 for an example: the vessel density in the inferior quadrant is the lowest (39.5%) although the biggest vessel appears there and simple numerical experiments as well as visual evaluation indicate that this is not accurate. Due to unreliable values from the in-built device software for big vessels, we decided to compare the VD values more globally within the 3mm parafoveal ring, in the following referred to as the 3-1 ring.

The quantitative results concerning the vessel density are presented in Table 1 stating the VD values in the 3-1 ring by the device (right) and our obtained segmentations (left) for all 10 eyes. The mean difference over all eyes is 1.54% and the largest discrepancy is 3.3%. The table indicates that the VD identification of

</table>

the OCTA device and our segmentation is globally very similar. These results are promising since VD identification is highly complicated, e.g. the best model in [13] leads to a mean VD difference of 6% in their data with manual annotations.

Remark 1. Our method enables the computation of more localized VD values than what is provided by the device. Based on the accurate binary segmentation of the blood vessels, local VD maps could help clinicians to identify more inconspicuous regions of capillary dropout (e.g., in diabetes patients). We can provide VD maps with any predefined sizes of locality, see Figure 6 where brighter areas indicate high and darker areas less blood flow.

**FAZ identification** To evaluate our FAZ segmentations quantitatively we compare the common quantities of area, perimeter and circularity, see e.g. [23]. These
numbers have also been provided by the OCTA device itself and furthermore, we computed them for the manual annotation performed by one expert. We can see in Table[1] that the values of the device (middle) and the grader (right) differ highly. Nonetheless, we can observe that the values provided by our segmentation are always close to one of the both results and often even lie in between, which also corresponds to our qualitative findings (see Section 3.1). Manual annotations performed by several graders will be needed to allow more distinct evaluation of this substep, including statistical analyses.

Outline Our next planned steps are the evaluation of the method on data from different devices and including the deep capillary plexus, and with diverse image quality as well as more detailed discussions with clinicians concerning pathologies. Moreover, we plan to adapt our algorithm to apply and compare it to the new publicly available data sets and algorithms presented in [13] and [18], including the computation of parameters from the vessel skeleton maps, see Figure[4](d), that have been identified as important parameters for quantitative assessment (cf.[12]).

4 Conclusion

We presented a novel algorithm for the segmentation of blood vessels of the superficial vascular network in OCTA scans, which is still a challenge for scientists in ophthalmology. The method is based on frequency filters that allow precise identification of smaller blood vessels. It yields convincing results visually as well as in quantitative comparison with in-built device values concerning VD and FAZ identification. Moreover, we observed that the VD in-built values are locally not consistent. Therefore, we suggest alternative representations of adaptive local VD maps based on our segmentation. Such maps might be helpful for clinical interpretation of various retinal and systemic diseases. To comprehensively assess our algorithm on the described data, more consistent evaluation schemes are needed. Thereby we are planning to create manual annotations by several graders.
