

APPROXIMATION OF MULTIPHASE MEAN CURVATURE FLOWS WITH ARBITRARY NONNEGATIVE MOBILITIES

ERIC BONNETIER, ELIE BRETIN, AND SIMON MASNOU

ABSTRACT. This paper is devoted to the robust approximation with a variational phase field approach of multiphase mean curvature flows with possibly highly contrasted mobilities. The case of harmonically additive mobilities has been addressed recently using a suitable metric to define the gradient flow of the phase field approximate energy. We generalize this approach to arbitrary non-negative mobilities using a decomposition as sums of harmonically additive mobilities. We establish the consistency of the resulting method by analyzing the sharp interface limit of the flow: a formal expansion of the phase field shows that the method is of second order. We propose a simple numerical scheme to approximate the solutions to our new model. Finally, we present some numerical experiments in dimensions 2 and 3 that illustrate the interest and effectiveness of our approach, in particular for approximating flows in which the mobility of some phases is zero.

1. INTRODUCTION

Motion by mean curvature is the driving mechanism of many physical systems, in which interfaces are moving due to the thermodynamics of phase changes. Such situations are encountered in the modeling of epitaxial growth of thin films [10], in the fabrication of nano-wire by vapor-liquid-solid growth [12, 33], in the modeling of wetting or de-wetting of substrates by crystalline materials [7, 16], or in the evolution of grain boundaries in polycrystalline materials [27].

A time-dependent collection of smooth domains $t \rightarrow \Omega(t) \subset \mathbb{R}^d$ is a motion by mean curvature if, for every t , the normal velocity $V(x, t)$ at each point $x \in \partial\Omega(t)$ is proportional to the mean curvature $H(x, t)$ of $\partial\Omega(t)$ at x . Up to a time rescaling, the equation of evolution takes the form

$$V(x, t) = H(x, t), \quad x \in \partial\Omega(t),$$

and can be viewed as the L^2 -gradient flow of the perimeter of $\Omega(t)$

$$P(\Omega(t)) = \mathcal{H}^{d-1}(\partial\Omega(t)),$$

where \mathcal{H}^{d-1} denotes the $(d-1)$ -dimensional Hausdorff measure. The seminal work of Modica and Mortola [26] has shown that the perimeter can be approximated (in the sense of Γ -convergence) by the smooth Van der Waals-Cahn-Hilliard functional

$$(1) \quad P_\varepsilon(u) = \int_Q \left(\frac{\varepsilon}{2} |\nabla u|^2 + \frac{1}{\varepsilon} W(u) \right) dx.$$

defined for smooth functions u , with $Q \subset \mathbb{R}^2$ a fixed bounded domain that contains strictly the convex envelope of $\Omega(0)$ (so that $\partial\Omega(t)$ stays at positive distance from ∂Q), $\varepsilon > 0$ a small parameter, and W a smooth double-well potential, typically

$$W(s) = \frac{1}{2} s^2 (1-s)^2.$$

Key words and phrases. Mean curvature flow, phase field approximation, Allen-Cahn, multiphase system, mobilities, numerical approximation.

It follows from Modica-Mortola's Γ -convergence result [26] that, when Ω is a set of finite perimeter, its characteristic function 1_Ω can be approximated in L^1 by sequences of functions of the form $u_\varepsilon = q(\text{dist}(x, \Omega)/\varepsilon)$, such that $P_\varepsilon(u_\varepsilon) \rightarrow c_W P(\Omega)$, with $c_W = \int_0^1 \sqrt{2W(s)} ds$. Here, $\text{dist}(x, \Omega)$ denotes the signed distance to the set Ω (negative inside, positive outside), and q is a so-called *optimal profile* that depends on the potential W and is defined by

$$q = \operatorname{argmin}_p \left\{ \int_{\mathbb{R}} \sqrt{W(p(s))} |p'(s)| ds, p(-\infty) = 1, p(0) = 1/2, p(+\infty) = 0 \right\},$$

where $p : \mathbb{R} \rightarrow \mathbb{R}$ ranges over the set of Lipschitz continuous functions. A simple derivation of the Euler equation associated with this minimization problem shows that

$$(2) \quad q'(s) = -\sqrt{2W(q(s))} \quad \text{and} \quad q''(s) = W'(q(s)), \quad \text{for all } s \in \mathbb{R},$$

which implies that $q(s) = (1 - \tanh(s))/2$ in the case of the standard double-well potential $W(s) = \frac{1}{2}s^2(1-s)^2$ considered above.

The L^2 -gradient flow of the Van der Waals–Cahn–Hilliard energy P_ε , gives the Allen–Cahn equation [1]. Up to a time rescaling, it takes the form

$$(3) \quad u_t = \Delta u - \frac{1}{\varepsilon^2} W'(u).$$

Given smooth initial and boundary conditions, this nonlinear parabolic equation has a unique solution in short time which satisfies a comparison principle [2]. Furthermore, a smooth motion by mean curvature $t \mapsto \Omega(t)$ can be approximated by

$$\Omega^\varepsilon(t) = \left\{ x \in \mathbb{R}^d, u^\varepsilon(x, t) \geq \frac{1}{2} \right\},$$

where u^ε solves (3) with initial condition

$$u^\varepsilon(x, 0) = q\left(\frac{\text{dist}(x, \Omega(0))}{\varepsilon}\right).$$

A formal asymptotic expansion of u^ε near the boundary $\partial\Omega^\varepsilon(t)$ shows [4] that u^ε is quadratically close to the optimal profile, i.e.

$$u^\varepsilon(x, t) = q\left(\frac{\text{dist}(x, \Omega^\varepsilon(t))}{\varepsilon}\right) + O(\varepsilon^2),$$

and the normal velocity V^ε along $\partial\Omega^\varepsilon(t)$ satisfies

$$V^\varepsilon = H_{\partial\Omega^\varepsilon(t)} + O(\varepsilon^2).$$

Convergence of $\partial\Omega_\varepsilon(t)$ to $\partial\Omega(t)$ has been rigorously proved for smooth flows with a quasi-optimal convergence order $O(\varepsilon^2 |\log \varepsilon|^2)$ [18, 19, 5]. The fact that u^ε is quadratically close to the optimal profile has inspired the development of very effective numerical methods [26, 18, 8, 30, 11].

1.1. Multiphase flows. In the presence of several phases, the motion of interfaces obeys a relation of the form

$$V_{ij} = m_{ij} \sigma_{ij} H_{ij},$$

where V_{ij} , H_{ij} , and σ_{ij} denote, respectively, the normal velocity, the mean curvature and the surface tension along the interface Γ_{ij} that separates the phases i and j . The mobilities m_{ij} describe how fast adatoms from one phase may be adsorbed in another phase as the front advances. These parameters are associated with the kinetics of the moving front, not with the equilibrium shape of the crystal, contrarily to the surface tensions σ_{ij} .

Assuming that the material phases partition an open region $Q \subset \mathbb{R}^n$, $n = 2, 3$ into closed sets Ω_i occupied by the phase i , the perimeter functional takes the form

$$P(\Omega_1, \Omega_2, \dots, \Omega_N) = \frac{1}{2} \sum_{1 \leq i < j \leq N} \sigma_{ij} \mathcal{H}^{d-1}(\Gamma_{ij} \cap Q).$$

with $\Gamma_{ij} = \partial\Omega_i \cap \partial\Omega_j$. We assume throughout this work that the surface tensions are additive, i.e., that there exist $\sigma_k \geq 0$, $1 \leq k \leq N$, such that

$$\sigma_{ij} = \sigma_i + \sigma_j, \quad 1 \leq i < j \leq N.$$

The additivity property is always satisfied when $N \leq 3$ and when the set of coefficients $\{\sigma_{ij}\}$ satisfy the triangle inequality. In particular, this is the case of the evolution of a single chemical species in its liquid, vapor and solid phases. The perimeter functional can then be rewritten in the form

$$P(\Omega_1, \Omega_2, \dots, \Omega_N) = \sum_i^N \sigma_i \mathcal{H}^{d-1}(\partial\Omega_i \cap Q),$$

and therefore lends itself to approximation by the multiphase Cahn-Hilliard energy defined for $\mathbf{u} = (u_1, u_2, \dots, u_N)$ by

$$P_\varepsilon(\mathbf{u}) = \begin{cases} \frac{1}{2} \sum_{i=1}^N \int_Q \sigma_i \left(\varepsilon \frac{|\nabla u_i|^2}{2} + \frac{1}{\varepsilon} W(u_i) \right) dx, & \text{if } \sum_{i=1}^N u_i = 1, \\ +\infty & \text{otherwise.} \end{cases}$$

Modica-Mortola's scalar Γ -convergence result was generalized to multiphase in [28] when $\sigma_i = 1$, $1 \leq i \leq N$. For more general Γ -convergence results, we refer to [3, 14] for inhomogeneous surface tensions, and to [22, 21] for anisotropic surface tensions.

The L^2 -gradient flow of P_ε yields the following system of Allen-Cahn equations:

$$(4) \quad \partial_t u_k^\varepsilon = \sigma_k \left[\Delta u_k^\varepsilon - \frac{1}{\varepsilon^2} W'(u_k^\varepsilon) \right] + \lambda^\varepsilon, \quad \forall k = 1, \dots, N,$$

where the Lagrange multiplier λ^ε accounts for the constraint $\sum_{k=1}^N u_k^\varepsilon = 1$. In practice, however, the numerical schemes derived from (4) do not prove as accurate as in the single-phase case. To improve the convergence, one may localize the Lagrange multiplier λ near the diffuse interface, as was proposed in [13], and consider instead of (4) the modified system

$$(5) \quad \partial_t u_k^\varepsilon = \sigma_k \left[\Delta u_k^\varepsilon - \frac{1}{\varepsilon^2} W'(u_k^\varepsilon) \right] + \lambda^\varepsilon \sqrt{2W(u_k)} \quad \forall k = 1, \dots, N,$$

where the effect of λ is essentially felt in the vicinity of the interfaces. A rigorous proof of convergence of this modified Allen-Cahn system to multiphase Brakke's mean curvature flow is established in [32].

1.2. Incorporating mobilities. As mentioned above, mobilities are kinetic parameters that model how fast adatoms get attached to an evolving front. In [21, 22], mobilities are included in the definition of the surface potential $f(\mathbf{u}, \nabla \mathbf{u})$ and of the multi-well potential $\mathbf{W}(\mathbf{u})$ that define the Allen-Cahn approximate energy $\mathbf{u} = (u_1, u_2, \dots, u_N)$ as

$$P_\varepsilon(\mathbf{u}) = \begin{cases} \int_Q \varepsilon f(\mathbf{u}, \nabla \mathbf{u}) + \frac{1}{\varepsilon} \mathbf{W}(\mathbf{u}) dx, & \text{if } \sum_{i=1}^N u_i = 1, \\ +\infty & \text{otherwise.} \end{cases}$$

Examples of surface potential f and multiple well potential \mathbf{W} that have been considered are

$$\begin{cases} f(\mathbf{u}, \nabla \mathbf{u}) &= \sum_{i < j} m_{ij} \sigma_{ij} |u_i \nabla u_j - u_j \nabla u_i|^2, \\ \mathbf{W}(\mathbf{u}) &= \sum_{i < j} \frac{\sigma_{ij}}{m_{ij}} u_i^2 u_j^2 + \sum_{i < j < k} \sigma_{ijk} u_i^2 u_j^2 u_k^2. \end{cases}$$

In these models, both surface tensions and mobilities appear in the Cahn-Hilliard energy. It is shown in [23, 22] that taking the sharp interface limit imposes constraints on the limiting values of the surface tensions and mobilities, in particular in the anisotropic case. From a numerical perspective it follows that the mobilities are likely to impact the size of the diffuse interfaces, as they appear in the energy, especially in situations where the contrast of mobilities is large.

In this work, we assume that the flux of adatoms is a linear function of the normal velocity of the interface Γ_{ij} , with a proportionality constant equal to m_{ij} . From the modeling point of view, this amounts to considering the surface tensions as geometric parameters which govern the equilibrium, and the mobilities as parameters related to the evolution of the system from an out-of-equilibrium configuration, which only affect the metric used for the gradient flow.

It is proposed in [12] to take the mobilities into account through the metric used to define the gradient flow. The mobilities that are considered in [12] mimic the properties of additive surface tensions, i.e., it is assumed that the m_{ij} 's, for $1 \leq i < j \leq N$, can be decomposed as

$$(6) \quad \frac{1}{m_{ij}} = \frac{1}{m_i} + \frac{1}{m_j},$$

for a suitable collection of coefficients $m_k > 0$, $1 \leq k \leq N$. We extend the definition of m_{ij} to all $1 \leq i, j \leq N$, $i \neq j$, by the natural symmetrization $m_{ji} = m_{ij}$.

The Allen-Cahn system associated to a set of mobilities with such a decomposability property takes the form

$$(7) \quad \partial_t u_k^\varepsilon = m_k \left[\sigma_k \left(\Delta u_k^\varepsilon - \frac{1}{\varepsilon^2} W'(u_k^\varepsilon) \right) + \lambda^\varepsilon \sqrt{2W(u_k)} \right], \quad \forall k \in \{1, \dots, N\},$$

where the Lagrange multiplier λ^ε is again associated to the constraint $\sum u_i^\varepsilon = 1$ and given by

$$\lambda^\varepsilon = - \frac{\sum_k m_k \sigma_k \left(\Delta u_k^\varepsilon - \frac{1}{\varepsilon^2} W'(u_k^\varepsilon) \right)}{\sum_k m_k \sqrt{2W(u_k)}}.$$

This model has the following advantages [12]:

- It is quantitative in the sense that the coefficients σ_i and m_i can be identified from the mobilities and surface tensions m_{ij} and σ_{ij} ,
- Numerical tests indicate an accuracy of order two in ε , and suggest that the size of the diffuse interface does not depend on the m_{ij} 's,
- A simple and effective numerical scheme can be derived to approximate the solutions to (7).

Positive mobilities that satisfy (6) are called *harmonically additive*. For convenience, we extend the definition to nonnegative mobilities using the convention $\frac{1}{0^+} = +\infty$ and $\frac{1}{+\infty} = 0^+$. The Allen-Cahn equation associated with a null coefficient $m_i = 0$ reduces to $\partial_t u_i^\varepsilon = 0$.

1.3. General mobilities. The main motivation of the paper is to introduce a phase field model similar to (7), but not limited to harmonically additive mobilities. For example, in the case of a 3-phase system ($N = 3$), the triplet of mobility coefficients $(m_{12}, m_{13}, m_{23}) = (1, 0, 0)$ is indeed harmonically additive as one can choose $m_1 = m_2 = 2$ and $m_3 = 0$. However, this is far from general, and there seems to be no physical (even practical) reason that justifies this hypothesis. The situation studied in [12], that models the vapor-liquid-solid (VLS) growth of nanowires, is an illustration of this remark. Indeed, VLS growth can be viewed as a system of three phases

with mobilities $m_{LS} = m_{LV} = 1, m_{SV} = 0$. In such a system, the vapor-solid interface remains fixed, as growth only takes place along the liquid-solid interface. It is easy to check that a triplet of mobilities of the form $(m_{12}, m_{13}, m_{23}) = (1, 1, 0)$ fails to be harmonically additive (or more generally, any triplet $(1, 1, \beta)$ as soon as $\beta < 1/2$).

To derive a numerical scheme adapted to general nonnegative mobilities and ensuring that the width of the diffuse interface does not depend on the possible degeneracy of the mobilities, we decompose each mobility as a sum of harmonically additive mobilities. In other words, for each $m_{ij}, i \neq j$, we consider $P \in \mathbb{N}$ and nonnegative coefficients $\{m_{ij}^p\}$ and $\{m_i^p\}$ such that

$$(8) \quad m_{ij} = \sum_{p=1}^P m_{ij}^p \quad \text{and} \quad \frac{1}{m_{ij}^p} = \frac{1}{m_i^p} + \frac{1}{m_j^p},$$

with the convention that $\frac{1}{0^+} = +\infty$ and $\frac{1}{+\infty} = 0^+$.

It is easy to check that one can *always* find such a decomposition, provided all the m_{ij} 's are nonnegative. For instance, a canonical choice is

$$(9) \quad m_{ij} = \sum_{1 \leq k < \ell \leq N} m_{ij}^{k\ell},$$

with $m_{ij}^{k\ell} = m_{ij} \delta_k(i) \delta_\ell(j)$ satisfying

$$\frac{1}{m_{ij}^{k\ell}} = \frac{1}{m_i^{k\ell}} + \frac{1}{m_j^{k\ell}},$$

where, for every $1 \leq \alpha \leq N$, $m_\alpha^{k\ell} = 2m_{k\ell}(\delta_k(\alpha) + \delta_\ell(\alpha))$.

We associate to this decomposition a phase field model of the form

$$(10) \quad \partial_t u_k^\varepsilon = m_k^* \left[\sigma_k \left(\Delta u_k^\varepsilon - \frac{1}{\varepsilon^2} W'(u_k^\varepsilon) \right) + \lambda_k^\varepsilon \sqrt{2W(u_k)} \right], \quad \forall k \in \{1, \dots, N\}$$

where we define

- the coefficients m_k^* as

$$m_k^* = \sum_{p=1}^P m_k^p.$$

- the Lagrange multipliers λ_k^ε as

$$\lambda_k^\varepsilon = \frac{1}{m_k^*} \sum_{p=1}^P m_k^p \lambda^{p,\varepsilon}, \quad \text{with} \quad \lambda^{p,\varepsilon} = - \left(\frac{\sum_{k=1}^N m_k^p \sigma_k \left(\Delta u_k^\varepsilon - \frac{1}{\varepsilon^2} W'(u_k^\varepsilon) \right)}{\sum_{k=1}^N m_k^p \sqrt{2W(u_k)}} \right).$$

Remark 1.1. The difference between the two models (7) and (10) lies in the definition of the Lagrange multipliers λ_k^ε . In the first case, the components λ_k^ε are identical and do not differentiate interfaces according to the mobilities for the satisfaction of the constraint $\sum \partial_t u_k = 0$. In the second model, the λ_k^ε 's are weighted in terms of the m_k^p 's.

Remark 1.2. There is, in general, no unique way of decomposing a given set of nonnegative mobilities $(m_{ij})_{1 \leq i < j \leq N}$ as a sum of harmonically additive mobilities. In view of the tests we performed, it seems that the particular choice of decomposition does not have a strong influence on the numerical results.

Proving the consistency of our new phase field model (10) is the main theoretical result of the present work. More precisely, we show that smooth solutions to the above system are close up to order 2 in ε to a sharp interface motion.

Proposition 1.3. Assume that \mathbf{u}^ε is a smooth solution to (10) and define the set

$$E_i^\varepsilon(t) = \{x \in \Omega, \quad u_i^\varepsilon(x, t) \geq 1/2\}$$

and the interface

$$\Gamma_{ij}^\varepsilon(t) = \partial E_i^\varepsilon(t) \cap \{x \in \Omega, \quad u_j^\varepsilon(x, t) \geq u_k^\varepsilon(x, t) \quad \forall k \neq i\}.$$

Then, in a neighborhood of Γ_{ij}^ε , \mathbf{u}^ε satisfies

$$\begin{cases} u_i^\varepsilon &= q\left(\frac{d_i^\varepsilon(x, t)}{\varepsilon}\right) + O(\varepsilon^2), \\ u_j^\varepsilon &= 1 - q\left(\frac{d_j^\varepsilon(x, t)}{\varepsilon}\right) + O(\varepsilon^2), \\ u_k^\varepsilon &= O(\varepsilon^2), \text{ for } k \in \{1, \dots, N\} \setminus \{i, j\}, \end{cases}$$

where $d_i^\varepsilon(x, t)$ denotes the signed distance to $E_i^\varepsilon(t)$, with $d_i^\varepsilon(x, t) < 0$ if $x \in E_i^\varepsilon(t)$. Define further $V_{ij}^\varepsilon(x, t) = \partial_t d_i^\varepsilon(x, t)$ for $x \in \Gamma_{ij}^\varepsilon$. Then the following estimate holds:

$$V_{ij}^\varepsilon = m_{ij}\sigma_{ij}H_{ij} + O(\varepsilon).$$

The paper is organized as follows: Proposition 1.3 is proven formally in Section 2, using the method of matched asymptotic expansions (the formal proof is given for general nonnegative mobilities, thus including of course the more restrictive case of harmonically additive mobilities considered in [12]). In Section 3, we propose a numerical scheme based on the phase-field system (10). To illustrate its simplicity, we give an explicit **Matlab** implementation of the scheme in dimension 2 that requires less than 50 lines. In the last section, we provide examples of simulations of multiphase flows in dimensions 2 and 3 that illustrate the consistency and effectiveness of the method, and the influence of mobilities on the flow.

2. ASYMPTOTIC EXPANSION OF SOLUTIONS TO THE ALLEN-CAHN SYSTEM

This section is devoted to the formal identification of sharp interface limits of solutions $\mathbf{u}^\varepsilon = (u_1^\varepsilon, \dots, u_N^\varepsilon)$ to the Allen-Cahn system (10). To this aim, we use the method of matched asymptotic expansions proposed in [15, 29, 6, 25, 13, 12], which we apply around each interface Γ_{ij} . Henceforth, we fix $i, j \in \{1, \dots, N\}$ and we assume that \mathbf{u}^ε is a solution to (10) that is smooth near the interface Γ_{ij}^ε .

2.1. Preliminaries.

Outer expansion far from Γ_{ij}^ε . We assume that the *outer expansion* of u_k^ε , i.e. the expansion far from the front Γ_{ij}^ε , has the form:

$$u_k^\varepsilon(x, t) = u_k^0(x, t) + \varepsilon u_k^1(x, t) + O(\varepsilon^2), \text{ for all } k \in \{1, \dots, N\}.$$

In particular, and analogously to [25], it is not difficult to see that if $E_i^\varepsilon(t) = \{x \in \Omega, u_i^\varepsilon \geq \frac{1}{2}\}$, then

$$u_i^0(x, t) = \begin{cases} 1 & \text{if } x \in E_i^\varepsilon(t) \\ 0 & \text{otherwise} \end{cases}, \quad u_j^0(x, t) = \begin{cases} 0 & \text{if } x \in E_i^\varepsilon(t) \\ 1 & \text{otherwise} \end{cases}$$

and $u_i^1 = u_j^1 = 0$, $u_k^0 = u_k^1 = 0$ for all $k \in \{1, \dots, N\} \setminus \{i, j\}$.

Inner expansions around Γ_{ij}^ε . In a small neighborhood of Γ_{ij}^ε , we define the stretched normal distance to the front as $z = \frac{1}{\varepsilon}d_i^\varepsilon(x, t)$, where $d_i^\varepsilon(x, t)$ denotes the signed distance to $E_i^\varepsilon(t)$ such that $d_i^\varepsilon(x, t) < 0$ in $E_i^\varepsilon(t)$. The *inner expansions* of $u_k^\varepsilon(x, t)$ and $\lambda^{p,\varepsilon}(x, t)$, i.e. expansions close to the front, are assumed of the form

$$u_k^\varepsilon(x, t) = U_k^\varepsilon(z, x, t) = U_k^0(z, x, t) + \varepsilon U_k^1(z, x, t) + O(\varepsilon^2), \text{ for all } k \in \{1, \dots, N\},$$

and

$$\lambda^{p,\varepsilon}(x, t) = \Lambda^{p,\varepsilon}(z, x, t) = \varepsilon^{-2}\Lambda^{p,-2}(z, x, t) + \varepsilon^{-1}\Lambda^{p,-1}(z, x, t) + O(1).$$

Moreover, if n denotes the unit normal to Γ_{ij} and V_{ij}^ε the normal velocity to the front (pointing to the inside of E_i^ε) for $x \in \Gamma_{ij}$

$$V_{ij}^\varepsilon = \partial_t d_i^\varepsilon(x, t) = V_{ij}^0 + \varepsilon V_{ij}^1 + O(\varepsilon^2), \quad n = \nabla d_i^\varepsilon(x, t).$$

where ∇ refers to the spatial derivative only. Following [29, 25] we assume that $U_k^\varepsilon(z, x, t)$ does not change when x varies normal to Γ_{ij} with z held fixed, or equivalently $(\nabla U_k^\varepsilon)_{z=\text{const.}} \cdot n = 0$. This amounts to requiring that the blow-up with respect to the parameter ε is consistent with the flow.

Following [29, 25], it is easily seen that

$$(11) \quad \begin{cases} \nabla u_k^\varepsilon = \nabla_x U_k^\varepsilon + \varepsilon^{-1} n \partial_z U_k^\varepsilon, \\ \Delta u_k^\varepsilon = \Delta_x U_k^\varepsilon + \varepsilon^{-1} \Delta_{d_i} \partial_z U_k^\varepsilon + \varepsilon^{-2} \partial_{zz}^2 U_k^\varepsilon, \\ \partial_t u_k^\varepsilon = \partial_t U_k^\varepsilon + \varepsilon^{-1} V_{ij}^\varepsilon \partial_z U_k^\varepsilon. \end{cases}$$

Recall also that in a sufficiently small neighborhood of Γ_{ij} , according to Lemma 14.17 in [24], we have

$$\Delta d_i(x, t) = \sum_{k=1}^{d-1} \frac{\kappa_k(\pi(x))}{1 + \kappa_k(\pi(x))d_i(x, t)} = \sum_{k=1}^{d-1} \frac{\kappa_k(\pi(x))}{1 + \kappa_k(\pi(x))\varepsilon z},$$

where $\pi(x)$ is the projection of x on Γ_{ij} and κ_k are the principal curvatures on Γ_{ij} . In particular this implies that

$$\Delta d_i^\varepsilon(x, t) = H_{ij} - \varepsilon z \|A_{ij}\|^2 + O(\varepsilon^2),$$

where H_{ij} and $\|A_{ij}\|^2$ denote, respectively, the mean curvature and the squared 2-norm of the second fundamental form of Γ_{ij} at $\pi(x)$.

Matching conditions between outer and inner expansions. The matching conditions (see [25] for more details) can be written as:

$$\lim_{z \rightarrow +\infty} U_i^0(z, x, t) = 0, \quad \lim_{z \rightarrow -\infty} U_i^0(z, x, t) = 1, \quad \lim_{z \rightarrow \pm\infty} U_i^1(z, x, t) = 0,$$

$$\lim_{z \rightarrow +\infty} U_j^0(z, x, t) = 1, \quad \lim_{z \rightarrow -\infty} U_j^0(z, x, t) = 0, \quad \lim_{z \rightarrow \pm\infty} U_j^1(z, x, t) = 0,$$

and

$$\lim_{z \rightarrow \pm\infty} U_k^0(z, x, t) = \lim_{z \rightarrow \pm\infty} U_k^1(z, x, t) = 0, \text{ for all } k \in \{1, \dots, N\} \setminus \{i, j\}.$$

Moreover, recall that the definition of z implies that $U_i^0(0, x, t) = \frac{1}{2}$ and $U_i^1(0, x, t) = U_i^2(0, x, t) = 0$.

2.2. Analysis of the Allen-Cahn system. We insert the form (11) in (10) and match the terms according to their powers of ε .

Order ε^{-2} . Identifying the terms of order ε^{-2} gives for all $k \in \{1, \dots, N\}$:

$$\sigma_k (\partial_{zz}^2 U_k^0 - W'(U_k^0)) + \frac{1}{m_k^*} \sum_p m_k^p \Lambda^{p,-2} \sqrt{2W(U_k^0)} = 0,$$

and

$$\left[\sum_{k=1}^N m_k^p \sqrt{2W(U_k^0)} \right] \Lambda^{p,-2} = - \sum_{k=1}^N m_k^p \sigma_k (\partial_{zz}^2 U_k^0 - W'(U_k^0)).$$

Assuming $\Lambda^{p,-2} = 0$ shows that $\partial_{zz}^2 U_k^0 - W'(U_k^0) = 0$ for all $k \in \{1, \dots, N\}$. Now, using boundary conditions, we deduce that $U_k^0(z, x, t) = 0$ for all $k \in \{1, \dots, N\} \setminus \{i, j\}$ as $\lim_{z \rightarrow \pm\infty} U_k^0(z, x, t) = 0$. About the case $k = i$, recall that the phase field profile q , defined as the solution of $q''(z) = W'(q)$ with $\lim_{z \rightarrow +\infty} q(z) = 0$, $\lim_{z \rightarrow -\infty} q(z) = 1$ and $q(z) = 1/2$, satisfies $q(z) = (1 - \tanh(z))/2$. Now by remarking that $U_i^0(0, x, t) = \frac{1}{2}$, $\lim_{z \rightarrow +\infty} U_i^0(z, x, t) = 0$ and $\lim_{z \rightarrow -\infty} U_i^0(z, x, t) = 1$, we show that $U_i^0(z, x, t) = q(z)$. The function U_j^0 can then be identified to $U_j^0 = 1 - q(z) = q(-z)$ thanks to the partition constraint $\sum_{k=1}^N U_k^0(z, x, t) = 1$.

Order ε^{-1} . Matching the next order terms shows that for $k \neq \{1, \dots, N\} \setminus \{i, j\}$,

$$\frac{1}{m_k^*} V_{ij}^0 \partial_z U_k^0 = \sigma_k [\partial_{zz}^2 U_k^1 - W''(U_k^0) U_k^1 + H_{ij} \partial_z U_k^0] + \frac{1}{m_k^*} \sum_p m_k^p \Lambda^{p,-1} \sqrt{2W(U_k^0)}$$

and

$$\left[\sum_{k=1}^N m_k^p \sqrt{2W(U_k^0)} \right] \Lambda^{p,-1} = - \sum_{k=1}^N m_k^p \sigma_k [\partial_{zz}^2 U_k^1 - W''(U_k^0) U_k^1 + H_{ij} \partial_z U_k^0].$$

Then, for all $k \in \{1, \dots, N\} \setminus \{i, j\}$, as $U_k^0 = 0$, we deduce that $(\partial_{zz}^2 U_k^1 - W''(0) U_k^1) = 0$ which, in view of the matching boundary conditions $\lim_{z \rightarrow \pm\infty} U_k^1(z, x, t) = 0$, yields $U_k^1 = 0$.

Moreover, recalling from (2) that $\sqrt{2W(q(z))} = -q'(z)$, the equations for U_i^1 and $\Lambda^{p,-1}$ become

$$V_{ij}^0 q'(z) = \sigma_i m_i^* (\partial_{zz}^2 U_i^1 - W''(q(z)) U_i^1) + \sigma_i q'(z) H_{ij} - \sum_p m_i^p \Lambda^{p,-1}(z, x, t) q'(z),$$

and

$$\begin{aligned} (m_i^p + m_j^p) q'(z) \Lambda^{p,-1}(z, x, t) &= m_i^p \sigma_i (\partial_{zz}^2 U_i^1 - W''(q(z)) U_i^1) + m_i^p \sigma_i q'(z) H_{ij} + \\ &+ m_j^p \sigma_j (\partial_{zz}^2 U_j^1 - W''(q(z)) U_j^1) - m_j^p \sigma_j q'(z) H_{ij}, \end{aligned}$$

where the minus sign before the term $m_j^p \sigma_j q'(z) H_{ij}$ comes from $\partial_z U_j^0 = \partial_z (1 - q(z)) = -q'$.

In particular, multiplying the last equation by $\frac{m_i^p}{m_i^p + m_j^p}$ and summing over p , we find that

$$\begin{aligned} \sum_p [m_i^p \Lambda^{p,-1}(z, x, t) q'(z)] &= \left(\sum_p \frac{m_i^p}{m_j^p} m_{ij}^p \right) [\sigma_i (\partial_{zz}^2 U_i^1 - W''(q(z)) U_i^1) + \sigma_i q'(z) H_{ij}] \\ &+ \left(\sum_p m_{ij}^p \right) [\sigma_j (\partial_{zz}^2 U_j^1 - W''(q(z)) U_j^1) - \sigma_j q'(z) H_{ij}]. \end{aligned}$$

where we have used the equality $m_{ij}^p = (\frac{1}{m_i^p} + \frac{1}{m_j^p})^{-1} = \frac{m_i^p m_j^p}{m_i^p + m_j^p}$.

Then, by injecting this expression into the first equation, we see that

$$\begin{aligned} V_{ij}^0 q'(z) &= \left[\left(m_i^* - \sum_p \frac{m_i^p}{m_j^p} m_{ij}^p \right) \sigma_i + \left(\sum_p m_{ij}^p \right) \sigma_j \right] q'(z) H_{ij} \\ &\quad + \left(m_i^* - \sum_p \frac{m_i^p}{m_j^p} m_{ij}^p \right) \sigma_i (\partial_{zz}^2 U_i^1 - W''(q(z)) U_i^1) \\ &\quad - \left(\sum_p m_{ij}^p \right) \sigma_j (\partial_{zz}^2 U_j^1 - W''(q(z)) U_j^1). \end{aligned}$$

Moreover, remarking that

$$\left(m_i^* - \sum_p \frac{m_i^p}{m_j^p} m_{ij}^p \right) = \sum_p m_i^p - \sum_p \frac{(m_i^p)^2}{m_i^p + m_j^p} = \sum_p \frac{m_i^p m_j^p}{m_i^p + m_j^p} = \sum_p m_{ij}^p = m_{ij} \quad \text{and} \quad \sigma_i + \sigma_j = \sigma_{i,j},$$

we deduce that U_i^1, U_j^1 , and V_{ij}^0 satisfy

$$V_{ij}^0 q'(z) = \sigma_{i,j} m_{ij} q'(z) H_{ij} + m_{ij} \sigma_i (\partial_{zz}^2 U_i^1 - W''(q(z)) U_i^1) - m_{ij} \sigma_j (\partial_{zz}^2 U_j^1 - W''(q(z)) U_j^1).$$

Multiplying this equation by q' and integrating over \mathbb{R} leads to the interface evolution

$$V_{ij}^0 = m_{ij} \sigma_{i,j} H_{ij},$$

as

$$\int_{\mathbb{R}} (\partial_{zz}^2 U(z) - W''(z) U(z)) q'(z) dz = \int_{\mathbb{R}} U(z) (q''(z) - W'(q(z)))' dz = 0.$$

Moreover, as $U = \sigma_i U_i^1 - \sigma_j U_j^1$ satisfies the equation $\partial_{zz}^2 U - W''(q) U = 0$ and the boundary conditions $\lim_{z \rightarrow \pm\infty} U = 0$, we deduce that $\sigma_i U_i^1 - \sigma_j U_j^1 = 0$. It follows from the partition constraint $\sum_{k=1}^N U_k^1 = U_i^1 + U_j^1 = 0$ that $U_i^1 = U_j^1 = 0$.

Moreover, we have

$$(m_i^p + m_j^p) q'(z) \Lambda^{p,-1}(z, x, t) = m_i^p \sigma_i q'(z) H_{ij}(x) - m_j^p \sigma_j q'(z) H_{ij}(x),$$

which shows that

$$\Lambda^{p,-1} = \left(\frac{m_{i,j}^p}{m_i^p} \sigma_i - \frac{m_{i,j}^p}{m_j^p} \sigma_j \right) H_{i,j},$$

and Proposition 1.3 ensues.

3. NUMERICAL SCHEME AND IMPLEMENTATION

In this section we introduce a Fourier spectral splitting scheme [17] to approximate the solutions to the Allen-Cahn system

$$\partial_t u_k^\varepsilon = m_k^* \left[\sigma_k \left(\Delta u_k^\varepsilon - \frac{1}{\varepsilon^2} W'(u_k^\varepsilon) \right) + \lambda_k^\varepsilon \sqrt{2W(u_k)} \right], \quad k \in \{1, \dots, N\},$$

where $m_k^* = \sum_{p=1}^P m_k^p$ and

$$\lambda_k^\varepsilon = \frac{1}{m_k^*} \sum_{p=1}^P m_k^p \lambda^{p,\varepsilon}, \quad \text{with} \quad \lambda^{p,\varepsilon} = - \left(\frac{\sum_{k=1}^N m_k^p \sigma_k (\Delta u_k^\varepsilon - \frac{1}{\varepsilon^2} W'(u_k^\varepsilon))}{\sum_{k=1}^N m_k^p \sqrt{2W(u_k)}} \right).$$

The solutions to the system are approximated numerically on a square box $Q = [0, L_1] \times \dots \times [0, L_d]$ with periodic boundary conditions.

We recall that the Fourier K -approximation of a function u defined in a box Q is given by

$$u^K(x) = \sum_{\mathbf{k} \in K_d} c_{\mathbf{k}} e^{2i\pi \xi_{\mathbf{k}} \cdot x},$$

where $K_d = [-\frac{K_1}{2}, \frac{K_1}{2} - 1] \times [-\frac{K_2}{2}, \frac{K_2}{2} - 1] \dots \times [-\frac{K_d}{2}, \frac{K_d}{2} - 1]$, $\mathbf{k} = (k_1, \dots, k_d)$, and $\xi_{\mathbf{k}} = (k_1/L_1, \dots, k_d/L_d)$. In this formula, the $c_{\mathbf{k}}$'s denote the K^d first discrete Fourier coefficients of u . The inverse discrete Fourier transform leads to $u_{\mathbf{k}}^K = \text{IFFT}[c_{\mathbf{k}}]$ where $u_{\mathbf{k}}^K$ denotes the value of u at the points $x_{\mathbf{k}} = (k_1 h_1, \dots, k_d h_d)$ and where $h_i = L_i/N_i$ for $i \in \{1, \dots, d\}$. Conversely, $c_{\mathbf{k}}$ can be computed as the discrete Fourier transform of $u_{\mathbf{k}}^K$, i.e., $c_{\mathbf{k}} = \text{FFT}[u_{\mathbf{k}}^K]$.

3.1. Definition of the scheme. Given a time discretisation parameter $\delta_t > 0$, we construct a sequence $(\mathbf{u}^n)_{n \geq 0}$ of approximations of \mathbf{u} at the times $n\delta_t$, by adapting the splitting discretization schemes proposed in the previous works [13, 12]. More precisely, we iteratively

- minimize the Cahn-Hilliard energy without the constraint $\sum_{k=1}^N u_k^n = 1$.
- compute the contribution of the Lagrange multipliers λ_k^ε and update the values of u_k^n .

This approach provides a simple scheme, and our numerical experiments (see Section 4) together with Proposition 3.2 indicate that it is effective, stable, and that it conserves the partition constraint in the sense that

$$\sum_{k=1}^N u_k^{n+1} = \sum_{k=1}^N u_k^0, \quad \forall n \in \mathbb{N}.$$

Let us now give more details about our scheme.

Step 1: Solving the decoupled Allen-Cahn system (i.e., without the partition constraint):

Let $\mathbf{u}^{n+1/2}$ denote an approximation of $\mathbf{v}(\delta_t)$, where $\mathbf{v} = (v_1, \dots, v_N)$ is the solution with periodic boundary conditions on ∂Q to:

$$\begin{cases} \partial_t v_k(x, t) &= m_k^* \sigma_k [\Delta v_k(x, t) - \frac{1}{\varepsilon^2} W'(v_k(x, t))] , & (x, t) \in Q \times [0, \delta_t], \\ \mathbf{v}(x, 0) &= \mathbf{u}^n(x), & x \in Q. \end{cases}$$

Here, our motivation is to introduce a stable scheme in the sense that the associated Cahn-Hilliard energy decreases with the iterations. A totally implicit scheme would require the resolution of a nonlinear system at each iteration, which in practice would prove costly and not very accurate. Rather, we opt for a semi-implicit scheme in which the non linear term $W'(v_k)$ is integrated explicitly. More precisely, we consider the scheme

$$(I_d - \delta_t m_k^* \sigma_k (\Delta - \alpha/\varepsilon^2 I_d)) u_k^{n+1/2} = u_k^n - \frac{\delta_t m_k^* \sigma_k}{\varepsilon^2} (W'(u_k^n) - \alpha u_k^n),$$

where α is a positive stabilization parameter, chosen sufficiently large to ensure the stability of the scheme. Indeed, it is known that the Cahn-Hilliard energy decreases unconditionally as soon as the explicit part, i.e. $s \rightarrow W'(s) - \alpha s$, is the derivative of a concave function [20, 31]. This is the case for the potential $W(s) = \frac{1}{2} s^2 (1 - s)^2$, as soon as $\alpha > 2$. We also note that even when $\alpha = 0$, the semi-implicit scheme is stable under the classical condition $\delta_t \leq \frac{C}{\varepsilon^2}$, where $C = \sum_{s \in [0, 1]} |W''(s)|$. Further, as the fields u_k^n are required to satisfy periodic boundary conditions on ∂Q , the action of the inverse operator $(I_d - m_k \delta_k \delta_t (\Delta - \alpha/\varepsilon^2 I_d))^{-1}$ is easily computed in Fourier space [17] using the

Fast Fourier Transform. Remark that this strategy can also be generalized to anisotropic flows [9].

Step 2: Explicit projection onto the partition constraint $\sum u_k = 1$.

The advantage of an implicit treatment of the Lagrange multiplier λ_k^ε is not significant enough considering the complexity and the algorithmic cost of this approach. We rather prefer an explicit approach for which we will prove that the processing is exact in the sense that $\sum_{k=1}^N u_k^{n+1} = \sum_{k=1}^N u_k^n$, $\forall n \in \mathbb{N}$. More precisely, for all $k \in \{1, \dots, N\}$, we define u_k^{n+1} by

$$u_k^{n+1} = u_k^{n+1/2} + \delta_t m_k^* \lambda_k^{n+1/2} \sqrt{2W(u_k^{n+1/2})}$$

where

$$\lambda_k^{n+1/2} = \frac{1}{m_k^*} \sum_{p=1}^P m_k^p \lambda_k^{p,n+1/2}, \quad \text{and} \quad \lambda_k^{p,n+1/2} = -\frac{\sum_{i=1}^N m_i^p \alpha_i^{n+1/2}}{\sum_{i=1}^N m_i^p \sqrt{2W(u_i^{n+1/2})}}.$$

Here $\alpha_i^{n+1/2}$ is a semi-implicit approximation of $\sigma_i [\Delta u_i(x, t) - \frac{1}{\varepsilon^2} W'(u_i(x, t))]$ at time $t_{n+1/2}$ defined by

$$\alpha_i^{n+1/2} = \frac{u_i^{n+1/2} - u_i^n}{\delta_t m_i^*}.$$

Remark 3.1. Notice that we can always assume that $\sum_i m_i^p > 0$, as otherwise $m_{i,j}^p = 0$ for all i, j and there is no contribution of the p -th mobility. Moreover, the above definitions of $\alpha_i^{n+1/2}$ and $\lambda_k^{n+1/2}$ only make sense when the m_k^* 's or the sum $\sum_{i=1}^N m_i^p \sqrt{2W(u_i^{n+1/2})}$ do not vanish. In practice (see the code in Table 1), to overcome this difficulty and avoid any division by zero, it is more convenient to work with $\tilde{\lambda}_k^{n+1/2} = m_k^* \lambda_k^{n+1/2}$ and to use the following regularized version of the scheme :

$$u_k^{n+1} = u_k^{n+1/2} + \delta_t \tilde{\lambda}_k^{n+1/2} \left(\sqrt{2W(u_k^{n+1/2})} + \beta \right), \quad \tilde{\lambda}_k^{n+1/2} = \sum_{p=1}^P m_k^p \tilde{\lambda}_k^{p,n+1/2},$$

and

$$\tilde{\lambda}_k^{p,n+1/2} = -\frac{\sum_{i=1}^N m_i^p \tilde{\alpha}_i^{n+1/2}}{\sum_{i=1}^N m_i^p (\sqrt{2W(u_i^{n+1/2})} + \beta)}, \quad \text{and} \quad \tilde{\alpha}_i^{n+1/2} = \frac{u_i^{n+1/2} - u_i^n}{\delta_t \max\{m_i^*, \beta\}},$$

where $\beta \simeq 2.2210^{-16}$ is the machine precision.

The next proposition shows that our scheme conserves the partition constraint and conserves each phase whose mobilities at each of its interfaces are zero.

Proposition 3.2. *With the above notations:*

- (1) Assume that $m_i^* > \beta$ for all $i \in \{1, \dots, N\}$ and $\sum_i m_i^p > 0$ for all $p \in \{1, \dots, P\}$, then the previous scheme preserves the partition constraint, i.e.

$$\sum_{k=1}^N u_k^{n+1} = \sum_{k=1}^N u_k^n.$$

- (2) Let $i \in \{1, \dots, N\}$. Assume that $m_{i,j} = 0$ for all $j \in \{1, \dots, N\}$, $j \neq i$, then

$$u_i^{n+1} = u_i^n.$$

Proof of (1) : As

$$u_k^{n+1} = u_k^{n+1/2} - \sum_{p=1}^P m_k^p \left[\frac{\sum_{i=1}^N m_i^p (u_i^{n+1/2} - u_i^n) / \max\{m_i^*, \beta\}}{\sum_{i=1}^N m_i^p (\sqrt{2W(u_i^{n+1/2})} + \beta)} \right] (\sqrt{2W(u_k^{n+1/2})} + \beta)$$

it follows that

$$\begin{aligned} \sum_{k=1}^N u_k^{n+1} &= \sum_{k=1}^N u_k^{n+1/2} - \sum_{p=1}^P \left[\sum_{i=1}^N m_i^p (u_i^{n+1/2} - u_i^n) / m_i^* \right] \frac{\sum_{k=1}^N m_k^p (\sqrt{2W(u_k^{n+1/2})} + \beta)}{\sum_{i=1}^N m_i^p (\sqrt{2W(u_i^{n+1/2})} + \beta)} \\ &= \sum_{k=1}^N u_k^{n+1/2} - \sum_{i=1}^N (u_i^{n+1/2} - u_i^n) \sum_{p=1}^P m_i^p / m_i^* = \sum_{k=1}^N u_k^n. \end{aligned}$$

as $\sum_{p=1}^P m_i^p = m_i^*$.

Proof of (2) : By definition, $\sum_p m_{ij}^p = m_{ij} = 0$. All m_{ij}^p 's being nonnegative, we deduce that $m_{ij}^p = 0$, $p \in \{1, \dots, P\}$, $j \in \{1, \dots, N\} \setminus \{i\}$. Moreover, as m_{ij}^p is harmonically additive, i.e. $1/m_{ij}^p = (1/m_i^p + 1/m_j^p)$ (using the convention $\frac{1}{0^+} = +\infty$ and $\frac{1}{+\infty} = 0^+$), it follows that, for every $q \in \{1, \dots, P\}$, either $m_i^q = 0$, or $m_i^q > 0$ and $m_j^q = 0$ for all $j \in \{1, \dots, N\} \setminus \{i\}$. In the latter case, $m_{kj}^q = 0$ for every $k \neq j$, so the q -th term is useless in the decomposition of all mobility coefficients m_{kj} , $k \neq j$, and can be removed. Using the same argument for every $q \in \{1, \dots, P\}$, and discarding the trivial situation where *all* mobility coefficients m_{kj} are zero, we finally obtain that necessarily $m_i^q = 0$, $\forall q \in \{1, \dots, P\}$ (using for simplicity the same notation P for the new number of elements in the decomposition). Now, the first step of our scheme yields $u_i^{n+1/2} = u_i^n$ as $m_i^* = \sum_p m_i^p = 0$, and the second step gives $\tilde{\lambda}_i^{n+1/2} = \sum_{p=1}^P m_i^p \tilde{\lambda}_i^{p,n+1/2} = 0$ and $u_i^{n+1} = u_i^{n+1/2} = u_i^n$, as $\tilde{\lambda}^{p,n+1/2}$ is bounded and $m_i^p = 0$ for all $p \in \{1, \dots, P\}$.

Remark 3.3. The above argument brings the following natural question: given a collection of coefficients $\{m_{k\ell}^p, 1 \leq k < \ell < N\}$, $p \in \{1, \dots, P\}$, how can we compute the coefficients m_i^p ? In the case of positive coefficients, the following formula can be used, whose proof is straightforward:

$$\frac{1}{m_i^p} = \frac{1}{2} \left(\frac{1}{m_{ij}^p} + \frac{1}{m_{ik}^p} - \frac{1}{m_{kj}^p} \right).$$

In practice, in particular in a numerical code, this formula can be extended to general nonnegative coefficients by simply replacing each null coefficient with the machine precision.

3.2. Matlab code. We present in Table 1 an example of Matlab code with less than 50 lines which implements our splitting scheme in the case of $N = 3$ phases in dimension $d = 2$. Here is a short description of a few lines of the code:

- Lines 5 to 8 correspond to the initialization of the phase u_k for $k = 1, 2, 3$.
- Lines 11 to 18 implement a canonical decomposition of the mobility coefficients m_{ij} :

$$\begin{aligned} (m_{12}, m_{13}, m_{23}) &= (m_{12}^1, m_{13}^1, m_{23}^1) + (m_{12}^2, m_{13}^2, m_{23}^2) + (m_{12}^3, m_{13}^3, m_{23}^3) \\ &= (m_{12}, 0, 0) + (0, m_{13}, 0) + (0, 0, m_{23}) \end{aligned}$$

and provide the associated coefficients m_i^p .

- Lines 20 to 24 provide the operators necessary in Step 1 of the scheme for the numerical resolution of the equation

$$(I_d - \delta_t m_k^* \sigma_k (\Delta - \alpha/\varepsilon^2 I_d)) u_k^{n+1/2} = u_k^n - \frac{\delta_t m_k^* \sigma_k}{\varepsilon^2} (W'(u_k^n) - \alpha u_k^n),$$

Two operators are introduced:

$$OP(u, m) = u - \frac{\delta_t m \sigma}{\varepsilon^2} (W'(u) - \alpha u) \quad \text{and} \quad OL(u, m) = (I_d - \delta_t m \sigma (\Delta - \alpha/\varepsilon^2 I_d))^{-1} u$$

- Lines 33-39 correspond to the computation of each Lagrange multiplier $\lambda^{p,n+1/2}$.

TABLE 1. Example of a **Matlab** implementation of the scheme described in Section 3.1 in the case of $N = 3$ phases in dimension 2.

4. NUMERICAL EXPERIMENTS AND VALIDATION

In this section, we report numerical experiments in dimensions $d = 2$ and $d = 3$, with $N = 3$ or $N = 4$ phases. In each case, the computational domain Q is a unit cube $[-0.5, 0.5]^d$ discretized in each direction with $K = 2^8$ nodes in 2D and $K = 2^7$ in 3D. We use the classical double-well potential $W(s) = \frac{1}{2}s^2(1-s)^2$.

4.1. Validation of the consistency of our approach. This first test illustrates the consistency of the numerical scheme in the case of $N = 3$ phases. We consider the evolution of two circles by the flow (10) associated to the following surface tensions and mobilities:

$$(\sigma_{12}, \sigma_{13}, \sigma_{23}) = (1, 1, 1) \quad \text{and} \quad (m_{12}, m_{13}, m_{23}) = (1, 1, \frac{1}{4}).$$

Notice that this set of mobilities is not harmonically additive as

$$\frac{1}{m_1} = \frac{1}{2} \left(\frac{1}{m_{13}} + \frac{1}{m_{12}} - \frac{1}{m_{23}} \right) = \frac{1}{2}(1 + 1 - 4) = -1 < 0.$$

We use therefore our approach with the canonical decomposition which reads

$$(m_{12}, m_{13}, m_{23}) = \sum_{p=1}^3 (m_{12}^p, m_{13}^p, m_{23}^p),$$

with

$$(m_{12}^1, m_{13}^1, m_{23}^1) = (m_{12}, 0, 0), \quad (m_{12}^2, m_{13}^2, m_{23}^2) = (0, m_{13}, 0), \quad \text{and} \quad (m_{12}^3, m_{13}^3, m_{23}^3) = (0, 0, m_{23}),$$

where

$$(m_1^1, m_2^1, m_3^1) = (2m_{12}, 2m_{12}, 0), \quad (m_1^2, m_2^2, m_3^2) = (2m_{13}, 0, 2m_{13}), \quad \text{and} \quad (m_1^3, m_2^3, m_3^3) = (0, 2m_{23}, 2m_{23}).$$

Moreover, the initial sets are chosen in the following way:

- the phase u_1 fills a circle of radius $r_1 = 0.2$ centered at $x = (-0.25, 0, 0)$
- the phase u_2 fills a circle of radius $r_2 = 0.2$ centered at $x = (0.25, 0, 0)$

These initial sets should evolve as circles with radius:

$$R_1(t) = \sqrt{r_1^2 - 2\sigma_{13}m_{13}t} \quad \text{and} \quad R_2(t) = \sqrt{r_2^2 - 2\sigma_{23}m_{23}t}.$$

The following parameters are used for the computations: $\varepsilon = 1.5/K$, $\delta_t = 0.25/K^2$, and $\alpha = 0$. Figure 1 shows the numerical multiphase solution $\mathbf{u}^\varepsilon = (u_1^\varepsilon, u_2^\varepsilon, u_3^\varepsilon)$ at different times. The first graph in Figure 2 shows a very good agreement between the approximative radii R_1^ε and R_2^ε and their expected theoretical values. The second graph in Figure 2 shows that the numerical error on the constraint $\sum_k u_k = 1$ is of the order of 10^{-12} in this context.

4.2. Influence of the choice of a particular decomposition of mobilities. The decomposition (8) is not unique and it is therefore legitimate to question its effect on the numerical approximation of the flow. We consider here the simplest case using $N = 3$ phases, homogeneous surface tensions $\sigma_{i,j} = 1$ and homogeneous mobility coefficients $m_{ij} = 1$. We then compare the numerical approximations associated with the following decompositions of the mobilities:

- the canonical choice with $P = 3$:

$$(m_{12}^1, m_{13}^1, m_{23}^1) = (1, 0, 0), \quad (m_{12}^2, m_{13}^2, m_{23}^2) = (0, 1, 0) \quad \text{and} \quad (m_{12}^3, m_{13}^3, m_{23}^3) = (0, 0, 1)$$

where

$$(m_1^1, m_2^1, m_3^1) = (2, 2, 0), \quad (m_1^2, m_2^2, m_3^2) = (2, 0, 2) \quad \text{and} \quad (m_1^3, m_2^3, m_3^3) = (0, 2, 2).$$

FIGURE 1. Mean curvature flow of two circular phases, with $\sigma_{12} = \sigma_{13} = \sigma_{23} = 1$ and $m_{12} = 1, m_{13} = 1, m_{23} = \frac{1}{4}$. The images show the values of the function $2u_2 + u_3$ at different times using a colormap such that u_1, u_2 , and u_3 are represented in blue, red and green, respectively.

FIGURE 2. Mean curvature flow of two circular phases. Surface tensions are identical, mobilities are $(m_{12}, m_{13}, m_{23}) = (1, 1, \frac{1}{4})$. Left : Comparison of the radii $R_k(t)$ and their theoretical values $R_i(t)$ associated with the phases $u_k, k=1,2$. Right: Plot of $\|1 - \sum_k u_k(., t)\|_{L^\infty}$.

- a sparse decomposition with $P = 1$:

$$(1, 1, 1) = (m_{12}, m_{13}, m_{23}) = \sum_{p=1}^1 (m_{12}^p, m_{13}^p, m_{23}^p) = (m_{12}^1, m_{13}^1, m_{23}^1),$$

where $(m_1^1, m_2^1, m_3^1) = (2, 2, 2)$. Notice that $(m_{12}, m_{13}, m_{23}) = (1, 1, 1)$ is indeed harmonically additive which explains why we can use $P = 1$.

The following numerical parameters $\varepsilon = 1.5/K$, $\delta_t = 0.25/K^2$, and $\alpha = 0$ are used. Figure 3 shows the numerical multiphase solution $\mathbf{u}^\varepsilon = (u_1^\varepsilon, u_2^\varepsilon, u_3^\varepsilon)$ at different times. The rows correspond to the canonical and sparse decomposition of the m_{ij} 's, respectively. We observe that the two flows are quite similar, which suggests that the choice of a particular decomposition has little influence.

4.3. Validation of our approach for highly contrasted mobilities. Our next tests show that our approach can handle highly contrasted mobilities. One expects that when m_{ij} is small (or vanishes) the corresponding interface Γ_{ij} hardly moves. The tests also show that mobilities are parameters that may strongly affect the flow. The computations have been performed with $\varepsilon = 1/K$, $\delta_t = 1/K^2$, and $\alpha = 2$. Figure 4 represents a first series of numerical experiments in which $\sigma_{12} = \sigma_{13} = \sigma_{23} = 1$. The rows depict the flow associated with the mobilities $(m_{12}, m_{13}, m_{23}) = (1, 1, 1)$, $(0, 1, 1)$, and $(0, 1, 0)$ respectively, with the same initial condition. On each image, the phases u_1

FIGURE 3. Influence of the choice of a particular decomposition of the mobilities: the canonical decomposition is used on the first row, a sparse decomposition on the second. The images show the values of $2u_2 + u_3$ at different times, with the suitable colormap so that u_1 , u_2 , and u_3 are represented in blue, red and green, respectively.

and u_2 are plotted in blue and red respectively. As expected, the blue-red interface Γ_{12} does not move when $m_{12} = 0$ (second line), or when m_{23} (third line).

Figure 5 represent similar experiments with the non-identical surface tensions $\sigma_{12} = 0.1$ and $\sigma_{13} = \sigma_{23} = 1$. The same conclusions hold.

4.4. Numerical experiments with $N = 4$ phases. We show now that our method can handle flows involving more than 3 phases. We consider a configuration with 4 phases and a canonical decomposition of the mobilities $\mathbf{m} = (m_{12}, m_{13}, m_{14}, m_{23}, m_{24}, m_{34})$, which takes the form

$$(m_{12}, m_{13}, m_{14}, m_{23}, m_{24}, m_{34}) = \sum_{p=1}^6 (m_{12}^p, m_{13}^p, m_{14}^p, m_{23}^p, m_{24}^p, m_{34}^p),$$

where

$$(m_{12}^p, m_{13}^p, m_{14}^p, m_{23}^p, m_{24}^p, m_{34}^p) = \begin{cases} (m_{12}, 0, 0, 0, 0, 0) & \text{if } p = 1 \\ (0, m_{13}, 0, 0, 0, 0) & \text{if } p = 2 \\ \vdots & \\ (0, 0, 0, 0, 0, m_{34}) & \text{if } p = 6 \end{cases}$$

Figure 6 shows a series of numerical experiments using

$$(\sigma_{12}, \sigma_{13}, \sigma_{14}, \sigma_{23}, \sigma_{24}, \sigma_{34}) = (1, 1, 1, 1, 1, 1).$$

The rows correspond to $\mathbf{m} = (1, 1, 1, 1, 1, 1)$, $\mathbf{m} = (0, 1, 1, 1, 1, 1)$, and $\mathbf{m} = (0, 0, 1, 1, 1, 1)$, respectively. In each image, the phases u_1, u_2, u_3, u_4 are depicted in light blue, red, blue, and green, respectively. These results show good agreement with the expected theoretical flows.

FIGURE 4. Mean curvature flows with highly contrasted mobilities, identical surface tensions. The rows correspond to $(m_{12}, m_{13}, m_{23}) = (1, 1, 1)$, $(m_{12}, m_{13}, m_{23}) = (0, 1, 1)$, and $(m_{12}, m_{13}, m_{23}) = (0, 1, 0)$, respectively. Images show the values of the function $2u_2 + u_3$ at different times using a colormap such that u_1 , u_2 , and u_3 appear in blue, red and green, respectively.

4.5. Numerical experiments in dimension 3. Figure 7 shows the 3D version of the 2D computations reported in Figure 4. The surface tensions are identical, $\sigma_{ij} = 1$. The rows represent the evolutions from the same initial condition with mobilities (m_{12}, m_{13}, m_{23}) equal to $(1, 1, 1)$, $(0, 1, 1)$, and $(0, 1, 0)$ respectively. In each image, the phases u_1 and u_2 are depicted in blue and red, respectively.

Our last example, shown in Figure 7, concerns a more complex situation with 3 phases where the initial geometry represents a toy truck. We compare evolutions obtained with different sets of mobilities, and with surface tensions $\sigma_{i,j}$ all equal to 1.

5. CONCLUSION

We introduced in this paper a numerical scheme for the approximation of multiphase mean curvature flow with additive surface tensions and general nonnegative mobilities. The scheme uses a decomposition of the set of mobilities as sums of harmonically additive mobilities. We provided a formal asymptotic expansion showing that smooth solutions of the associated Allen-Cahn system approximate a sharp interface motion driven by $V_{ij} = m_{i,j}\sigma_{ij}H_{ij}$, $1 \leq i < j \leq N$, up to order 2 in the order parameter ε . The numerical tests we report are consistent with this expected accuracy. In particular, when the contrast between mobilities is large, our scheme

FIGURE 5. Mean curvature flows with highly contrasted mobilities, non-identical surface tensions. The rows correspond to $(m_{12}, m_{13}, m_{23}) = (1, 1, 1)$, $(m_{12}, m_{13}, m_{23}) = (0, 1, 1)$, and $(m_{12}, m_{13}, m_{23}) = (0, 1, 0)$, respectively. Images show the values of the function $2u_2 + u_3$ at different times using a colormap such that u_1 , u_2 , and u_3 appear in blue, red and green, respectively.

provides approximate flows characterized by a width of the diffuse interface between phases that is not affected by the mobility contrast.
