Abstract

Purpose: To implement and evaluate a new dictionary-based technique for native myocardial T_1 and T_2 mapping using Cartesian sampling.

Methods: The proposed technique (Multimapping) consisted of single-shot Cartesian image acquisitions in 10 consecutive cardiac cycles, with inversion pulses in cycle 1 and 5, and T_2 preparation (TE: 30ms, 50ms and 70ms) in cycles 8-10. Multimapping was simulated for different T_1 and T_2 , where entries corresponding to the k-space centers were matched to acquired data. Experiments were performed in a phantom, 16 healthy subjects and three patients with cardiovascular disease.

Results: Multimapping phantom measurements showed good agreement with reference values for both T₁ and T₂, with no discernable heart-rate dependency for T₁ and T₂ within the range of myocardium. In vivo mean T₁ in healthy subjects was significantly higher using Multimapping (T₁=1114±14ms) compared to the reference (T₁=991±26ms) (p<0.01). Mean Multimapping T₂ (47.1±1.3ms) and T₂ spatial variability (5.8±1.0ms) was significantly lower compared to the reference (T₂=54.7±2.2ms, p<0.001; spatial variability=8.4±2.0ms, p<0.01). Increased T₁ and T₂ was detected in all patients using Multimapping.

Conclusions: Multimapping allows for simultaneous native myocardial T_1 and T_2 mapping with a conventional Cartesian trajectory, demonstrating promising in vivo image quality and parameter quantification results.

Keywords: Cardiac magnetic resonance fingerprinting, dictionary matching, Cartesian sampling, T_1 mapping, T_2 mapping.

Introduction

In the last decade, there has been tremendous interest in developing and clinically applying MRI techniques for quantitatively mapping relaxation times in the myocardium (1–3). Myocardial T_1 and T_2 mapping can be used to discriminate between a range of different cardiomyopathies (4). T_1 mapping can be used to detect diffuse and focal fibrosis, and can also be employed to calculate extracellular volume fraction which is altered in many cardiomyopathies, while T_2 mapping is most commonly used to assess myocardial edema and inflammation (5–7). For some diseases, a combination of T_1 or T_2 mapping provides the most diagnostic power, for example to detect myocarditis (8,9).

The most clinically used quantitative techniques enable T_1 or T_2 mapping as separate scans. For T_1 mapping, the modified Look-Locker inversion recovery (MOLLI) has been the most widely used due to its relatively high precision (10,11). There is less consensus regarding the optimal T₂ mapping technique, and methods using either dark-blood fast spin echo or brightblood T₂-preparation balanced steady-state free precession (T₂bSSFP) have been used extensively (12–14). In recent years, there has been a growing interest in simultaneous T_1 and T_2 mapping techniques for the myocardium (15–22). Some of this work has been based on the magnetic resonance fingerprinting (MRF) paradigm (23-25). MRF involves devising a pulse sequence which yields different magnetization evolution patterns for tissues with different T₁ and T_2 (but it could also include other quantities), and find the best match between the measured signal and a simulated dictionary with known T_1 and T_2 . Typically, such dictionary-based fingerprinting schemes rely on heavily undersampled spiral or other non-Cartesian trajectories (26–28), where a measurement on the magnetization evolution time-curve is obtained from each aliased spoke. However, dictionary-based parameter mapping may also be combined with a Cartesian trajectory, in which case fewer time-points along the magnetization evolution curve can be used for dictionary matching, only those corresponding to the acquisition of the k-space center (29). The advantage of using Cartesian as opposed to spiral sampling is lower susceptibility to B₀-inhomogeneity, no signal aliasing and simplified reconstruction. Therefore, a Cartesian sampling strategy for dictionary-based T₁ and T₂ mapping may be more readily incorporated into a clinical setting.

The purpose of this work was to implement and perform initial optimization on a new dictionary-based technique for myocardial T_1 and T_2 mapping using Cartesian sampling. The

proposed simultaneous T_1 and T_2 mapping technique (termed Multimapping) was tested in phantoms, healthy subjects and patients with cardiovascular disease.

Methods

Multimapping pulse sequence design

The proposed Multimapping pulse sequence consists of 10 single-shot images, ECG-triggered to the mid-diastolic rest period, and incorporating inversion and T₂ preparation (T₂prep) pulses to introduce T₁ and T₂ sensitization, respectively. The image acquisition consists of a balanced steady-state free precession (bSSFP) sequence with Cartesian sampling. Imaging parameters for all experiments and simulations are: field-of-view = 320×320 mm, spatial resolution = 2×2 mm, slice thickness = 10 mm, nominal flip angle = 50° , bandwidth = 1076 Hz/pixel, TR = 2.3 ms, TE = 1.2 ms, SENSE factor = 2, linear profile order. Ten startup radiofrequency (RF) pulses are used with linearly increasing flip angles. An adiabatic inversion pulse is used with an assumed inversion efficiency of 0.94 for the in vivo experiments (30), corresponding to an inversion angle of 160° . For the T₂prep module, hard 90° tip down and up pulses are used with four adiabatic refocusing pulses in between.

The timings of the inversion and T_2 prep pulses may be optimized to improve T_1 and T_2 sensitivity. Specifically, using more inversion pulses with different delays may increase sensitivity to different T_1 , while using more T_2 prep with different echo times may yield better T_2 sensitivity. To provide some preliminary optimization in this regard, Multimapping pulse sequences with different pre-pulse settings were implemented and evaluated, the details of which are provided in Supporting Information Section 1. The optimized Multimapping pulse sequence is illustrated in Figure 1, consisting of inversion pulses in cycles 1 and 5, and T_2 prep modules in cycles 8, 9 and 10 with different echo times of 30, 50 and 70 ms, respectively.

Figure 1. Pulse sequence and post-processing steps for the proposed single-shot Cartesian Multimapping technique, acquired across 10 consecutive cardiac cycles, using inversion pulses and T_2 prep modules with varying echo times to introduce T_1 and T_2 sensitization, respectively. After image reconstruction, motion correction (MoCo) is performed to spatially align the 10 source images, followed by phase sensitive inversion recovery (PSIR) correction to determine the polarity of the magnetization. Dictionary matching is then performed (Dict match 1) incorporating B_1 , and coarsely resolved (CR) T_1 and T_2 , to determine a global B_1 which is applied to the second dictionary matching step (Dict match 2) where highly resolved (HR) T_1 and T_2 maps are generated. For the dictionary matching, the acquired data at each pixel is matched to the dictionary entry which best matches the simulated sequence for a certain combination of T_1 and T_2 (and B_1 for the first dictionary matching step), to yield parametric maps. Because a Cartesian trajectory is used, only the simulated center of k-space is matched to the acquired signal.

Image post-processing, dictionary generation and feature extraction

The Multimapping post-processing steps are summarized in Figure 1. The Multimapping dictionaries (denoted as [lower value: step size: upper value]) are generated by simulating the pulse sequence using the extended phase graph (EPG) framework for ranges of T_1 , T_2 and B_1 . The RR-intervals are recorded for each scan and, along with the patient-specific trigger delays, used to simulate a subject-specific dictionary. Unlike previous similar dictionary-based cardiac mapping techniques, which uses spiral or radial sampling to measure the transverse magnetization (M_{xy}) for each RF-pulse in the mid-diastolic acquisition window, here a Cartesian trajectory is used which results in a single M_{xy} measurement per cardiac cycle. As a result, only the simulated M_{xy} for the corresponding center of k-space acquisition in the cardiac cycle is used for the dictionary. To avoid the 'curse of dimensionality' (16) which results in extremely long dictionary generation times, the radiofrequency B_1^+ field (B_1) is first estimated using a relatively coarse grid for T_1 [500:100:1500] and T_2 [40:30:140] and a B_1 range of [0.5:0.05:1]. The estimated B₁ is calculated as the mean B₁ in a manually selected region of interest (ROI) in the ventricular septum and is used as input for the more highly resolved T_1 and T_2 dictionaries. These dictionaries which are only partially resolved for T_1 and T_2 are generated separately, where each dictionary contain a highly resolved and a coarsely resolved parameter, to reduce dictionary generation time. For the in vivo experiments, the partially resolved T₁ dictionary (T₁ Dict_{PR}) has a T₁ range of [200:1:2500] and T₂ range of [20:30:150], and the partially resolved T_2 dictionary (T_2 Dict_{PR}) has a T_1 range of [200:50:2500] and T_2 range of [1:1:150]. The T₂ and T₁ time-steps for the T₁ Dict_{PR} and T₂ Dict_{PR}, respectively, were empirically determined to provide a reasonable trade-off between short processing time and low quantification error, using in vivo data from three healthy subjects. Details on this optimization are provided in Supporting Information Section 2. For the phantom experiments, the dictionary has a T₁ range of [1:10:2500] and T₂ range of [1:4:400]. MATLAB scripts for the dictionary generation and feature extraction can be downloaded from github, including example Multimapping source images from healthy subject one (https://github.com/Multimapping/Matlab_files).

Prior to dictionary matching, in vivo images are motion corrected using non-linear image registration to minimize respiratory or cardiac-induced motion. The motion correction procedure consists of a total variation regularization algorithm implementation with default parameters (31). A second processing step performs phase sensitive correction on the acquired images to determine the polarity of the signal (32). Dictionary matching is then performed using

the dot product between the dictionary entries and the motion and polarity corrected images, similar to previous dictionary-based techniques (23).

MRI experiments

All experiments were performed on a Philips 1.5T Ingenia scanner (Philips Healthcare, Best, The Netherlands) with a 28-channel cardiac coil. All subjects provided written informed consent and the study was approved by the local ethics committee. Imaging parameters for all experiments are outlined in the Multimapping pulse sequence section. Images were reconstructed on the scanner and transferred to an offline workstation with an Intel Core i7-8565U (1.80 GHz) processor and 16Gb RAM for post-processing using MATLAB (The MathWorks, Natick, MA). With this setup, the B₁ dictionary took approximately 10 seconds to generate, and T₁ Dict_{PR} and T₂ Dict_{PR} approximately 13 minutes in total.

Phantom studies

The International Society for Magnetic Resonance in Medicine/National Institute of Standards and Technology (ISMRM/NIST) phantom was scanned to evaluate any heart-rate dependency (33,34). Multimapping scans were performed with different heart-rates, from 40 bpm to 120 bpm with 20 bpm increments, to determine any heart-rate dependency. Reference T_1 and T_2 values were obtained using inversion recovery spin echo (IRSE) for T_1 , and multi-echo spin echo (MESE) for T_2 . Imaging parameters for the reference scans were: 2×2 mm spatial resolution, 10 mm slice thickness, 8 inversion times from 50 to 2000 ms, 7000 ms TR for the IRSE experiment, and 8 echoes with TR/TE/ Δ TE = 7000/15/15 ms for the MESE experiment. Only vials with T_1 and T_2 values within physiologically relevant ranges (50 ms to 2200 ms for T_1 and 5 to 400 ms for T_2) were considered. To evaluate agreement between reference T_1 and T_2 values in the phantom and those measured with Multimapping, correlation coefficients (\mathbb{R}^2) and normalized root mean square errors (NRMSE) were calculated.

Repeatability of the in vitro T_1 and T_2 quantification was assessed by performing a second Multimapping phantom experiment (Scan 2) two months after the experiments described in the previous paragraph. For this experiment, only a simulated heart rate of 60 bpm was performed and compared to the corresponding scan with the same simulated heart rate in the previous phantom experiments (Scan 1). Multimapping T_1 and T_2 values were compared between Scan 1 and Scan 2 by calculating R^2 and Bland-Altman analysis.

In vivo experiments

In vivo experiments were performed in 16 healthy subjects (11 male, age: 30 ± 5.3 years, heart rate: 65 ± 6.4 bpm), one patient with dilated cardiomyopathy (47-year-old male, heart rate: 61 bpm) and two patients with acute myocarditis (one 49-year-old female, heart rate: 44 bpm; one 41-year-old female, heart rate: 58 bpm). A Multimapping slice was acquired in mid-ventricular short axis view in all subjects. Additionally, 5(3b)3 MOLLI was acquired for comparison of T_1 values, while T_2bSSFP with 4 different T_2 weighting (0, 23, 46, and 70 ms echo times, three pause cardiac cycles between each image) was acquired to compare T_2 values. Both MOLLI and T_2bSSFP were acquired in the same mid-ventricular short-axis location as the Multimap slice with identical imaging parameters, apart from the flip angle which was 35° for MOLLI and T_2bSSFP . MOLLI used an adiabatic inversion pulse, identical to the one used for Multimapping, while the T_2prep module for T_2bSSFP was also the same as the one for Multimapping. Vendor-provided online curve fitting algorithms were used for parameter estimation of both MOLLI and T_2bSSFP . To assess in vivo intra-scan repeatability, Multimapping, MOLLI and T_2bSSFP were repeated in six of the healthy subjects in the same scan session, waiting approximately 10 minutes between the acquisitions.

The Multimapping B_1 maps were validated in three healthy subjects in which B_1 mapping was performed using the single-shot dual refocusing echo mode (DREAM) technique (35,36), in addition to the Multimapping technique. Details of the B_1 mapping validation experiments are provided in Supporting Information Section 3.

To compare Multimapping parameter maps to MOLLI and T₂bSSFP, ROIs were manually drawn in the T₁ and T₂ maps according to the 6 mid-ventricular segments of the American Heart Association (AHA) model (37). Additionally, measurements were performed across the entire mid-ventricular slice. Differences in mean values and standard deviations (spatial variability) were analyzed using pair-wise t-tests with significance threshold of P < 0.05.

To investigate the influence of the B_1 correction, T_1 and T_2 maps generated using B_1 estimated from an ROI in the septum were compared to maps generated without correction (B_1 =1). This comparison was performed by calculating the sum of squared differences (SSD) between the measured and the simulated signal with and without B_1 correction. B_1 was measured in the 6 AHA segments to evaluate homogeneity across the slice. The B_1 analysis was performed for all healthy subject datasets.

Results

Phantom

Multimapping phantom measurements (Figure 2) showed good agreement with reference values for both T_1 and T_2 . There did not appear to be noticeable systematic errors in general for Multimapping T_1 or T_2 for the different heart-rates, although T_2 values above 120 ms were higher compared to reference values for heart-rates of 100 and 120 bpm. The R^2 between T_1 and T_2 estimated using Multimapping compared to reference values was above 0.99 for all simulated heart-rates. The T_1 NMRSE was largest for the heart-rate of 40 bpm at 4.2% with a range of 0.5% to 11.5%. The T_2 NMRSE was largest for the heart-rate of 120 bpm at 11.9% with a range of 2.4% to 32.9%. The T_1 and T_2 NMRSE and ranges for all simulated heart rates are summarized in Supporting Information Table S1.

Figure 2. T_1 and T_2 values measured with Multimapping in the ISMRM/NIST phantom and for different heart rates from 40 to 120 bpm, compared to reference values. A good agreement between reference and Multimapping T_1 was found without any discernable heart rate dependency. A good agreement for T_2 was also found for values less than approximately 100 ms. A slight over-estimation for higher T_2 was observed. The images on the bottom row show Multimapping T_1 and T_2 maps for the ISMRM/NIST phantom T_2 slice for a simulated heart rate of 60 bpm. Dictionary matching was only performed for the T_1 range of 50 to 2500 ms and a T_2 range of 5 to 400 ms which means that not all vials could be visualized.

Repeatability assessment of Mutimapping T_1 and T_2 quantification yielded a R^2 of more than 0.99 with no significant bias (T_1 bias = -1.1 ms, T_2 bias = -1.2 ms). The correlation and Bland-Altman plot from the phantom repeatability experiments are shown in Supporting Information Figure S7.

In vivo

Segment-wise B₁ measurements for all 16 healthy subjects are shown in Supporting Information Figure S8. The mean \pm standard deviation (SD) relative B₁ across all segments and subjects was 0.60 \pm 0.04 and the mean SD for each subject (intra-subject relative B₁ variability) was 0.02. An example demonstrating the usefulness of B₁ correction for Multimapping is shown in Figure 3. The figure shows in vivo T₁ and T₂ maps from one healthy subject incorporating B₁ measured in the septum, with lower difference between measured and simulated signal compared to no B₁ correction (B₁ = 1). The mean \pm SD sum of squared distance of the simulated and measured magnetization (in M_{xy}/M₀) for the myocardium in the healthy subjects using B₁ correction was 0.0035 \pm 0.0012, significantly smaller than for no B₁ correction (0.010 \pm 0.0022; *p* < 0.0001). Without B₁ correction the mean T₁ across all 16 healthy subjects was 1128 \pm 20 ms and T₂ was 57.5 \pm 3.4, significantly higher than with B₁ correction (T₁ = 1114 \pm 14 ms, *p* < 0.01; T₂ = 47.1 \pm 1.3 ms, *p* < 0.01).

Figure 3. Multimapping parameter maps from one healthy subject using B_1 optimized from a septal region-of-interest and applied to the T_1 and T_2 dictionaries (top row). The Multimapping B_1 map was first calculated using dictionary matching from coarsely sampled T_1 and T_2 in the range of native myocardium. For comparison, T_1 and T_2 maps were generated without B_1

correction ($B_1=1$), shown in the bottom row. Pixel-wise sum of squared distance (SSD) between simulated and measured signal is lower for the B_1 optimized simulations compared to simulations using $B_1=1$, suggesting systematic errors caused by B_1 is reduced.

Multimapping T_1 and T_2 maps generated with and without respiratory motion correction are shown in Supporting Information Figure S9 from the healthy subject with the largest respiratory motion amplitude. Representative Multimapping T_1 and T_2 maps for two healthy subjects are shown in Figure 4, along with MOLLI and T₂bSSFP for comparison. Comparable image quality between the Multimapping images and reference techniques can be observed. Bullseye plots of the group mean T_1 and T_2 measurements for the healthy subjects are shown in Figure 5, including segmental and global measurements. Group-wise mean T₁ for the entire slice was significantly higher using Multimapping ($T_1 = 1114 \pm 14$ ms) compared to MOLLI ($T_1 = 991 \pm$ 26 ms; p < 0.01). Furthermore, group-wise mean Multimapping T₂ (47.1 ± 1.3 ms) was significantly lower compared to T₂bSSFP for the entire slice (T₂ = 54.7 \pm 2.2 ms; p < 0.001). Bland-Altman plots of myocardial T₁, blood T₁ and myocardial T₂ for the entire slice from Multimapping, MOLLI and T_2 bSSFP are shown in Figure 6. Bullseve plots of the T_1 and T_2 mean spatial variability for Multimapping and reference techniques are shown in Figure 7. There was no difference in T_1 spatial variability between Multimapping (63.5 ± 12.8 ms) and MOLLI (66.1 \pm 15.4 ms) for the entire slice (p = 0.62). However, T₂ spatial variability was significantly lower for Multimapping $(5.8 \pm 1.0 \text{ ms})$ compared to T₂bSSFP $(8.4\pm 2.0 \text{ ms})$ for the entire slice (p < 0.01). A Multimapping source image, T₁ and T₂ map for one healthy subject are shown in Supporting Information Figure S10. Although T_1 and T_2 are homogeneous across the myocardium, quantification differences, particularly for T₂, can be observed for peripheral subcutaneous fat.

Figure 4. T_1 and T_2 Multimaps and reference maps for two healthy subjects. The image quality is similar for the Multimaps and reference techniques, with a slightly increased signal-to-noise ratio for the T_2 Multimap compared to the reference technique (T_2bSSFP).

Figure 5. Bullseye plots of the group-wise mean \pm standard deviation for the mean T_1 and T_2 measured in the mid ventricular slice for the 6 AHA segments and for the entire slice (in the center of each bullseye). Multimapping mean T_1 was higher compared to MOLLI T_1 , but T_2 was lower than T_2 bSSFP.

Figure 6. Bland-Altman plots comparing Multimapping to the in vivo reference techniques. The thick line indicates the bias and thin dashed lines the 95% limits of agreement.

Figure 7. Bullseye plots of the group-wise mean \pm standard deviation for the spatial variability (as measured with the standard deviation) of T_1 and T_2 measured in the mid ventricular slice for the 6 AHA segments and for the entire slice (in the center of each bullseye). Multimapping spatial variability for T_1 was similar as MOLLI, but T_2 spatial variability was lower than that of T_2 bSSFP.

Bland-Altman plots comparing the repeated Multimapping, MOLLI and T₂bSSFP scans in six healthy subjects, for the six AHA segments (and left ventricular blood pool for T₁), are shown in Figure 8. All techniques yielded biases less than 1 ms between the repetitions. However, the 95% limits of agreement were smaller for Multimapping T₁ (-24.7 to 26.3 ms) compared to MOLLI (-34 to 32.3 ms), and Multimapping T₂ (-1.6 to 1.6 ms) compared to T₂bSSFP (-2.9 to 2.4 ms).

Figure 8. Bland-Altman plots of repeated MOLLI, T_2 bSSFP and Multimapping scans from six healthy subjects with T_1 and T_2 measured for each of the 6 mid-ventricular AHA segments and left ventricular blood pool for T_1 .

 T_1 maps, T_2 maps and late gadolinium enhancement (LGE) images from the patient with dilated cardiomyopathy are shown in Figure 9. Septal T_1 and T_2 from the Multimap (which overlaps with a region of LGE) was increased in this patient compared to the values in the cohort of

healthy subjects. Increased T₁ but not T₂ was measured with the reference techniques, although the T₁ increase was more modest compared to the difference measured with Multimapping. Multimaps, reference maps and LGE images for the 49-year-old patient with acute myocarditis (Figure 10) reveal an area of acute inflammation in the anterior segment. Multmapping T₁ in this area was 1373 ms, compared to 1111 ms in the inferolateral segment without enhancement. Corresponding MOLLI T₁ was 1267 ms in the anterior segment, and 1004 ms in the inferolateral segment. Multimapping T₂ was 72.9 ms and 46.4 ms in the anterior and inferolateral segments, respectively. Corresponding T₂bSSFP T₂ was 82.5 ms and 57.3 ms, respectively. Multimaps, LGE and short tau inversion recovery (STIR) images for the 41-year-old patient with acute myocarditis are show in Supporting Information Figure S11. In this patient the T₁ and T₂ values were significantly increased globally. However, due to the diffuse and global nature of the disease in this patient, myocardial contrast agent uptake was relatively difficult to appreciate in the T₁-weighted LGE images, while the T₂-weighted STIR images also yielded an apparent constant signal which was only borderline pathological (signal intensity ratio of myocardium versus skeletal muscle = 2.0).

Figure 9. Multimap, reference maps and a late gadolinium enhancement (LGE) image for the patient with dilated cardiomyopathy. T_1 and T_2 measured with Multimapping in the septal area with LGE is increased compared to the ranges measured in the healthy subjects for T_1 and T_2 . For the reference techniques, a modest T_1 increase is measured with MOLLI, but T_2 measured with T_2 bSSFP is within the normal range.

Figure 10. Multimaps and reference T_1 and T_2 maps for the 49-year-old patient with acute myocarditis. An area of acute inflammation is seen in the anterior segment (arrows) in the T_1 and T_2 maps and LGE image.

Discussion

In this work, the single-shot Cartesian Multimapping technique was proposed for simultaneous myocardial T_1 and T_2 mapping using dictionary-matching. Multimapping yields generally accurate T_1 and T_2 times independently of the heart rate, as demonstrated in the phantom study. Studies in healthy subjects showed consistently different T_1 and T_2 values between Multimapping and reference techniques, although particularly for T_1 this is to be expected due to the known bias of MOLLI which underestimates T_1 (11,38).

Inversion pulses and T_2 prep modules are frequently used for myocardial mapping techniques to provide T_1 and T_2 sensitization, respectively. The configuration of these pulses may be modified and optimized to increase accuracy and precision (30,39). A number of Multimapping embodiments were investigated in simulations and in vivo, all restricted to 10 cardiac cycle acquisitions, but with different inversion and T_2 prep settings. There was a good agreement between simulation and in vivo results, showing that the highly T_1 sensitized approach fared better for T_1 quantification, while T_2 quantification suffered. Conversely, sensitizing primarily for T_2 yielded good T_2 quantification at the expense of T_1 . The 'balanced' approach with two inversion pulses and three T_2 prep modules appears to provide a good tradeoff between T_1 and T_2 quantification error. Nevertheless, this small optimization study was limited in scope and extent. Further experiments, using a more exhaustive range of Multimapping embodiments should be considered, which could also include using different or varying (between images) flip angles.

An assumption of the proposed Multimapping approach is that the B_1 field is homogeneous and can be represented by an ROI in the septum. Evaluation of B_1 across the healthy subjects scanned in this study and using a reference B_1 mapping technique suggests this is a valid assumption, with little variation across the left ventricle. However, the inter-subject B_1 variability was significant and approximately twice as large as the intra-subject variability, which justifies the use of a subject-specific B_1 determination rather than an empirically determined B_1 for all subjects. Incorporating subject-specific B_1 in the proposed fashion, as a pre-processing step, reduces the computational complexity of the dictionary matching, keeping the generation times low while avoiding overfitting the data and reducing precision. However, further studies are required to evaluate if this approach is valid in a more varied cohort of subjects, across vendor platforms, and importantly at different field strengths. Field inhomogeneity is typically more pronounced at 3T and an alternative strategy may be needed to ensure accurate quantification. Furthermore, the need for manual interaction to define the septal B₁ measurement is an obvious limitation of the technique, but one which could be solved using automation (40). Signal variations caused by B₀ inhomogeneities were also not considered in this work. The bSSFP technique used for Multimapping image acquisition is sensitive to B₀ field inhomogeneities, which may affect quantification. This was seen particularly in the image periphery, where B₀ is less homogeneous and T₂ quantification of subcutaneous fat yielded differences of approximately 40% (Supporting Information Figure S10). However, myocardial T₁ and T₂ did not suffer noticeably from such spatial variability, as very similar T₁ and T₂ was measured across the myocardium in the healthy subjects. Again, B₀ inhomogeneity is likely a greater source of errors at 3T, and strategies to mitigate against this should be considered such as including B₀ in the dictionary matching or using a spoiled gradient echo readout.

The emphasis of this work has been to develop a dictionary-based cardiac parameter mapping technique, similar to previously proposed cardiac MRF, but without the requirement for complex and time-consuming post-processing. This may potentially lower the barrier for clinical adoption of simultaneous multi-parametric mapping. Previous efforts in cardiac parameter mapping (particularly T₁ mapping) has resulted in standardized imaging parameters with the aim of producing comparable quantification across platforms, and this could be readily translated to Multimapping which uses a nearly identical Cartesian bSSFP image acquisition scheme. A long-standing challenge in conventional T_1 and T_2 mapping, where mapping is performed as separate scans, is the relatively large inter-subject variability of the quantification. Although some of this variability may be attributed to factors such as age, sex or even hydration status (41,42), T_1 mapping may be confounded by T_2 effects, particularly if bSSFP readouts are used, and vice-versa T_2 mapping can be confounded by T_1 differences in tissue (43). An advantage of simultaneous T₁ and T₂ mapping such as Multimapping is that these confounders are minimized as they are both included in the signal model. This may explain why the intersubject variability of both T₁ and T₂ for Multimapping were lower than for the reference in vivo techniques.

Although the mean Multimapping T_1 of 1114 ms was higher than for MOLLI, it is still just under 100 ms shorter than reported values in what is considered accurate techniques such as SASHA or SAPPHIRE at 1.5T (44,45). Correction for sources of systematic errors such as slice profile correction may yield T_1 values in a similar range, and will be the focus of future work. Nevertheless, the in vivo precision of Multimapping for quantifying myocardial T₁, as indicated by the spatial variability, was comparable to MOLLI, which is considered the most precise of the widely used T_1 mapping methods (11). There are several factors which influence the precision of a cardiac T₁ mapping method, including which kind of pre-pulse is used (inversion or saturation) and how many source images are used for the curve fitting or dictionary matching procedure (11,46–48). In both these aspects MOLLI and Multimapping are very similar, which could explain the near equivalence in T₁ precision. For T₂, there was a significant difference in mean values between Multimapping and the reference technique of -7.6 ms. There is less consensus regarding the true T₂ for healthy myocardium at 1.5T, which ranges from approximately 46 to 58 ms, depending on the technique or vendor used (49-52). However, for previous comparable cardiac MRF techniques, T₂ values in the range of 41 to 45 ms have been reporter (28,53–55), which is lower than the T_2 observed with Multimapping of 47.1 ms. Compared to T_2 bSSFP, Multimapping produced T_2 maps with significantly less spatial variability. Similar as for T₁ mapping, T₂ precision for T₂bSSFP is related to the number of source images used which is typically limited by the need for long waiting times to allow for near complete T₁ recovery between image acquisitions (56). The lower spatial variability of Multimapping T_2 may be explained by the use of more images for the mapping procedure. While T₂bSSFP only used four source images for the fitting, 10 images were used for Multimapping. Even if only three cardiac cycles were preceded by T₂-preparation to increase T_2 sensitization in the Multimapping pulse sequence, the bSSFP readout itself provide T_2/T_1 contrast which is exploited by the dictionary-based Multimapping technique but not with T₂bSSFP (57).

The ability of Multimapping to detect pathological changes in T_1 and T_2 was demonstrated in three patients, one with dilated cardiomyopathy and two with acute myocarditis. In all cases a significant increase in T_1 and T_2 , well above the healthy ranges, was observed. This finding is consistent with previous studies using mapping techniques in these patient cohorts (58–60). Although a similar increase was also found using the reference techniques in both patients with acute myocarditis, T_2 bSSFP did not find a significant T_2 increase in the patient with dilated cardiomyopathy compared to the healthy subjects. Further studies are ongoing in patients with various cardiovascular diseases to compare Multimapping parameter values to clinical reference techniques and values obtained in healthy controls.

Long dictionary generation times is a significant impediment to the integration of dictionarybased techniques into the clinical workflow (25). To limit dictionary generation times while providing T_1 and T_2 maps with high parameter granularity, an approach using partially resolved dictionaries was proposed in this study. Comparison with a reference dictionary showed that this can be a practical solution to this problem, as T_1 and T_2 maps could be generated on a standard computer without optimized Matlab code within minutes, with excellent agreement for T_2 and good agreement for T_1 in the myocardium. Note, that this evaluation specifically considered native T_1 and T_2 for myocardium and may not be directly extended to tissues with other T_1 and T_2 values.

The proposed Multimapping technique shares similarities, but also has important differences compared to recent cardiac MRF techniques (27,28). Like cardiac MRF, inversion pulses and T_2 -preparation are combined in the same pulse sequence and are the primary sources of T_1 and T₂ sensitization, respectively. However, Multimapping does not suffer from the signal aliasing that is intrinsic to non-Cartesian MRF, which has some important implications. The number of data points that can be used to match measurements to simulations for each dictionary entry is smaller for the proposed Cartesian approach by nearly two orders of magnitude (10 measurements for Multimapping versus approximately 1000 for conventional cardiac MRF). Although the number of acquired images could be increased to mitigate against overfitting, this would either increase the breath-hold duration or require the use of free-breathing acquisition strategies (15,53). An advantage of avoiding signal aliasing in the measurements, particularly for cardiothoracic and abdominal application, is that tissue outside the ROI such as subcutaneous fat does not degrade the measurements. Solutions to this problem for cardiac MRF have relied on non-Cartesian multi-echo acquisition strategies which lowers the acquisition efficiency and requires more complicated reconstruction algorithms (26,28). A Cartesian dictionary-based technique similar to Multimapping, proposed by Kvernby et al. (29), uses a simpler Bloch equation formulation which is limited to spoiled gradient echo readouts and has a signal-to-noise ratio penalty compared to the bSSFP readout used in this study. Another comparable Cartesian dictionary-based technique using EPG simulations to enable bSSFP readouts was recently proposed for T_2 mapping of the prostate (61), which uses a segmented k-space acquisition but demonstrates the feasibility of this approach. Finally, a dictionary-based Cartesian approach for myocardial T₁ and T₂ mapping was recently proposed by Milotta et al. using EPG simulations to generate the dictionaries (39). However, that study used a spoiled gradient echo, segmented k-space trajectory acquired during free breathing which combines data across multiple cardiac cycles which are subject to variability and susceptible to cardiac and respiratory motion artifacts. Conversely, the proposed approach uses

a bSSFP single-shot trajectory acquired in a breath-hold, where the inversion delays and timings are tailored and specific to each image to account for heart rate variability or arrhythmia.

This study has several limitations. Only a small number of healthy subjects and a few patients were included in this study to demonstrate proof-of-concept. Larger studies in healthy subjects and patients with cardiovascular disease are required to establish quantification ranges to discriminate between healthy and diseased myocardium. A very limited in vivo intra-scan repeatability evaluation was performed in this study and a more extensive evaluation, including reproducibility and inter-scan repeatability, is required to comprehensive assess its clinical potential. Although the reference techniques included in this study, MOLLI and T₂bSSFP, may be considered the most clinically used and relevant, there are alternative mapping techniques which provide improvements in accuracy or precision which may be more appropriate reference techniques to assess these important quantification error metrics (44,49,62–64). The phantom used for in vitro experiments covers a wide range of T_1 and T_2 , including those of pre- and postcontrast myocardium and blood. However, the phantom does not include the specific T_1/T_2 (~1200/50 ms) combinations found in the myocardium, which may have implication for assessing the accuracy of myocardial T₁ and T₂ quantification. In vitro studies using phantoms with similar T_1/T_2 combination as the myocardium will be performed in the future (65). Correction for confounders such as slice profile, inversion imperfections or B₁ were not considered in this work. Previous studies using MRF have demonstrated how this may be incorporated into the dictionary to improve accuracy at the expense of increasing dictionary generation times (27,28,66,67). Although this could improve the accuracy of the technique, it may also reduce precision. This consideration, in addition to the desire to limit the dictionary generation time to a short duration, was the rationale for only including T_1 and T_2 in the main dictionaries. Further work will explore if accuracy can be increased without compromising on precision or post-processing durations, for example by using machine learning (68).

Conclusion

Multimapping allows simultaneous T_1 and T_2 mapping of the myocardium with a Cartesian trajectory, demonstrating good agreement with reference techniques in vitro and promising in vivo image quality and parameter quantification results. The post-processing time could be significantly reduced by generating partially resolved T_1 and T_2 dictionaries, and the Multimapping approach for acquisition and post-processing is well-suited for integration into clinical routine. Further studies using Mugltimapping in healthy subjects and patients with cardiovascular disease are warranted.

Data availability statement

To support the findings of the manuscript, all MATLAB source code for generating the Multimapping dictionaries and feature extraction are available at https://github.com/Multimapping/Matlab_files, including example Multimapping source images for one healthy subject.

Supporting Information 1: Magnetization preparation pulse optimization

Four embodiments of the Multimapping pulse sequence were implemented and evaluated to investigate the effects of different magnetization preparation configurations. MM NoPrep does not contain any pre-pulses which should yield poor T_1 and T_2 sensitivity. MM 3I-2T₂p, which is sensitized towards T_1 , consists of three inversion pulses spaced three cardiac cycles apart, with variable inversion times, followed by two cardiac cycles with T_2 prep echo times of 30 and 70 ms, respectively. The more T_2 -sensitized MM 1I-5T₂p consists of a single inversion pulse, in the second cardiac cycle, in order to sample the baseline magnetization in the first cycle. The five last cycles are acquired with different T_2 prep echo time, from 30 to 110 ms with 20 ms increments. MM 2I-3T₂p consists of two inversion pulses, spaced four cycles apart and with fixed delays. The last three cycles are acquired with T_2 prep with different echo times of 30, 50 and 70 ms, respectively.

Figure S1. Pulse sequence diagrams of different versions of the Multimapping techniques with variations of the magnetization preparation pulses (pre-pulses) to manipulate T_1 and T_2 sensitization. MM NoPrep does not contain any pre-pulses which should yield poor T_1 and T_2 sensitivity. MM 3I-2 T_2 p is particularly sensitized to T_1 and contain three inversion pulses at different inversion times and two T_2 preparation modules with echo times of 30 and 70 ms. MM 11-5 T_2 p is sensitized to T_2 and contains a single inversion pulse and five T_2 preparation modules, with echo times ranging from 30 to 110 ms with 20 ms increments. Finally, MM 2I-3 T_2 p aims to balance T_1 and T_2 sensitivity and consist of two inversion pulses and three T_2 preparation modules with echo times of 30, 50 and 70 ms.

Simulations were performed to compare the four candidate Multimapping pulse sequences using a numerical phantom, with T_1 and T_2 values of myocardium (T_1 =1200 ms, T_2 =50 ms) and blood (T_1 =1800 ms, T_2 =250 ms) modified for a field strength of 1.5T. The heart rate was set to 80 bpm. The root mean square error was calculated for the myocardium and used to compare

the simulated scans. Images from the numerical phantom, simulating the four candidate Multimapping pulse sequences, are shown in Figure S2. A high RMSE was found for MM NoPrep of 137 ms for T_1 and 25 ms for T_2 . While a low T_1 RMSE of 0.7 ms was measured for MM 3I-2T₂p, the T_2 RMSE was higher at 6.2 ms. Conversely, MM 1I-5T₂p yielded RMSE of 42 ms and 0.2 ms for T_1 and T_2 , respectively. MM 2I-3T₂p resulted in a T_1 and T_2 RMSE of 2.3 ms and 0.6 ms, respectively.

Figure S2. Simulations of the Multimapping pulse sequences illustrated in Figure S1 for a numerical phantom of the heart. Differences in configuration of inversion and T_2 preparation pulses lead to different root mean square errors (RMSE) for T_1 and T_2 of myocardium. A comparably low RMSE for both T_1 and T_2 is achieved using Multimapping MM 2I-3T₂p.

Three Multimapping pulse sequences (MM 3I-2T₂p, MM 1I-5T₂p, MM 2I-3T₂p) were performed in two healthy subjects to evaluate in vivo the influence of the different pre-pulse settings. MM NoPrep was not performed in vivo as it was considered unlikely to provide reasonable parameter maps. Multimapping T₁ and T₂ maps from one healthy subject comparing MM 3I-2T₂p, 1I-5T₂p and 2I-3T₂p are shown in Figure S3. A similar mean myocardial T₁ was measured for both MM 3I-2T₂p (subject 1=1099 ms, subject 2 = 1109 ms) and MM 2I-3T₂p (1097 ms, 1099 ms), but a higher myocardial T₁ was found for MM 1I-5T₂p (1158 ms, 1174 ms). In both subjects, a slightly lower myocardial T₁ spatial variability was found for MM 3I-2T₂p (50 ms, 41 ms) compared to MM 2I-3T₂p (65 ms, 43 ms), but both were much lower than MM 1I-5T₂p (82 ms, 65 ms). For mean T₂, there was no noticeable trend for higher or lower T₂ for any of the sequences. However, T_2 spatial variability was highest for MM 3I-2 T_2p (6.7 ms, 5.6 ms), and lowest for MM 1I-5 T_2p (4.9 ms, 4.4 ms), with MM 2I-3 T_2p in between (5.3 ms, 5.1 ms).

Figure S3. T_1 and T_2 Multimaps generated using the $3I-2T_2p$, $1I-5T_2p$ and $2I-3T_2p$ schemes in one healthy subject. $3I-2T_2p$ and $2I-3T_2p$ generate similar T_1 maps, although the latter scheme has a slightly higher spatial variability as indicated by the standard deviation. In comparison, $1I-5T_2p$ yields higher myocardial mean T_1 and spatial variability. Mean T_2 was approximately the same for all schemes, while T_2 spatial variability was highest for $3I-2T_2p$ and lowest for $1I-5T_2p$.

Supporting Information 2: Partial dictionary error versus processing time

To minimize the processing time for the scan specific T_1 and T_2 dictionaries, partially resolved dictionaries were generated which had a highly resolved and a coarsely resolved T_1 or T_2 component. Using a highly resolved dictionary for both T_1 and T_2 that were simulated for three healthy subjects as references, normalized root mean square errors (NMRSE) for partially resolved dictionaries with different ΔT_1 and ΔT_2 time steps were calculated. For the partially resolved T_1 dictionaries, ΔT_2 steps from 10 to 50 ms with 10 ms increments were evaluated. For the partially resolved T_2 dictionaries, ΔT_1 steps of 10, 25, 50, 100 and 200 ms were evaluated. NMRSE was calculated for each pixel in the myocardium of the three T_1 and T_2 datasets, considering the difference between maps from the reference dictionaries and the partially resolved dictionaries and normalized by the expected T_1 (1100 ms) and T_2 (48 ms). The mean NMRSE was averaged across the myocardium for each subject and the final NMRSE for each time-step was the average across the three subjects. The highly resolved T_1 and T_2 reference dictionary had T_1 and T_2 ranges centered around healthy myocardium (900 to 1500 ms for T_1 and 20 to 80 ms for T_2) to minimize computational time and memory requirements. All processing was implemented in MATLAB (The MathWorks, Natick, MA) and performed on an Intel Core i7-8565U (1.80 GHz) processor with 16Gb RAM. The dictionary generation time was recorded for all partially resolved dictionaries. For both partially resolved T_1 and T_2 dictionaries a NRMSE less than 0.5% for either parameter was considered acceptable. As shown in Figure S1, this corresponds to ΔT_2 =30 ms for the T_1 Dict_{PR} and ΔT_1 =50 ms for the T_2 Dict_{PR}. With these settings the T_1 Dict_{PR} takes approximately 460 seconds and the T_2 Dict_{PR} approximately 310 seconds to generate.

Figure S4. Normalized root mean square error (NRMSE) versus processing time for the T_2 partial dictionary (left) and NRMSE versus processing time for the T_1 partial dictionary (right).

Supporting Information 3: B₁ mapping validation

To validate the Multimapping B_1 maps, additional reference B_1 maps were acquired in three healthy subjects using the dual refocusing echo mode (DREAM) technique (1,2). The DREAM scan was acquired using an ECG-triggered Cartesian 2D single-shot trajectory with 8 averages in the same mid-ventricular location as the Multimapping slice. Two 60° pulse, spaced 5 ms apart, preceded the image acquisition, which consisted of dual echo readouts to separate the free induction decay and the stimulated echo components. Other imaging parameters were: field-of-view = 350×350 mm, spatial resolution = 4×4 mm, slice thickness = 10 mm, flip angle = 20°, bandwidth = 721 Hz/pixel, TR/TE₁/TE₂ = 5.3/1.6/3.1 ms, SENSE factor = 2. The acquisition time for each single-shot image was 200 ms, and triggered to coincide with the middiastolic rest period. DREAM B₁ maps were generated using a vendor-provided algorithm (2). Mean B₁ was measured in the Multimapping and DREAM maps according to the 6 AHA segments, as well as across the entire slice.

Example Multimapping and DREAM B_1 maps from one healthy subject are shown in Figure S5.

Figure S5. Example Multimapping and dual refocusing echo mode (DREAM) B_1 maps from one healthy subject. Note, B_1 cannot be accurately estimated in the blood pool for Multimapping due to significant through-plane blood flow.

The B_1 measurements for all segments and subjects are shown in Figure S6. Multimapping B_1 is in good agreement with DREAM and provide maps within 0.1 relative B_1 for 14 out of 18 (78%) analyzed segments. Differences in septal B_1 are all within 0.08 relative B_1 suggesting this is a preferable location to estimate B_1 . Finally, mean intra-subject relative B_1 variability, defined as the mean standard deviation between segments for the three subjects, was 0.046 for DREAM, indicating that B_1 is homogeneous across the slice. These findings justify the use of a septal measurement to estimate B_1 for the entire slice for Multimapping.

Figure S6. Multimapping and DREAM relative mean B_1 for the three subjects (S1-3).

Figure S7. Correlation and Bland-Altman plots for the phantom T_1 *and* T_2 *repeatability experiments.*

Figure S8. Mean relative B_1 for all 16 healthy subjects using Multimapping for the 6 mid-ventricular AHA segments (A=anterior; AL=anterolateral; IL=inferolateral; I=inferior; IS=inferoseptal; AS=anteroseptal), and averaged across the slice.

Figure S9. Multimaps acquired in one healthy subject with substantial respiratory motion, generated with no motion correction (NMC), and with motion correction (MC) using nonlinear image registration. Improved sharpness can be noted in the septum of the motion corrected T_1 maps, while the removal of a motion-induced artifact in the anterior segment can be seen in the motion corrected T2 maps.

Figure S10. Multimapping source image, T_1 and T_2 map from one healthy subject showing differences in quantification of subcutaneous fat (arrows), which is particularly noticeable for T_2 . T_1 in the superior region-of-interest (orange arrow) was 298 ms, while T_1 in the inferior region-of-interest (blue arrow) was 320 ms. T_2 in the corresponding regions were 112 ms and 78 ms, respectively.

Figure S11. T_1 and T_2 Multimaps, late gadolinium enhancement (LGE) and short tau inversion recovery (STIR) in the 41-year-old patient with acute myocarditis. Significant increases in T_1 and T_2 were seen throughout the myocardium, particularly in the inferolateral segment as shown in the bullseye plots on

the right. The LGE images indicate gadolinium uptake in the myocardium, although it is relatively diffuse, while the STIR (image intensity ratio = 2.0) is borderline suggestive of edema.

Heart rate (bpm)	T ₁ NMRSE (%) mean [min max]	T ₂ NMRSE (%) mean [min max]
40	4.2 [0.5 11.5]	6.2 [0 15.2]
60	2.9 [0 7.6]	6 [0 15.4]
80	2.6 [0 7.1]	10 [2.5 20.7]
100	2.6 [0.3 6.4]	7.7 [0 18.5]
120	2.4 [0 6.4]	11.9 [2.5 32.9]

Table S1. Normalized mean root square error (NMRSE) for T_1 *and* T_2 *in the phantom scans.*
