Abstract

Time-of-flight measurement is an important method to study distributed mode coupling and differential group delay in multimode fibers (MMFs). However, current approaches using regular photodetectors prevents us from studying very weak signals/interactions in fiber due to a limited sensitivity. Here we demonstrate the use of a high-sensitivity superconductive nanowire single-photon detector (SNSPD) to measure the intensity transfer matrix of a commercial 45-mode graded-index multimode fiber. We also observed cladding modes of the MMF as a pedestal of the pulse in the measurement. This work paves way for applications like quantum communication using spatial modes of fiber in the future.

1. Introduction

The capability of detecting light at the single-photon level has enabled breakthroughs in many fields, such as reconfigurable photonics \cite{1}, light detection and ranging (LiDAR) \cite{2}, and optical quantum information applications \cite{3}, including quantum computing \cite{4} and quantum key distribution \cite{5} in communication.

Mode-division multiplexing (MDM) in MMF as a potential candidate for the next generation high-capacity optical transmission system, has attracted great research interests in the last decade \cite{6, 7}. Spatial modes in a real fiber tend to couple with each other due to perturbations from environment or imperfect geometry. Optical pulses propagating in MMF also suffer from modal dispersion, that each mode travels at a different group velocity. The arrival time difference of two modes in a fiber is defined as differential group delay (DGD). DGD has been well studied in the optical fiber communication community in the last decade as it directly determines the number of equalizers taps necessary to compensate the mode coupling \cite{8}. Measuring the intensity impulse response is an important method to study DGD and mode coupling.

Current method that measures the impulse response of MMF, including the time-of-flight techniques \cite{9, 10}, swept-wavelength interferometry (SWI) \cite{11}, optical time-domain reflectometry (OTDR) \cite{12}, or using digital signal processing (DSP) \cite{13}, fails to measure long fiber spans or very weak inter-modal interactions due to the limited sensitivity of regular photodetectors. Recently, using ultrasensitive single-photon detectors to study fiber modes has attracted a lot of attention. In 2019, Johnson et al. demonstrated using a single-pixel camera (SPAD detector) and a digital micro-mirror device (DMD) to measure the temporal evolution of orbital angular momentum (OAM) modes at telecommunication wavelengths \cite{14}. In 2020, Chandrasekharan et al. measured the group velocity dispersion, differential mode group delay, and the effective refractive index difference of different spatial modes in a 6-mode fiber using a two-dimensional (2D) single-photon avalanche diode (SPAD) array, over a broad bandwidth (500 nm ~ 610 nm) in the visible regime \cite{15}. However, no 2D SPAD array has been created at telecommunications wavelength because of the high cost in fabricating pixelated arrays. What’s more, it’s well known SPADs have a low performance compared to the superconductive nanowire single-photon detector (SNSPD). At 1550nm, the commercially available SPADs have a timing jitter of ~100 ps, a quantum efficiency of ~20-30 %, and dark count rates of ~kHz. In contrast, the commercial SNSPD (Single Quantum Eos) in our group has a timing jitter of ~10 ps, a system quantum efficiency of ~85%, and dark count rates of ~10Hz. What’s more, SNSPDs with sub-3 ps temporal resolution has been demonstrated \cite{16}. In 2021, Mazur et al. did a proof-of-principle impulse response measurement of a few-mode fiber using the SNSPD and a 3-mode photonic lantern as the mode demultiplexer \cite{17}.
In this paper, we measure the impulse response of a dual-polarization 45×45 transfer matrix of a commercial OM3 multimode fiber. With the high sensitivity of a SNSPD, we build the histogram of the impulse response at a single-photon level, enabling us to study the very weak modal interactions. The very low dark count rate (~200) determines a noise floor of -136 dBm, giving us the capability to observe the cladding modes directly at the foot of the pulse. Using the high timing accuracy of ~10 ps, the differential mode group delay can be accurately measured. Two high performance 45-mode multiplexer/demultiplexer and optical switches are used to excite and receive one specific mode of the MMF at every single step.

This paper is structured into four sections. Section 2 describes the experimental setup and some critical components used in the measurement. Section 3 discusses the measurement results of two cases: the back-to-back (BTB) and with the MMF inserted. Finally, section 4 concludes the paper.

2. Experimental setup

The experimental setup is outlined in Fig. 1. A swept-signal generator (Agilent 83650B) provided a clock signal for the pulse pattern generator (PPG, Anritsu MP1763B), which was used to drive a directly modulated laser (DML). This DML is a distributed feedback (DFB) laser with a measured wavelength of 1545 nm on an optical spectrum analyzer (OSA). The swept-signal generator also provided an external clock signal for the quTAG (qutools company) for synchronization. The DML has a pulse repetition rate of 1 MHz, and each pulse has a measured full width at half maximum (FWHM) of 70 ps. We chose a repetition rate of 1 MHz as the detectors have peak efficiency (~85%) at this speed, and usually the detection efficiency drops as the repetition rate increases. The average output power of the DML was measured to be -36.0 dBm. To fully characterize the dual-polarization 45 × 45 transfer matrix, a manually controlled polarization switch, shown in Fig. 1(c), was used in front of the mode multiplexer, and a fiber-based polarization beam splitter (PBS) was used after the mode demultiplexer to realize a polarization-diverse measurement. The polarization switch, as shown in Fig. 1(c), consists of a polarization controller (PC), a 50:50 fiber coupler, a fiber-based PBS (Thorlabs, PBC1550SM-APC) and a power meter (HP 8153A). A pair of optical switches (DiCon MEMS 64-channel model) and MPLCs constitute the function of mode-diverse measurement (This part is highlighted with a green background color in Fig. 1(a)). Outputs from the second PBS are connected to two independent channels of the SNSPD. Since the meandering nanowires inside the SNSPD is polarization sensitive, two PCs are added between the second PBS and the SNSPD.
Any path mismatch induced relative time shift of pulses of different channels either due to different fiber lengths or RF cable lengths, were corrected during the post-processing of data.

In experiment to control the polarization with the polarization switch shown in Fig. 1(c), we first adjusted the PC manually until reading the maximum (-39.6 dBm) power on the power meter, to launch x polarization state into the system. Then we scan all 45 channels of switch 1 and switch 2 sequentially, with the received x and y polarization states recorded simultaneously in the condition of the x polarization launch. Then we adjusted the PC until reading the minimum power (about -70.0 dBm), to launch y polarization state and repeat the above mode-diverse measurement. In this way, we make sure x and y polarization launch states are orthogonal. Those two optical switches and the quTAG were controlled by one single computer to record data. For every element of the 45×45 matrix, 30 s of raw data was saved to accumulate enough data points to plot the histogram. Measuring a complete dual-polarization transfer matrix needs roughly 34 hours. We measured the 45×45 transfer matrix in a back-to-back (BTB) experiment first (splice the pig-tail fibers of two MPLCs directly). After taking data of the entire transfer matrix of the BTB, we insert a spool of commercial MMF and repeat the measurement. The VOA helps to attenuate light to single-photon level. It has an attenuation of 33 dB for the BTB measurement and was adjusted to 30 dB after inserting the MMF. In this way, the SNSPD reads a similar photon count rate for BTB and MMF measurement.

In the BTB when both switches were switched to channel 1 (HG_{00} mode to HG_{00} mode coupling), the total power went into the SNSPD was estimated to be -95 dBm. Since such a low power cannot be measured directly with a normal photo detector, we set the VOA to 0 dB attenuation first, and measured the power before the second PBS was -62 dBm. The total insertion loss of these two switches and MPLCs was measured to be 18 dB. Other losses in the link are from the 50:50 fiber coupler, connectors, and some single mode fiber (SMF) connecting components between two labs.

The SNSPDs are cooled down by helium to 2.6 K inside a closed-cycle cryostat, providing a low temperature environment for the superconducting nanowires. The superconducting nanowires are biased with a direct current close to the critical current, above which the superconductivity of the nanowire breaks down. Part of the detector transits from a superconducting state to a resistive state upon absorption of a photon. This transition will give a fast electrical pulse that is amplified by the SNSPD driver. In our experiment, the bias current of each individual detector was optimized below the critical current, with a dark count rate of about 200 counts/s, corresponding to a sensitivity of -136 dBm. All lights in the lab are off when calibrating the dark count rate, and most of the setup including the MMF fiber spool and MPLCs are covered with aluminum foil to reduce the influence from surrounding light. Covering the setup is important to reach a low dark count rate because previous publications indicate background light may couple into the fiber through blackbody radiation [18].

This SNSPD has 4 independent channels, of which channel 3 and channel 4 are used in the experiment to register the received light with x and y polarizations separately. At 1550 nm, channel 3 and 4 has a system detection efficiency of 81% and 85%, respectively. The calibrated timing jitter of channels 3 and 4 are 19.0 ps and 13.2 ps in term of FWHM, respectively. The measured relaxation time (full recovery time after each detection event) is about 100 ns, limiting the maximum count rate to 10 MHz. The detection speed however, is much lower than the regular balanced photodetectors (BPDs) commonly used in coherent optical communications, which can have a bandwidth up to 100 GHz. The quTAG is a fast time-to-digital converter and time tagging device for time correlated single-photon counting (TCSPC). The quTAG has a measured single channel timing jitter of 5.94 ps in terms of RMS and 14.00 ps in terms of FWHM.

A spool of commercially available OM3 graded-index multimode fiber (GI-MMF, OFS LaserWave FLEX 300) was measured in the experiment. The fiber has a total length of 8851m, and it supports 9 mode groups at 1550 nm. The same fiber has been used in a mode-division multiplexed transmission experiment in 2014 by Roland Ryf et al. [19]. According to [19], this OM3 MMF has a measured loss of 0.34 dB/km for the LP01 and LP11 modes at 1550 nm, and the chromatic dispersion was approximately 20-24 ps/nm/km.
We use two multi-plane light converters (MPLCs) as the mode multiplexer/demultiplexer. This 45-mode MPLC is a free space device consisting of a collimated linear SMF array, a phase mask plane, a dielectric mirror, and a collimated GI-MMF at the output, as shown in Fig. 2(a). Input beam bounces back-and-forth in the mask-mirror cavity, and the device maps every input Gaussian spot from the SMF array into a specific Hermite-Gaussian (HG) mode through a unitary transformation [20, 21]. As a reciprocal device, this device can be used either as a mode multiplexer (input through SMF end) or a mode demultiplexer (input through GI-MMF end). The performance of the two MPLCs are qualitatively shown by imaging the free space output modes using an InGaAs camera, as shown in Fig. 2 (b) and (c). HG modes in Fig. 2(c) is not as clear as that in Fig. 2 (b), indicating the 2nd MPLC that used as the mode demultiplexer has a compromised performance compared to the first one. This was due to an imperfect packaging after assembling, leading to a large insertion loss (IL) and mode dependent loss (MDL).

3. Results and Discussion

30s of time-of-flight measurement data were saved per polarization per element of the 45×45 transfer matrix. The data were used to build a histogram covering 1 μs, i.e., the pulse period of the DML. A zoom-in time window around the pulse is plotted in the supplementary figure 1 for BTB and supplementary figure 2 for MMF.

Fig. 3 shows the histograms of the 4×4 matrix of the up-left corner of the entire 45×45 transfer matrix of the BTB measurement, with all polarizations presented in one plot. The 2nd and 3rd peak appearing at about 33ns and 46 ns, corresponding to a round trip fiber delay of 1.5 m and 2.7 m respectively, were due to reflections from the experimental setup [17]. Similar to Fig. 3, Fig. 4 shows the histograms of the 4×4 matrix on the up-left corner of the entire 45×45 transfer matrix with the OM3 MMF inserted. As discussed above, the 2nd and 3rd peak are due to reflections in the system and the distributed mode coupling should be observed around the 1st main peak (between 690 and 705 ns), where the crosstalk plateau between peaks is clearly sign of mode mixing.
Fig. 3 Histograms of photon arrival time of the BTB experiment. Photon count rates has been normalized by bin size. This figure shows the 4×4 matrix of the up-left corner of the entire 45×45 transfer matrix, with all polarizations presented in one plot. Readers interested in the complete 45×45 matrix can find it in the supplementary figure 1.

Fig. 4 Histograms of photon arrival time with the MMF inserted. Photon count rates has been normalized by bin size. This figure shows the 4×4 matrix of the up-left corner of the entire 45×45 transfer matrix, with all polarizations presented in one plot. Readers interested in the complete 45×45 matrix can find it in the supplementary figure 2.
With the MMF, the dynamic range is about 38-45 dB, limited by a pedestal at the foot of the pulse. As shown in Fig. 4 and supplementary figure 2, the value of the pedestal changes for different elements in the 45×45 matrix. The general trend is for diagonal elements, which has larger count rates, also possess a higher pedestal level. Some off-diagonal elements, e.g., Fig. 5 (b) the 2-39 coupling, the pedestal is too small that it cannot be distinguished from the noise floor determined by the dark count rate (~200 counts/s, -136 dBm). Histograms of the BTB data in Fig. 3 lacks the pedestal, indicating that the pedestal is not due to the limited extinction ratio of the DML, but from the spool of the MMF, which we believe is from the cladding mode of the MMF. The silica cladding of the fiber can support hundreds of cladding modes and bending or other environment perturbations may violate the total internal reflection condition and cause mode energy leave the core mode and couple to cladding modes [22]. The coupling back-and-forth between core modes and cladding modes during propagation and coupling among different coils of the fiber spool are responsible for the cladding mode.

![Image](image-url)

**Fig. 5** Some elements chosen from the entire 45×45 transfer matrix with the MMF inserted: (a) 4-2 coupling, (b) 2-39 coupling, (c) 19-32 coupling and (d) 42-39 coupling. For some elements, e.g. the 2-39 at the off-diagonal region of the 45×45 matrix, the pedestal is not obvious as other elements. The DGD values are easy to read out from the impulse response graph. In (a) the relative delay of the 2nd, 3rd, and 4th peak to the 1st are 1.7 ns, 3.3 ns, and 4.7 ns, respectively, close to the DGD numbers in a previous publication that used the same commercial OM3 fiber in a mode-multiplexed transmission experiment [19].

The complete 45×45 mode transfer matrix of BTB and MMF, averaged over polarizations, are shown in Fig. 6 (a) and (b), respectively. Fig. 6(b) is smoother than Fig. 6(a) due to the mode mixing in the 8.8km MMF. The group-summed 9×9 transfer matrix of the BTB and MMF in Fig. 6(c) and (d), also averaged over all polarizations, give the crosstalk among mode groups. Note that the mode mixing in Fig. 6(a) and (c) are partly due to the short pig-tail fiber at the output of each MPLC, and partly due to the imperfection of the packaged MPLC mode multiplexer/demultiplexer.
Fig. 6 The complete 45×45 mode transfer matrix, averaged over all polarizations, of (a) BTB and (b) MMF, shows the coupling among all modes. (b) is smoother than (a) due to the mode mixing in the 8.8km MMF. The group-summed transfer matrix of the (c) BTB and (d) MMF shows the crosstalk between mode groups. Mode mixing in (a) and (c) are partly due to the short pig-tail fiber at the output of each MPLC, and partly due to the imperfection of the 2nd MPLC, as shown in Fig. 2(c). Note that (a) and (b), (c) and (d) are plotted using different colormap ranges intentionally because BTB and MMF have slightly different photon count rates (input powers).

4. Conclusion
In conclusion, SNSPD offers unprecedented opportunity to study weak modal interactions in multimode optical fibers. Using SNSPD and two 45-mode MPLCs, we measure the transfer matrix of a commercial OM3 multimode fiber with the time-of-flight method. High sensitivity (~ -136 dBm) and high timing accuracy (~ 10 ps) give us unprecedented capability to measure very weak modal dynamics, including distributed mode coupling, differential group delay, and cladding modes of multimode fibers. This research is important for applications like quantum key distribution in multimode fibers.
