Experimental observation of anomalous supralinear response of single-photon detectors

Josef Hloušek, Ivo Straka, and Miroslav Ježek

Department of Optics, Faculty of Science, Palacký University, 17. listopadu 12, 77146 Olomouc, Czechia

The linearity of single-photon detectors allows accurate optical measurements at low light levels and using non-classical light in spectroscopy, biomedical imaging, optical communication, and sensing. However, in practice the response of single-photon detectors can exhibit intriguing nonlinear effects that may influence the performed measurements. Here, we demonstrate a direct single-source method for absolute measurement of nonlinearity of single-photon detectors with unprecedented accuracy. We discover a surprising supralinear behavior of single-photon avalanche diodes and show that it cannot be explained using known theoretical models. We also fully characterize sub- and supra-linear operation regimes of superconducting nanowire single-photon detectors and uncover the supralinearity under faint continuous illumination. The results identify new detector anomalies that supersede existing knowledge of nonlinear effects at the single-photon level. These effects are of particular importance to cutting-edge applications of single-photon detectors in quantum metrology.

I. INTRODUCTION

A majority of radiometric, spectroscopic, imaging, and optical communication methods rely on comparing two or more levels of light intensity measured by a photodetector and assuming that its response is proportional to the incident radiation. Transmittance measurement represents the simplest example where the optical power is detected with and without the sample under test, see Fig. 1(A). For an ideal detector, the power ratio would be the same as the actual transmittance of the sample. The measurement accuracy is, however, impaired by any deviation from a perfectly linear response of the detector. One can correct for the detection imperfections on the condition that the model of the nonlinear effect is known and accurate enough. A constant dark current may serve as an example of a simple detector nonlinearity which can be corrected for.

With the advent of ultra-sensitive detectors and quantum-enhanced metrology, we tend to perform measurements at the ultimate sensitivity levels dictated by the laws of physics [1, 2]. The goal is to reach the quantum advantage regime—that is, to improve the sensitivity of a measurement beyond the shot-noise limit, or to relax the requirements of the measurement, such as the minimum required detection efficiency. Shaping the statistics of light and using nonclassical optical signals as measurement probes allow for increasing the precision of length measurements [3, 4], imaging and particle tracking [5, 9], and spectrophotometry [10, 11]. Optical transmittance measurement assisted by correlated photons and single-photon detectors can serve as a prominent example of a quantum-enhanced measurement scheme [12, 13].

The measurement precision at the single-photon level is severely affected by the nonlinearity of the employed photonic detectors. The reason is that the other systematic errors need to be eliminated to reach the quantum regime, while the single-photon detectors themselves maintain strong inherent nonlinearity. One can observe a complex interplay of detector-specific phenomena, such as dark counts, dead time, recovery transition, multiphoton response, and latching. These effects cause highly nontrivial nonlinear behavior that is much stronger compared to classical photodiodes—see Fig. 1(B). Not only does the nonlinear response distort the measurement of the average photon flux, it also distorts the measured photon statistics and prevents us from reaching the ultimate precision of quantum-enhanced measurements. Notable experiments deteriorated by detection nonlinearity are the tests of fundamental physics; namely confirming the validity of Born’s rule in quantum mechanics [16–21].

Here we explore the nonlinearity of actively and passively quenched single-photon avalanche diodes (SPADs) and a superconducting nanowire single-photon detector (SNSPD) for various bias currents. The employed nonlinearity measurement does not require a calibrated reference detector, calibrated attenuators, or time-resolved detection, which considerably simplifies the characterization of the single-photon detectors. The nonlinearity characterization is performed with unprecedented accuracy; we reliably detect nonlinearities smaller than 1:1000, and cover seven orders of magnitude of incident illumination. We discover a supralinear region of SPAD operation, which is not consistent with any known theoretical models and has not been reported yet. We also characterize the nonlinear behavior of an SNSPD with a complex structure of sub- and supra-linear operation regions. We observed, for the first time, supralinearity of a SNSPD under continuous illumination at very low detection rates.

A. Single-photon detectors

Before discussing the main results, let us briefly review the fundamentals of single-photon detectors and basic principles of nonlinearity characterization.
A single-photon detector outputs an electronic pulse when one or more photons are detected \(22, 26\). The detection events (also termed counts) arrive at random times with a statistical distribution given by the detected state and the response of the detector. The detection rate \(R_{\text{det}}\) is then a function of the incident rate \(R\); the rate is given in units of counts/s, or simply Hz. Sometimes the detector outputs a pulse even when no photon is detected due to various background contributions (dark counts) or as a result of a previous detection (SPAD afterpulses). Furthermore, the detector occasionally fails to detect photons because it is not ready to do so after the previous detection event, such as during dead time or a latched state. Figure 1(B) illustrates the nonlinear behavior of a single-photon detector. A simple expectation is a \(\int\)-shaped sub-linear dependence, where background count rate and dead-time saturation dominate on opposite sides of the power range. However, we found that some detectors exhibit an S-shaped response where the slope gets supralinear in the middle. Supralinearity has been reported for silicon photodiodes for strong classical illumination \(27, 29\), but current SPAD models and measurements do not predict any such phenomenon. For SNSPDs, supralinear behavior has been observed for very high rates \((\geq 10 \text{ MHz})\) due to AC detector coupling \(30\) and for short optical pulses (mean photon number \(\geq 0.1\)) as a result of two-photon absorption \(31\). However, no observation of supralinearity of SNSPDs has been reported under continuous illumination with the detection rate below 1 MHz.

The particular detection imperfections are specific to SPADs and their quenching circuits \(23, 24\), or SNSPDs \(22, 25, 26\) due to their different operational principles. There is a great number of results in modelling the response of a SPAD with the ultimate goal of including all the relevant factors \(32, 36\). Their accuracy has been limited so far and many counter-examples exist for which the measured SPAD response differs significantly from the theoretical model. Consequently, determining the nonlinearity of the SPAD response and finding the optimum detection rate to access the minimum achievable deviation from the ideal linear behavior represents a significant challenge. This issue is even more pronounced for SNSPDs due to the lack of a precise theoretical model taking into account all physical processes \(31\). A semi-empirical model was proposed and tested with the accuracy \(10^{-2}\) \(37, 38\). Detector tomography based on probing with precisely calibrated signals was suggested to thoroughly characterize a detector and obtain the corresponding positive-operator-valued measure \(38, 46\). However, if the tomography does not include memory effects, the results can be compromised \(47\). The approach presented in the rest of the paper does not rely on a theoretical model or detector tomography. Instead, we focus on a direct measurement of the detector nonlinearity as a function of the detection rate.

B. Nonlinearity characterization

The nonlinearity of various photodetectors, mainly photodiodes, have been explored in great depth using relative and absolute measurement methods \(48\). Relative methods require a calibrated reference detector, calibrated attenuators, or time-resolved probe signals and detection. Absolute measurements, which are generally preferred, are based on a superposition method where the response of the detector to each optical signal is evaluated separately and then compared to the overall response to the superposition of the signals \(27, 49, 54\). The individual signals have to be incoherent to prevent optical interference. Often two independent optical sources are used for this reason \(54\), preferably exhibiting short co-
A stabilized super-luminescence diode is used as the source, first the detection rate of three measurements is performed, see Fig. 2(A). For a constant intensity level of the optical source, a sensitivity response to an incoherent superposition of the beams. Evaluation independently and then compared to the over-rates would need to be measured. However, without prior calibration, the 50:50 splitting is the only one that can be set with certainty, as \( R_A^\text{det} = R_B^\text{det} \).

The experimental setup is shown in the Fig. 2(B). A stabilized super-luminescence diode is used as the source, with the central wavelength 810 nm and the spectral width exceeding 20 nm. The signal is attenuated by neutral density filters and a polarization attenuator. A moving metal edge is used to scan the input power over the full dynamic range. The attenuated beam is split and joined using polarization beam splitters (PBS) to avoid phase interference. Furthermore, the 35-mm path difference is several orders of magnitude larger than the coherence length of the source. Mechanical shutters are used to block the individual paths to perform the measurement cycle. The output of the Mach-Zehnder is coupled into a single-mode optical fiber connected to the active area of the single-photon detector under test. The single-mode fiber coupling guarantees the same spatial profile of the signals at the detector. The coupling can, however, decrease the overall stability. An extra effort was made to ensure the long-term stability of the setup and, particularly, the fiber coupling stages (the stability is addressed in Appendix B).

In the case of SNSPD measurements, the source spectrum was reduced to 12 nm by an interference filter with a central wavelength of 800 nm, for which the detector is optimized. The reduced spectral width corresponds to a coherence length shorter than 30 \( \mu \)m. The coupling fiber is equipped with a polarizer and a polarization controller to set the optimal polarization for maximization of the SNSPD efficiency. In this case, the incoherence relies solely on the Mach-Zehnder path difference.

To verify the stability of the source, we performed a long-term measurement of its optical power. The corresponding relative Allan deviation is less than \( 10^{-4} \) for integration times up to hundreds of seconds. The acquisition time of each individual rate measurement was set to 20 s. Three measurements from which the nonlinearity was computed lasted 60 s. The complete characterization of a single detector typically took 20 hours, which includes the nonlinearity measurement repeated 30 times for 40 different rate levels. Randomness in the photon detection process limits the nonlinearity measurement precision (see Appendix C).

We measured three actively quenched SPADs (DET1–3), a passively quenched SPAD (DET4), and an SNSPD (DET5) for various values of bias current. The output of the detector under test is processed by a custom FPGA-based counter with a 2.2 ns pulse-pair resolution that is well below the dead time of any detector. For technical information, see Appendix A.

III. RESULTS AND DISCUSSION

A. Single-photon avalanche diodes

Figure 3 shows the measured nonlinearity as a function of the detection rate \( R_{\text{det}}^A \) for various SPADs. The typical log-log plot of the SPAD nonlinearity \( \Delta \) is V-shaped due to dark counts (left slope) and dead-time saturation (right slope). The nonlinearity reaches its minimum
expected nonlinearity as a function of detection rate is
paralyzable dead time $\tau$
into account the dark count rate $R$
takes effect, the probability of obtaining the measured
data or any worse data would be equal to the $p$-value.
This means that the model (2) already deviates from the
measurement with high statistical significance for 20 s
integration times. We have also tested more elaborate
response models such as Ref. [36] (including dead time,
afterpulses, and twilight pulses), and a combination of
paralyzable and non-paralyzable dead time [56–61] de-
veloped originally for Geiger–Müller detectors. None of
these can reproduce the measured results, which is shown
in Appendix E.

Because not all systematic errors can be visible in
Fig. 3, we evaluated the $\chi^2$ with the highest $p$-value being $p_{DET2} \sim 10^{-70}$. It means that under the assumption
that the model (2) is valid and only the statistical error
takes effect, the probability of obtaining the measured
data or any worse data would be equal to the $p$-value.
This means that the model (2) already deviates from the
measurement with high statistical significance for 20 s
integration times. We have also tested more elaborate
response models such as Ref. [36] (including dead time,
afterpulses, and twilight pulses), and a combination of
paralyzable and non-paralyzable dead time [56–61] de-
veloped originally for Geiger–Müller detectors. None of
these can reproduce the measured results, which is shown
in Appendix E.

Current evidence shows that SPADs exhibit neither
constant dark counts [62], nor constant recovery time
dead time + reset time) [36]. This means that state-
of-the-art models are insufficient, leaving the experi-
mentalist with two options: 1. a detailed characterization
of the SPAD involving time-resolved measurements and
circuit analysis. 2. direct nonlinearity measurement.

B. Superconducting nanowire single-photon
detectors

Figure 4 shows the nonlinearity of the SNSPD (DET5)
with respect to the bias current. The temperature of the
detector was kept at 2.7 K. Subfig. 4(A) shows the de-
pendence of dead time and dark counts on the bias. The
property affected the most is detection efficiency, shown
in subfig. 4(B). The detection efficiencies were calculated
relatively to the manufacturer’s specification of $86 \pm 3\%$
for 25 $\mu$A. The dashed line represents the detector effi-
ciency provided by the manufacturer. Subfig. (4(C) shows the
measured nonlinearity $\Delta$ as a function of the total de-
tected rate $R_{\text{det}}$. Each data set corresponds to a different
detected current, where the plot markers match the respective
points in subfig. 4(B).

The established model of the detection rate $R_{\text{det}}$ takes
into account the dark count rate $R_0$ and the non-
paralyzable dead time $\tau$ [36, 54], reading

$$R_{\text{det}} = f(R) = \frac{R + R_0}{1 + (R + R_0)\tau},$$  \tag{2}

where $R$ is the incident rate. The nonlinearity is mea-
sured in a balanced configuration, so that the incident
rates are $R_\text{A} = R_\text{B} = R_{\text{AB}}/2$. If we substitute the
detector model $R_{\text{det}} = f(R)$ given in Eq. (2), we obtain
the detection rates $R_{\text{det}}^\text{A} = R_{\text{det}}^\text{B} = f(f^{-1}(R_{\text{det}}^\text{AB})/2)$. The expected nonlinearity as a function of detection rate is

$$\Delta \left( R_{\text{det}}^\text{AB} \right) = 2f \left( \frac{1}{2} f^{-1} \left( R_{\text{det}}^\text{AB} \right) \right) - 1.$$  \tag{3}

The parameters of this model are the dark count rate $R_0$ and dead time $\tau$. More precise models of actively
quenched SPADs include afterpulses and twilight pulses [36], and are discussed in Appendix E.

The data were fit with Eq. (3) in Fig. 3, and they
are in significant disagreement with the model, affirming
the need for direct nonlinearity measurement. The most
prominent feature is the supralinear behavior ($\Delta < 0$) in
Fig. 3(C), which is a hitherto unreported phenomenon
for SPADs. Additionally, the fit parameters $R_0, \tau$ do not
agree with values that were obtained from independent
time-resolved measurements.

A comparison of dead times and directly observed re-
covery times is given in Table 1. For actively quenched
detectors (DET1–DET3), the measured recovery time $\tau_R$
also includes a brief detector reset time, and so must al-
ways be $\tau_R \geq \tau$ [36]. Reset effects like twilight pulsing
could therefore explain the difference for DET2, but not
for the other detectors DET1 and DET3 [36]. DET4 is
passively quenched and so the recovery and dead time
values differ significantly. Such detectors exhibit gradual
efficiency recovery after each detection, which would re-
quire a complex empirical model. As shown in Appendix E,
no other few-parameter models offer a better fit than
(2).

![Fig. 3. Nonlinear response of the tested detectors (A) DET1, (B) DET2, (C) DET3, and (D) DET4. Red solid line represents the theoretical SPAD model. Each point was measured 30 times and the error bars show the corresponding standard error of the mean.

TABLE I. Comparison of recovery times $\tau_R$ that were measured directly using time-resolved detection techniques [36], and the dead time values $\tau_{\text{fit}}$ that were the best fit of the model (2).

The nonlinearity is measured as $10^{-3} \sim 10^{-2}$ for detection rates between $10^4$ and $10^6$ Hz.

This means that the model (2) already deviates from the
measurement with high statistical significance for 20 s
integration times. We have also tested more elaborate
response models such as Ref. [36] (including dead time,
afterpulses, and twilight pulses), and a combination of
paralyzable and non-paralyzable dead time [56–61] de-
veloped originally for Geiger–Müller detectors. None of
these can reproduce the measured results, which is shown
in Appendix E.

Current evidence shows that SPADs exhibit neither
constant dark counts [62], nor constant recovery time
dead time + reset time [36]. This means that state-
of-the-art models are insufficient, leaving the experi-
mentalist with two options: 1. a detailed characterization
of the SPAD involving time-resolved measurements and
circuit analysis. 2. direct nonlinearity measurement.
The nonlinearity of the SNSPD is a combination of several phenomena. For lower rates, the effect of dark counts is easily recognizable. Around 10^4 Hz, all sub-critical regimes \( I_{\text{bias}} \leq 25 \mu\text{A} \) begin to exhibit supralinearity \( \Delta < 0 \). For higher count rates, two scenarios are observed. Bias currents corresponding to the efficiency plateau \( 20–25 \mu\text{A} \) lead to dead time saturation, while lower biases maintain the supralinearity. Finally, for \( R_{\text{det}} > 10^6 \text{ Hz} \), latching rapidly increases for all but the lowest biases. This introduces strong saturation and eventually results in an inverse detection response, where count rate decreases with increasing illumination.

Let us address the supralinear behavior, linked previously to two effects. With decreasing bias current, two-photon and higher-order detection efficiencies rise as indicated by detector tomography. So far, the two-photon absorption of SNSPDs was observed for ultrashort optical pulses in picosecond regime with mean photon numbers \( \geq 0.1 \). Under continuous illumination, the multi-photon absorption becomes challenging to model due to hotspot relaxation dynamics. The second factor is the AC coupling of the readout circuit – the settling of the bias current after each detection results in rate-dependent efficiency. The supralinear behavior due to the AC coupling was observed only for very high rates \( \geq 10 \text{ MHz} \). Our results represent the first observation of the SNSPDs supralinearity under continuous illumination with the detection rates as low as 10^3 Hz.

### IV. CONCLUSION

In summary, we designed and realized a direct absolute measurement of single-photon detection nonlinearity with exceptional accuracy over several orders of magnitude of light intensity. We performed the measurement for SPAD and SNSPD detectors. Their nonlinearity reflects complex detection processes including dynamic post-detection irregularities. The measurement technique does not require a calibrated reference detector or time-resolved detection.

For all SPADs, we found significant disagreement of established theoretical models with the measured data. We also discovered anomalous supralinear behavior of a SPAD. This phenomenon has been neither predicted nor observed yet. For the SNSPD, we performed its detailed nonlinearity analysis over 7 orders of magnitude of incident illumination and the full range of relevant values of bias current, which goes beyond any SNSPD characterization reported so far. We detected SNSPD supralinearity under continuous illumination at unprecedentedly low detection rates down to 10^3 Hz, which has not been observed before. The results for both SPADs and SNSPDs show that nonlinearity in single-photon detection is a complex mixture of non-trivial phenomena, which eludes accurate theoretical description.

Our findings can be applied to radiometric, spectroscopic, imaging, and optical communication methods that rely on precise assessment of illumination or transmission levels. Since correcting for various nonlinear aspects of single-photon detectors based on state-of-the-art response models is generally not sufficient, direct measurement of nonlinearity becomes a necessity. Accurate detector calibration is particularly critical for measuring photon statistics and reaching the quantum advantage in quantum metrology. The presented results open the way for ultra-precise identification and mitigation of nonlinear effects in single-photon detectors.

### Funding

The Czech Science Foundation project 21-18545S; MEYS and European Union’s Horizon 2020 (2014–2020) research and innovation framework programme (project HYPER-U-P-S, No. 8C18002); Project HYPER-U-P-S has received funding from the QuantERA ERANET Co-
fund in Quantum Technologies implemented within the European Union’s Horizon 2020 Programme; Palacký University projects IGA-PrF-2020-009, IGA-PrF-2021-006.

Disclosures

The custom-made counter used in the presented measurements is commercially available and sold by the Palacký University. M.J. is one of the developers and thus eligible for a percentage of the income. However, the presented measurements are not affected by the choice of the counter, as the necessary parameters can be met by other devices available on the market. All other authors declare they have no competing interests.

Data availability statement

Data underlying the results presented in this paper are available in Ref. [63].

Appendix A: Experimental setup

Figure 5 depicts the experimental setup for absolute measurement of nonlinearity using the single-source two-beam superposition method. The light source is a temperature-stabilized super-luminescence diode (QPhotonics QSDM-810-2) in constant current mode with the central wavelength of 810 nm and the spectral width exceeding 20 nm. Angled physical contacts (APC) between optical fibers reduce back-reflections approximately by 60 dB and improve the stability of the source. Attenuation by several orders of magnitude is needed to generate an optical signal in the dynamic range of the tested detector. For this purpose, the optical beam is strongly attenuated by a series of neutral density (ND) filters (Thorlabs). For this purpose, the optical beam is strongly attenuated by several orders of magnitude is needed to generate an optical signal with extinction ratio $P_T : P_S > 1000 : 1$. The Mach-Zehnder setup is used to split the attenuated beam into two spatially separated beams that can be individually blocked and superimposed again at the output. The combination of perpendicular polarizations and the path difference $L = 35.4 \text{ mm}$ between the individual arms ensure incoherent mixing at the second polarization beam splitter. Mechanical blocking of the two optical signals is done by compact home-made optical shutters using a digital RC servo (Savox SH-0262MG). Thin (0.5 mm) metal flag with dimensions $15 \times 70 \text{ mm}$ attached to the servo shaft blocks the collimated Gaussian beam that has a radius $w_0 = 1.03 \text{ mm}$. To perform the operation of opening or blocking the beam, it is necessary to turn the servo by $15^\circ$ with a total latency of 50 ms. The RC servo is controlled by a pulse-width modulation signal generated by Arduino Uno with a microprocessor AT-mega328. For more information about the employed shutters, see [64]. After the second PBS, the output light is fed into a single-mode fiber and coupled to the tested detector. Stray light is eliminated by a cut-off filter (Semrock BLP01-635R-25).

We investigated the response of five single-photon detectors, i.e. actively (DET1-3) and passively quenched (DET4) thick-junction silicon single-photon avalanche diodes (SPADs), and a NbTiN superconducting nanowire single-photon detector (DET5) with AC readout and room-temperature amplifier. Namely, DET1 – Excelitas SPCMAQRH CD3432H, DET2 – Perkin Elmer SPCM-AQ4C module s.n. 167, DET3 – Laser Components COUNT-20C-FC D4967, DET4 – ID Quantique ID120 s.n. 1518006, and DET5 – Single Quantum Eos CS SNSPD system s.n. SQ071. Investigated detectors differ in many technical parameters and physical effects such as active area, photon detection efficiency, dark count rate, dead time, and afterpulsing probability. The manufacturer’s specifications are shown in Table I. Detector DET4 (ID Quantique ID120) differs from other used SPADs DET1-3 not only by the passive quenching mechanism, but also being a free-space module with tunable temperature and bias voltage. All measurements were done at the temperature $T = -40^\circ \text{C}$ and bias voltage $V = 180 \text{ V}$.

The SNSPD (DET5) possesses a limited spectral region of the maximum efficiency. For this reason, the wide emission of SLED was reduced using a 12 nm band pass interference filter (Semrock FF01-800/12-25). Furthermore, the SNSPD is naturally sensitive to polarization due to its nanowire structure. The optical beams of the unbalanced Mach-Zehnder interferometer have orthogonally oriented linear polarizer (LP) at the output to make them indistinguishable for the detector. A fiber polarization controller (FPC) is used to optimize the detection efficiency with respect to polarization.

Electric output signals from the tested detectors were processed by an electronic counter. The most critical parameter of its pulse-pair resolution, which has to be better than the recovery time of all tested detectors. Initially, we were using a commercial 100 MHz counter (ORTEC 974C), which was used to measure detectors DET1-4. Later, we developed an FPGA-based 230 MHz counter with a 2.2 ns pulse-pair resolution and digitally tunable threshold voltages (QOLO Countex [65]). This counter was used to perform the measurements of DET5, as well as additional measurements on DET1 and DET3. Detectors DET1 and DET3 were measured using both counters with the same results. The entire nonlinearity measure-

Appendix B: Stability of the source and measurement setup

Intensity fluctuations of the light source affect the measurement accuracy. We investigated the stability of the SLED and also the intensity stability at the output of the setup. We performed a long-term measurement of optical intensity and evaluated the Allan deviation [60] to determine integration time T for which the measurement is least affected by intensity fluctuations. Figure 6 shows the relative Allan deviation σ\text{Allan} as a function of the integration time T. The deviation is better than 10⁻⁵ for integration times from 10 s to 10³ s. For the nonlinearity measurement setup, optimal integration times are shifted toward shorter times and the minimum relative Allan deviation gets worse, but still below 10⁻⁴ for integration times up to 6 × 10³ s. The raw data and their processing are available on GitHub [63].

Appendix C: Measurement uncertainty

1. Shot noise limitation

We performed an analysis of nonlinearity measurement uncertainty σ(Δ) to find its ultimate physical limits and find out whether the data approach the fundamental nonlinearity resolution. The statistical uncertainty was calculated for the case of a balanced experimental setup R_A^{\text{det}} = R_B^{\text{det}}; measurement time T = 20 s for each rate, and N = 30 repeated measurements.

The fundamental limit is represented by the shot noise of the Poisson counting process, where the measured number of events (R_{\text{det}}T) exhibits variance equal to the mean value. This implies the standard deviation of the detection rate σ(R_{\text{det}}) = \sqrt{R_{\text{det}}T}. If we introduce this standard deviation to each detection rate in the nonlinearity formula

\[ \Delta = \frac{R_A^{\text{det}} + R_B^{\text{det}} - 1}{R_A^{\text{det}}R_B^{\text{det}}} \]

through standard error propagation σ\text{2}(Δ) = \[ \sum_{i} \left[ \sigma(R_{\text{det}}^i) \times \partial \Delta / \partial R_{\text{det}}^i \right]^2 \], we obtain the standard deviation

\[ \sigma(\Delta) = \sqrt{\frac{(1 + \Delta)(2 + \Delta)}{R_A^{\text{det}}R_B^{\text{det}}T}} \approx \sqrt{\frac{2}{R_A^{\text{det}}T}} \]

The measured nonlinearity Δ is averaged from N measurements, so the standard deviation of the result is

\[ \sigma(\Delta) = \sigma(\Delta) / \sqrt{N} \]

This limit is compared to the experimental values in Fig. 7. The measured standard errors of the nonlinearity for SPADs meet their lower bound 10⁻⁴ for rates higher than 2 × 10⁵ (Fig. 7(a-d)). For higher rates, excess noise
FIG. 6. Optical intensity fluctuations represented by the relative Allan deviation. Shown are: (a) temperature-stabilized super-luminescence diode (QPhotonics QSDM-810-2) in constant current mode, and (b) signal from the same source transmitted through the experimental setup for nonlinearity measurement.

FIG. 7. The nonlinearity measurement standard error $\sigma(\Delta)$ of tested detectors (a) DET1, (b) DET2, (c) DET3, (d) DET4, and (e-f) DET5 as a function of detection rate $R_{\text{det}}$. Subplots (e-f) show $\sigma(\Delta)$ of an SNSPD DET5 with respect to the bias current. The measured standard errors are plotted as black dots, and the lower bound on the standard deviation is represented as a grey dashed line.
limits the measurement uncertainty; it nevertheless remains below $\sigma(\Delta) < 10^{-3}$. In this region, the mean nonlinearity value is larger than the uncertainty by at least one order of magnitude. Subfigures (e-l) show the nonlinearity measurement uncertainty of the SNSPD for several different values of bias current. Latching rapidly increases for bias current $I_{\text{bias}}$ higher than 25 $\mu$A and brings extra uncertainty to the measurement (Fig.3(k-l)).

The shot noise limit is well applicable to Poisson count rates. However, dead-time saturation will further affect the measurement, because the measured count rates become sub-Poissonian as they approach the limit $R_{\text{det}} \rightarrow 1/\tau$. Because the standard deviation of accumulated counts is complicated to calculate analytically [30], we are going to assume a sufficiently long integration time so that the number of accumulated counts is large: $n = R_{\text{det}} T \gg 1$. This is a reasonable assumption for high rates, where saturation occurs. Then, we can make the following derivation.

Upon measuring $n$ detections during a time $T$, we obtain the average time between detections, $\bar{\Delta}t = T/n$. Because each realization of $\Delta t$ is independent, the average time $\bar{\Delta}t$ is normally distributed with a standard deviation $\sigma(\Delta t) = \sigma(\Delta t)/\sqrt{n}$ according to the central limit theorem. We assume $\Delta t$ to be a dead time $\tau$ plus an exponentially distributed delay with a rate parameter $\lambda$, which makes $\langle \Delta t \rangle = \tau + 1/\lambda$ and $\sigma(\Delta t) = 1/\lambda$. Because $n \gg 1$, the standard deviation is small relative to the mean; $\sigma(\Delta t) \ll \langle \Delta t \rangle$. As a result, the mean rate $R_{\text{det}} = 1/\bar{\Delta}t$ is also normally distributed and the standard deviation is scaled based on the slope around the mean value,

$$\sigma(R_{\text{det}}) = \left| \frac{\partial R_{\text{det}}}{\partial \bar{\Delta}t} \right|_{\bar{\Delta}t = \langle \Delta t \rangle} \sigma(\Delta t) = (R_{\text{det}})^2 \sigma(\Delta t). \quad (C4)$$

Due to the large number of detections, on the right side

we can simplify $\bar{\Delta}t \approx \langle \Delta t \rangle \approx 1/R_{\text{det}}$, so

$$\sigma(R_{\text{det}}) = (1 - \tau R_{\text{det}}) \sqrt{R_{\text{det}}/T}. \quad (C5)$$

The resulting sub-Poissonian bounds are shown in Fig. 8 for two dead time values to illustrate the cases of an actively and passively quenched detectors. The bounds do not make a difference within the data range of Fig. 7.

2. Optimal measurement times

Here we address the optimal allocation of measurement time between various detection rates. Given the overall measurement time $T_O$ per one sample of $\Delta$, there exists an optimal distribution between measuring $R_{\text{det}}^A$, $R_{\text{det}}^B$, and $R_{\text{det}}^{AB}$. Assuming a balanced splitting $R_{\text{det}}^A \approx R_{\text{det}}^B$, the minimum uncertainty of $\Delta$ is reached for

$$T_{AB} = \frac{T_O}{1 + \sqrt{2}/(1 + \Delta)}, \quad (C6)$$

$$T_A = T_B = \frac{1}{2} (T_O - T_{AB}). \quad (C7)$$

In the regime where $|\Delta| \ll 1$, the approximate ratios are $T_A : T_B : T_{AB} = 0.3 : 0.3 : 0.4$. The assumption we made on the way is that the measurement time is long enough so that all the accumulated counts $C_i$ ($i = A, B, AB$) are approximately normally distributed. This holds if $\langle C_i \rangle = R_i T_i \gg 1$. 

FIG. 8. The effect of dead-time saturation on the fundamental limit of uncertainty resolution. The integration time is $T = 20$ s and the number of measurements $N = 30$.

FIG. 9. The repeatability of the nonlinearity measurement of the detector DET3 throughout the years. The nonlinearity $\Delta$ is a function of the detection rate $R_{\text{det}}^{AB}$, shown at different dates: black – February 2021, green – January 2016, and blue – November 2014.
FIG. 10. Nonlinearity $\Delta$ as a function of the detection rate $R_{AB}^{\text{det}}$ for (a) several different values of dark counts: $R_0 = 10, 100, 1000$ Hz ($\tau = \text{const.}$) and (b) dead time: $\tau = 5, 25, 50$ ns ($R_0 = \text{const.}$).

**Appendix D: Repeatability of the measurement**

In 2014 we built the experimental setup for absolute measurement of nonlinearity to characterize the detector response and since then, we have performed nonlinearity measurements repeatedly. As an example representing the consistency of the results obtained from the presented method, we chose the actively quenched SPAD from Laser Components (DET3). This detector exhibits anomalous supralinear behavior ($\Delta < 0$) for all measurements. Figure 9 shows individual nonlinearity measurements separated by years during which the detector was used in many other experimental setups. The first measurement of nonlinearity was performed in November 2014 using the Ortec counter (Fig. 9 – blue). In January 2016, we repeated the measurement—again using the Ortec counter—in order to confirm the supralinear response of the tested detector (Fig. 9 – green). This was the most accurate measurement, with acquisition time 120 s for each individual rate measurement, repeated 20 times. The last measurement was performed in February 2021 using the Countex counter (Fig 9 – black). Throughout the years, we have obtained consistent results.

**Appendix E: Theoretical models of the SPAD response function**

There have been many SPAD response models proposed that model saturation effects and noise [32, 33, 55, 62, 67]. The model used to fit the presented results considers a non-paralyzable dead time $\tau_{NP}$, dark count rate $R_0$, and neglects afterpulsing. The rate of detection events as a function of the incident rate $R$ then follows a standard formula

$$f_{NP}(R) = \frac{R + R_0}{1 + (R + R_0) \tau_{NP}}.$$ (E1)

In Fig. 10 we demonstrate the effects of dead time and dark counts, when this model is applied to the nonlinearity (C1). The left slope represents the background noise characterized by dark counts and the right slope represents dead time saturation. Other theoretical models given below yield similarly V-shaped nonlinearity $\Delta$ with analogous scaling. Because the basic model (E1) does not provide a satisfactory fit of the measured data, we should justify its use as opposed to other dead-time models, and quantify the effect afterpulsing has on nonlinearity.

1. **Dead time models**

The effect of dead time in Geiger-mode SPADs is akin to Geiger-Müller (GM) counters [56–60, 67–71]. Two basic types of idealized models for dead time have been defined [57, 58, 68]. Namely, it is the paralyzable dead time $\tau_P$ model

$$f_P(R) = (R + R_0) \exp(- (R + R_0) \tau_P),$$ (E2)

and the non-paralyzable dead time $\tau_{NP}$ model (E1). For the non-paralyzable case, each registered dead time $\tau_{NP}$ is followed by dead time, during which no further events are registered. In the paralyzable case, dead time follows every detection, even those that occur within a prior dead time and are not otherwise recorded. This case covers the fact that secondary detections in GM tubes still require quenching, but are not registered due to low voltage output.

In the case of GM counters, single-parameter dead-time models are just an approximation. Hybrid models were proposed by combining paralyzable and non-paralyzable dead times [61]. There are two variants; the NP-P model

$$f_{NP-P}(R) = \frac{(R + R_0) \exp(- (R + R_0) \tau_P)}{1 + (R + R_0) \tau_{NP}},$$ (E3)
FIG. 11. Nonlinearity data fits using two models: the $\tau_{NP}$ model (red), and the $\tau_P$ model (blue). Note the right-side turning point of the paralyzable model (blue), which is a consequence of non-monotonous response to illumination.

TABLE IV. Evaluated $\chi^2/\nu$ values of the fitted theoretical response models for tested detectors DET1–4.
and the P-NP model [59, 72]

\[ f_{P,NP}(R) = \frac{(R + R_0) e^{-(R+R_0)\tau_p}}{1 + (R + R_0) \tau_{NP} e^{-(R+R_0)\tau_p}}, \] (E4)

We have tested whether these theoretical models can be used empirically to fit the measured nonlinearity data. We found that all hybrid-model fits converge to either the paralyzable or non-paralyzable case. Fig. 11 shows both of these response models applied to the measured nonlinearity of all detectors. A complete list of the measured parameters and best-fit parameters is given in Table III. As in the main text, we evaluated \( \chi^2 \) to demonstrate that investigated models significantly deviate from the measured nonlinearity. In Table IV, we show the chi-squared per one degree of freedom, \( \chi^2/\nu \), where \( \nu \) is the number of data points minus the number of fitting parameters.

2. Afterpulsing

Actively quenched SPADs exhibit afterpulsing and twilight pulsing that affect the mean detection rate [36]. Both effects can be evaluated numerically [73], or if we neglect the temporal distribution of afterpulses – an approximate rate formula can be used [36].

\[ f_{AP}(R) = \left[ \frac{1}{R + R_0} - \alpha \right] e^{-(n_{AP})} + \tau_{NP} \] (E5)

The new parameters are the mean number of afterpulses per detection \( \langle n_{AP} \rangle \), and the twilight-pulse proportionality constant \( \alpha \). As one would expect, when both of these parameters are zero, the formula (E5) is reduced to the basic non-paralyzable model (E1).

The key observation here is parameter degeneracy. In the formula (E5), the effect of afterpulsing can be substituted by adjusting the dead time and dark count variables. If we put the model parameters in square brackets, the equivalence can be expressed as

\[ f_{AP} \left[ R_0, \tau_{NP}, \langle n_{AP} \rangle, \alpha \right] \equiv f_{NP} \left( R/e^{-(n_{AP})} \right) \left[ R_0/e^{-(n_{AP})}, \tau - \alpha e^{-(n_{AP})} \right]. \] (E6)

Let us now substitute both rate models into nonlinearity (E1), assuming balanced splitting \( R_{det}^{A} = R_{det}^{B} \) and the parameter equivalence (E6).

\[ \Delta = \frac{2R_{det}^{A}}{R_{det}^{AB}} - 1 = \frac{2f_{AP}^{-1}(R_{det}^{A})}{f_{NP}^{-1}(R_{det}^{A})} - 1. \] (E7)

One finds that \( \Delta_{AP} \equiv \Delta_{NP} \), which follows from the equivalence (E6), and the scaling of \( R \) by a linear factor there. The principle is that both \( f_{AP}^{-1} \) and \( f_{NP}^{-1} \) yield incident rates that differ by the same linear factor, and their ratio does not change upon the multiplication by 1/2. A subsequent application of \( f \) therefore gives identical rates for both models. As a result, all fitted models are identical and yield the same \( \chi^2 \) either with or without afterpulsing.

A further consideration would be a more complex afterpulsing model that considers the temporal distribution of afterpulses [36]. This model is numerical and so cannot be used for least-squares fitting. However, the difference between this full model \( \Delta_{full} \) and the simple model (E5) can be evaluated for an example case. In Fig. 12, the difference is shown for DET1 based on the afterpulsing data measured in Ref. [36]. The plot is shown in log-scale, so a difference of one corresponds to one order of magnitude in Fig. 11. Note that we have already established the equivalency of (E1) and (E5), so we can conclude that the full model introduces a very small correction to the basic model we used to fit the data.

3. Discussion of the models

An example case of an actively quenched SPAD, represented by DET1, shows that an afterpulsing correction to our nonlinearity model would yield a relative difference of \( \approx 1 : 1000 \) in \( \Delta \). A slightly simplified afterpulsing correction that can be used for data fitting yields no difference from the basic model. For this reason, we can conclude that afterpulses do not play a role in fitting the nonlinearity data of actively quenched SPADs.

The other detectors exhibit a much more complex behavior. Passively quenched SPADs exhibit paralyzable dead time, but also a rising efficiency curve after each detection [74], which makes the model too complex to be parameterized by a few measurable quantities.

SNSPDs show no afterpulsing, but, to our knowledge, their (non-)paralyzability has not been confirmed. Additionally, both SNSPDs and passively quenched SPADs exhibit changing efficiency after each detection, an effect that is both non-negligible and complex. In the case of
SNSPDs, the single-photon and two-photon efficiencies also depend on the bias current. For these reasons, no standard rate model has been formulated that would be sufficiently accurate.

Upon exploration of certain empirical models combining non-paralyzable and paralyzable dead time, we found that none of them offer a significant advantage over the basic non-paralyzable model. DET1-3 are non-paralyzable. DET2 and DET3 are better fitted with the paralyzable model, but the difference is very small, as can be seen from Fig. 11. DET4 is significantly better fitted by the non-paralyzable model. Consequently, we use a single model (E1) for all SPADs in the manuscript.
