Abstract

Despite strong performance in many sequence-to-sequence tasks, autoregressive models trained with maximum likelihood estimation suffer from exposure bias, i.e. a discrepancy between the ground-truth prefixes used during training and the model-generated prefixes used at inference time. Scheduled sampling is a simple and often empirically successful approach which addresses this issue by incorporating model-generated prefixes into the training process. However, it has been argued that it is an inconsistent training objective leading to models ignoring the prefixes altogether. In this paper, we conduct systematic experiments and find that it ameliorates exposure bias by increasing model reliance on the input sequence. We also observe that as a side-effect, it worsens performance when the model-generated prefix is correct, a form of catastrophic forgetting. We propose using Elastic Weight Consolidation as trade-off between mitigating exposure bias and retaining output quality. Experiments on two IWSLT’14 translation tasks demonstrate that our approach alleviates catastrophic forgetting and significantly improves BLEU compared to standard scheduled sampling.

1 Introduction

Autoregressive models trained with maximum likelihood estimation (MLE) constitute the dominant approach in several sequence-to-sequence (seq2seq) tasks, such as machine translation (Bahdanau et al., 2015), text summarization (See et al., 2017), and conversational modeling (Vinyals and Le, 2015). However, this paradigm suffers from a discrepancy between training and inference. During training, the model generates tokens by conditioning on the ground-truth prefixes, while at inference time model-generated prefixes are used instead. This is known as the exposure bias problem (Bengio et al., 2015; Ranzato et al., 2016). Since the model is never exposed to its own errors, if a token is mistakenly generated during inference, the error will be propagated along the sequence (Ross et al., 2011). Prior work has attributed to exposure bias various forms of text degeneration, such as repetitiveness, incoherence, and tediousness (Holtzman et al., 2020), and hallucinations (Wang and Sennrich, 2020), i.e. fluent outputs which contain information irrelevant and/or contradictory to the input sequence.

Bengio et al. (2015) introduced scheduled sampling to address exposure bias in MLE-trained autoregressive models. Scheduled sampling uses a stochastic mixture of ground-truth and model-generated prefixes during training, thereby allowing the model to learn how to recover from its own errors. While various schemes have been proposed as alternatives to MLE training for the purpose of mitigating exposure bias (Ranzato et al. (2016); Wiseman and Rush (2016); Shen et al. (2016); Bahdanau et al. (2017), inter alia), scheduled sampling remains one of the most popular due to its simplicity and performance improvements in many conditional sequence generation tasks (Bengio et al., 2015; Du and Ji, 2019; Zhang et al., 2019).

Conversely, other studies have reported that using scheduled sampling may hurt performance (Leblond et al., 2018; Mihaylova and Martins, 2019). The dominant hypothesis for these negative results is that it creates models that are more likely to recover from their own mistakes by training them to ignore the generated prefixes entirely (Huszar, 2015). However, no attempt has been made to empirically assess this hypothesis. Thus better understanding of how scheduled sampling affects training remains under-explored.

In this paper, we provide insights into the working mechanisms of scheduled sampling. Following Voita et al. (2020), we apply Layerwise Relevance Propagation (LRP) (Bach et al., 2015) to quantify the contributions of the input sequence...
and the model-generated prefix on the output generation process, and empirically evaluate the hypothesis of Huszar (2015). We find that models trained with scheduled sampling increase their reliance on the input sequence, and therefore mitigate exposure bias by depending less on the potentially incorrect generated prefix. However, we also observe that this leads to output degradation due to catastrophic forgetting (7) of how to predict when the model-generated prefix is correct. We propose using Elastic Weight Consolidation (EWC) (Kirkpatrick et al., 2016) to address catastrophic forgetting and allow improvements due to mitigating exposure bias, while also retaining output quality.

Experiments on the commonly-used IWSLT'14 GermanEnglish and VietnameseEnglish translation tasks show that our scheduled sampling variant mitigates catastrophic forgetting and significantly improves translation performance over standard scheduled sampling in long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) and Transformer (Vaswani et al., 2017) models. In particular, on GermanEnglish, our approach yields a BLEU gain of +0.62 over scheduled sampling for the LSTM model and a gain of +0.73 BLEU for the Transformer. Similarly, on VietnameseEnglish, our approach outperforms scheduled sampling by +0.54 BLEU and by +0.59 BLEU. Importantly, performance gains occur across different annealing schedules, making the scheduled sampling variant we introduce more robust and easier to tune.

2 Scheduled Sampling

Autoregressive models estimate the conditional probability of the output $y$ given the input $x$ one token at a time in a monotonic fashion:

$$P(y \mid x) = \prod_{t=1}^{T} p(y_t \mid y_{<t}, x; \theta),$$

where $y_t$ is the t-th token in $y$, $y_{<t}$ denotes all previous tokens, and $\theta$ is a set of model parameters.

Given a dataset $\mathcal{D} = \{(x^{(i)}, y^{(i)})\}_{i=1}^{N}$ of input-output pairs, the standard approach to optimize the parameters $\theta$ of an autoregressive model entails maximizing the conditional log-likelihood:

$$\hat{\theta}_{\text{MLE}} = \arg \max_{\theta} \mathcal{L}(\theta; \mathcal{D}),$$

where

$$\mathcal{L}(\theta; \mathcal{D}) = \sum_{i=1}^{N} \sum_{t=1}^{L^{(i)}} \log p(y_t^{(i)} \mid y_{<t}^{(i)}, x^{(i)}; \theta).$$

Here $i$ indicates the i-th output sequence in the dataset and $L^{(i)}$ is the length of the i-th output sequence. This training objective is known as teacher-forcing (Williams and Zipser, 1989), since the model conditions on the ground-truth prefix $y_{<t}^{(i)}$ to generate the token $y_t^{(i)}$. However, at inference time, the model generates the token $\hat{y}_t$ by conditioning using its own previous outputs, i.e. $\hat{y}_{<t}$ instead of $y_{<t}$. This limitation creates a discrepancy between training and inference known as the exposure bias problem (Bengio et al., 2015; Ranzato et al., 2016).

Bengio et al. (2015) introduced scheduled sampling to bridge the above-mentioned gap between MLE training and inference. Scheduled sampling uses the same training objective as teacher-forcing (Equation 3), the only difference being that the conditioning prefixes $\hat{y}_{<t}^{(i)}$ are a stochastic mixture of ground-truth $y_{<t}^{(i)}$ and model-generated prefixes $\hat{y}_{<t}^{(i)}$.

$$\mathcal{L}(\theta; \mathcal{D}) = \sum_{i=1}^{N} \sum_{t=1}^{L^{(i)}} \log p(y_t^{(i)} \mid \hat{y}_{<t}^{(i)}, x^{(i)}; \theta).$$

Finally, an annealing schedule is used to gradually decrease the probability $p$ of conditioning using the ground-truth $y_{<t}^{(i)}$ during training. Typically, for each mini-batch $b$, $p$ is decreased using the following annealing schedules:

- **Linear**: $p = \max(p - kb, 0)$
- **Exponential**: $p = k^b$
- **Inverse sigmoid**: $p = k/(k + \exp(b/k))$

Here $k$ is a hyperparameter which controls the speed of the decay of $p$ in each schedule.
2.1 Connections to DAGGER

Scheduled sampling is an adaptation to recurrent neural networks (RNNs) and autoregressive models more broadly of DAGGER (Ross et al., 2011), a well-known imitation learning (IL) technique for mitigating exposure bias. Like other IL algorithms (Daumé III et al., 2009), it relies on an oracle (or expert), who demonstrates the desired behavior during training and also provides information about how to recover from errors. Thus the main idea behind DAGGER is to iteratively construct a training dataset by using new data generated from a stochastic mixture of the oracle and the model, thereby allowing the latter to learn to recover from its own errors.

However, there are several important differences between scheduled sampling and DAGGER. First, scheduled sampling uses the ground-truth as an oracle by assuming that at each time step the ground-truth tokens are aligned with the model-generated tokens. Consequently, if the model-generated sequence deviates from the ground-truth this will cause repetitive loops. For example, if the ground-truth sequence is “I took a brief break,” and the model has generated “I took a break,” scheduled sampling will train the model to generate “break” twice (Daumé III, 2016; Ranzato et al., 2016). Second, scheduled sampling cannot penalize earlier mistakes in the sequence since the gradients are not back-propagated through the generated prefixes due to the discontinuation of the argmax operation (Ranzato et al., 2016; Goyal et al., 2017). Using the same example as above, if the model erroneously generates “I took a long nap,” scheduled sampling will only seek to increase the likelihood of “break” and will not attempt to address the initial error in the sequence, i.e. generating “long” instead of “brief.” Third, unlike Ross et al. (2011) who provide theoretical guarantees for the annealing schedule in DAGGER, Bengio et al. (2015) do not offer any justifications regarding the differences among the proposed annealing schedules for scheduled sampling. Finally, scheduled sampling assumes an online training algorithm (e.g. stochastic gradient descent), whereas DAGGER trains on datasets aggregated across iterations.¹

3 Analysis of Scheduled Sampling

In this section, we propose two systematic analyses to investigate how scheduled sampling works. First, we use Layerwise Relevance Propagation (LRP) (Bach et al., 2015) to examine the contribution of the input sequence and the model-generated prefix on the output generation process, and thus assess the hypothesis of Huszar (2015) regarding how scheduled sampling affects training. Then we treat scheduled sampling as a domain adaptation task by assuming that the model’s predictions can be viewed as a small domain we adapt the model after it is trained only on ground-truth data. To this end, we apply teacher-forcing at inference time to quantify the impact of catastrophic forgetting on models trained with scheduled sampling.

3.1 Prefixes under Scheduled Sampling

Huszar (2015) argued that scheduled sampling is an inappropriate training objective since it learns models that ignore the generated prefixes. This limitation arises because the model-generated outputs correspond to a distribution that is different from the ground-truth sequences the model is trained to generate. Therefore training might not converge to the correct model even as the dataset and the capacity of the model increase indefinitely.

To empirically verify this hypothesis, we apply LRP to quantify the influence of the input sequence and the prefix on the output generation process. The intuition behind this experiment is that if scheduled sampling creates models that ignore the prefixes, then the input sequence and the prefix contributions should remain relatively stable.

Given an input sequence token $x_i$ and a prefix token $y_j$, LRP computes the relevance scores $r_t(x_i)$ and $r_t(y_j)$ at every output generation step $t$ by back-propagating from the output to the input. Importantly, the total relevance scores for each generated token are equal to 1:

$$\sum_i r_t(x_i) + \sum_{j=1}^{t-1} r_t(y_j) = 1. \quad (5)$$

¹However, DAGGER has also been used in online settings as well (Daumé III et al., 2014).
In the general case, the relevance score $r_j^{(l)}$ for the $j$-th neuron in layer $l$ is computed as:

$$r_j^{(l)} = \sum_{k=1}^{K} \left( \alpha \frac{z_{jk}^+}{\sum_i z_{ji}^+} - \beta \frac{z_{jk}^-}{\sum_i z_{ji}^-} \right) r_k^{(l+1)}, \quad (6)$$

where $z_{jk} = x_j w_{jk}$. Here $K$ denotes the total number of neurons at each layer, $j$ and $k$ are neurons at two consecutive layers $l$ and $l+1$, $x_j$ is the activation of neuron $j$ at layer $l$, $w_{jk}$ is the weight connecting neurons $j$ and $k$, $r(l+1)$ is the relevance score at layer $(l+1)$, $+$ and $-$ indicate positive and negative contributions to $r(l+1)$, and finally, $\alpha$ and $\beta$ are hyperparameters that determine the importance of the positive ($+$) and negative ($-$) contributions.

### 3.2 Scheduled Sampling as Fine-Tuning

Our hypothesis is that scheduled sampling can be treated as a domain adaption task where a model trained on a large general-domain dataset, i.e. the ground-truth data, is then fine-tuned on a small in-domain dataset, i.e. the model’s own predictions. A commonly occurring issue in such approaches is that typically after fine-tuning, the model’s ability to produce general-domain outputs is negatively impacted due to catastrophic forgetting (??). To this end, inspired by Wu et al. (2018) who applied teacher-forcing during inference to investigate the influence of exposure bias in neural machine translation (NMT), we use the ground-truth prefix $y_{<t}$ instead of the model-generated prefix $\hat{y}_{<t}$ to generate the output token $\hat{y}_{t}$:

$$\hat{y}_{t} = \arg\max_{y} p(y \mid y_{<t}, x; \theta). \quad (7)$$

If there is no catastrophic forgetting, then the output quality is expected to improve when the model-generated prefixes are replaced with the ground-truth since the risk of exposure bias is mitigated.

### 4 Experiments

In this section, we apply the methods discussed in Section 3 to examine if models trained with scheduled sampling ignore the generated prefixes and also determine whether scheduled sampling causes catastrophic forgetting.

Data Following prior work exploring scheduled sampling in NMT (Goyal et al., 2017; Xu et al., 2019; Mihaylova and Martins, 2019), we conduct experiments on two commonly-used IWSLT’14 translation tasks, the German-English (deen) and Vietnamese-English (vien). The deen dataset consists of approximately 170K sentence pairs. For deen, we follow the same setup as in Ranzato et al. (2016). The vien dataset contains approximately 121K sentence pairs. We perform experiments on the vien following the setup of Luong and Manning (2015). We report cased, tokenized BLEU (Papineni et al., 2002) with multi-bleu.perl.3

Models We use LSTM (Hochreiter and Schmidhuber, 1997) and Transformer (Vaswani et al., 2017) models trained with default architectures and hyperparameters from fairseq (Ott et al., 2019). We report the mean and standard deviation over 5 runs with different random seeds.

---

2Since we use implementation of Voita et al. (2019), we adopt the LRP-$\alpha\beta$ rule (Bach et al., 2015; Binder et al., 2016) for computing relevance scores.

4.2 Results

Impact of Annealing Schedule  Before we proceed with our analyses, we first attempt to assess the effectiveness of scheduled sampling by examining the impact of the annealing schedule on performance, as there is no systematic study of it in any previous work, including Bengio et al. (2015). Table 1 shows that there is a considerable difference in performance between inverse sigmoid, and the linear and exponential annealing schedules. One potential factor for this is that when the annealing schedule starts decreasing the ground-truth probability too fast (as in the case of both the linear and exponential annealing schedules), the performance of the model deteriorates quickly. We also observe that all annealing baselines outperform scheduled sampling without annealing, i.e. using a fixed probability for the ground-truth throughout training, thus showing that this particular training objective benefits strongly from it. This is likely because the model is not capable of generating useful prefixes early on during training. Furthermore, the experimental results show that by using a carefully tuned annealing schedule, scheduled sampling leads to higher BLEU scores compared to MLE. In particular, on vien, it improves over the MLE baseline by +0.94 BLEU for the LSTM model and by +0.44 BLEU for the Transformer. In particular, on vien, it improves over the MLE baseline by +0.94 BLEU for the LSTM model and by +0.44 BLEU for the Transformer. Similarly, on deen, scheduled sampling yields a gain of +0.63 BLEU over the MLE-trained LSTM model and a gain of +0.57 BLEU over the MLE-trained Transformer. Given the superiority of inverse sigmoid, in the remainder of this paper we use this annealing schedule for all experiments unless otherwise stated.

Prefixes under Scheduled Sampling  Figure 1 shows the source contributions for model-generated prefixes. Following the experimental setup of Voita et al. (2020), we pick 100 randomly chosen source-target pairs from each test set with the same length in the source and target and average all results. We use the Transformer model to quantify contributions since the implementation of LRP by Voita et al. (2020) is tailored to this particular neural architecture. Figure 1 illustrates that at the beginning, MLE-trained models tend to use the source more, however, as the target prefix becomes longer, they rely less on the source and more on the prefix, given that $\sum_{j=1}^{t-1} r_t(y_j) = 1 - \sum_{i=1}^{t} r_t(x_i)$ (Equation 5). This behaviour is in agreement with prior work that has attributed the increasing reliance on the prefix to teacher-forcing (Wang and Sennrich, 2020; Voita et al., 2020). Conversely, scheduled sampling, which mitigates exposure bias, promotes the usage of source information to generate a target token, as the decrease in the influence of source contributions is less drastic compared to MLE-trained models. This suggests that scheduled sampling results in models that tend to ignore the generated prefix more than MLE-trained models, thus confirming the hypothesis discussed in Section 3. However, in contrast to Huszar (2015), we argue that this is a positive outcome in the context of NMT: the model-generated prefix is often incorrect, but the source that is being translated does not change, therefore learning to rely on it more is a reasonable approach to alleviate exposure bias.
Scheduled Sampling as Domain Adaptation

Table 2 empirically confirms the occurrence of catastrophic forgetting in models trained with scheduled sampling. We observe that when they condition using the ground-truth prefixes, the quality of generations drops heavily in terms of BLEU across both languages and neural architectures, suggesting that scheduled sampling results in forgetting how to predict when the prefix is correct. In particular, on deen, the BLEU score reduction is -3.76 for the LSTM model and -4.81 for the Transformer. Similarly, on vien, the BLEU score degrades by -4.66 and by -5.15. On the other hand, we see that in MLE-trained models, using teacher-forcing at inference time leads to consistent BLEU score improvements over conditioning with model-generated prefixes. Specifically, on deen the BLEU score gain is +1.95 for the LSTM model and 1.88 for the Transformer, and on vi, the BLEU score increases by +2.34 and by +2.01.

5 Elastic Weight Consolidation for Scheduled Sampling

Section 4 shows that even though scheduled sampling addresses exposure bias by increasing model reliance on the input sequence, it also leads to output degradation due to catastrophic forgetting (?). Elastic Weight Consolidation (EWC) (Kirkpatrick et al., 2016) is an effective regularization-based approach for mitigating catastrophic forgetting during domain adaptation in NMT (Thompson et al., 2019; Saunders et al., 2019).

EWC regularizes learning an in-domain task $I$ without forgetting an already learned general-domain task $G$ by retaining the parameters which are important for the latter, while adapting more on parameters that are less important:

$$\mathcal{L}_{EWC}(\theta; D) = \mathcal{L}(\theta; D^I) + \lambda \sum_j F_j (\theta_j^I - \theta_j^G)^2,$$

where $\mathcal{L}(\theta; D^I)$ is the standard log-likelihood loss (Equation 3) over the in-domain data, $\lambda$ is a hyperparameter which determines the importance of the general-domain task $G$, $\theta_j^I$ are the in-domain model parameters, $\theta_j^G$ are the general-domain model parameters, and $F_j = E[\nabla^2 \mathcal{L}(\theta_j^G)]$ is an estimate of how important the parameter $\theta_j^G$ is to the general-domain task $G$.

6 Experiments with EWC

In this section, we perform experiments with our proposed scheduled sampling variant following the setup described in Section 4.

Automatic Evaluation Table 3 shows that by using scheduled sampling in conjunction with EWC we obtain better BLEU scores on all annealing schedules across both languages and neural architectures compared to standard scheduled sampling. Specifically, for the best performing annealing schedule, on vien, our proposed scheduled sampling variant improves over scheduled sampling by +0.62 BLEU for the LSTM model and by +0.73 BLEU for the Transformer. Similarly, on deen, it yields a gain of +0.54 BLEU and +0.59 BLEU. Im-

provements are significant with $p < 0.01$.\footnote{We conduct statistical significance testing following Collins et al. (2005).} Furthermore, we observe that EWC brings the performance of less effective annealing schedules closer to that of MLE-trained models.

**Catastrophic Forgetting** We investigate whether using EWC addresses the catastrophic forgetting problem in models trained with scheduled sampling. To this end, we repeat the teacher-forcing during inference experiment discussed in Section 3. Table 4 shows consistent improvements in terms of BLEU scores compared to the results obtained with standard scheduled sampling (Table 2). In particular, on deen, the BLEU score gain for scheduled sampling with EWC is +2.69 for the LSTM model and +3.28 for the Transformer. Similarly, on vien, the BLEU score increases by +2.79 and by +3.04.

**Performance at Different Output Lengths**
Figure 3 shows BLEU scores on the deen test set for different output sequence lengths (by grouping them into bins of width 20). We observe that the output quality degrades as the sequence length increases across all training objectives. In particular, MLE-trained models suffer the most from this due to exposure bias. Conversely, our variant improves the BLEU score across all bins (compared to MLE and standard scheduled sampling), even for long sequences.

**Effect of $\lambda$** Figure 2 shows the BLEU scores on the deen test set under different values for $k$ (for the annealing schedule) and $\lambda$ (for EWC). We observe that scheduled sampling with EWC outperforms standard scheduled sampling (bottom row where $\lambda = 0$) across all hyperparameter pairs. Thus we conclude that the introduction of $\lambda$ does not increase the complexity of hyperparameter tuning, as it improves the robustness of scheduled sampling across schedules and their parameterizations. Huszár (2018) pointed out that EWC is an approximation of the joint optimization of the loss on two datasets, via encapsulating the information from the dataset representing the initial general-domain task in the model parameters that are fine-tuned. Scheduled sampling (without EWC) also aims at achieving the same goal, i.e. optimizing the parameters for generating outputs using both ground-truth prefixes and model-generated ones. In principle, this should be possible to achieve via a well-tuned annealing schedule, however, as Figure 2 shows, it is substantially easier to tune the hyperparameter controlling the EWC regularizer. Finally, in the theoretical analysis of SEARN which also uses an annealing schedule in a similar manner, Daumé III et al. (2009) argued that the theoretically guaranteed annealing rate would be too slow to be applied in practice.

7 Related Work

**Imitation Learning for NMT** Since Bengio et al. (2015), a number of research works have adapted standard IL algorithms (Daumé III et al., 2009; Ross et al., 2011; Ross and Bagnell, 2014; Chang et al., 2015) to autoregressive models to address exposure bias. SEARN (Leblond et al., 2018) is a neural adaptation of SEARN (Daumé III et al., 2009) that computes a local loss for each generated token. Goyal et al. (2017) proposed a differentiable scheduled sampling variant to mitigate the credit assignment problem, while Xu et al. (2019) aimed to fix the time step alignment issue between the oracle and the model-generated tokens. Zhang et al. (2019) introduced a sequence-level scheduled sampling variant which conditions on model-generated prefixes with the highest BLEU score. A separate family of methods focus on using IL algorithms for non-autoregressive NMT (Wei et al., 2019; Gu et al., 2019; Welleck et al., 2019; Xu and Carpuat, 2020) and knowledge distillation (Liu et al., 2018; Lin et al., 2020).

**Non-MLE Training Methods** The discrepancy between MLE training and inference has prompted the development of many alternatives training algorithms. Approaches based on reinforcement learning (RL), such as Actor-Critic (Bahdanau et al., 2017) and MIXER (Ranzato et al., 2016), optimize the task-level loss directly. GOLD (Pang and He, 2020) uses off-policy RL to learn from human demonstrations through importance weighting (Hastings, 1970). Reward augmented maximum-likelihood (RAML) (Norouzi et al., 2016)
Figure 2: Hyperparameter analysis using heatmaps. Better performance is achieved with different hyperparameter pairs over standard scheduled sampling (bottom row where $\lambda = 0$), thus showing the robustness of our proposed variant.

Figure 3: BLEU scores versus output sequence length (bins of width 20) for various models and training objectives.

maximizes the likelihood of sequences with respect to the exponentiated reward distribution. Minimum Risk Training (MRT) (Och, 2003; Smith and Eisner, 2006; Shen et al., 2016) optimizes model parameters by minimizing the expected loss directly with respect to the task-level loss. Other alternative non-MLE training methods include energy-based models (Deng et al., 2020), beam-search optimization (BSO) (Wiseman and Rush, 2016), and unlikelihood training (Welleck et al., 2020).

Mitigating Catastrophic Forgetting Despite recent progress, various state-of-the-art neural architectures in NLP fail to retain previously learned knowledge due to catastrophic forgetting (Yogatama et al., 2019). To this end, many approaches have been proposed to overcome this limitation in a plethora of NLP tasks, such as NMT (Miceli Barone et al., 2017; Khayrallah et al., 2018; Saunders et al., 2019; Thompson et al., 2019), reading comprehension (Xu et al., 2020), fact verification (Thorne and Vlachos, 2020), and visual question answering (Perez et al., 2018; Greco et al., 2019). Another line of research works investigates techniques which address catastrophic forgetting during the fine-tuning stage of deep pre-trained language models (Arora et al., 2019; Chronopoulou et al., 2019; Chen et al., 2019, 2020; Pilault et al., 2020).

8 Conclusion In this work, we conduct systematic analyses to examine the strengths and weaknesses of scheduled sampling. By applying LRP to quantify the influence of the input sequence and the model-generated prefix on the output generation process, we show that models trained with scheduled sampling increase their reliance on the former to address exposure bias. However, we also demonstrate that as a side-effect, this leads to output degradation due to catastrophic forgetting when the prefix generated by the model at inference time is correct. Accordingly, we propose using EWC to allow mitigating exposure bias while maintaining output quality. Our scheduled sampling variant alleviates catastrophic forgetting and significantly improves BLEU scores over standard scheduled sampling on two IWSLT’14 translation tasks.

In future work, we would like to assess the impact of using different oracles on training, e.g. dynamic oracles (Goldberg and Nivre, 2012) that can help the model when it devi-
ates from the ground-truth, and also investigate whether other domain-adaptation methods can be used to ameliorate catastrophic forgetting in scheduled sampling. Finally, we intend to examine whether the phenomenon of catastrophic forgetting occurs in IL-based training objectives apart from scheduled sampling.
