The first achievement of quantum supremacy has been claimed recently by Google for the random quantum circuit benchmark with 53 superconducting qubits. Here, we analyze the randomness of Google’s quantum random-bit sampling. The heat maps of Google’s random bit-strings show stripe patterns at specific qubits in contrast to the Haar-measure or classical random-bit strings. Google’s data contains more bit 0 than bit 1, i.e., about 2.8% difference, and fail to pass the NIST random number tests, while the Haar-measure or classical random-bit samples pass. Their difference is also illustrated by the Marchenko-Pastur distribution and the Girko circular law of random matrices of random bit-strings. The calculation of the Wasserstein distances shows that Google’s random bit-strings are farther away from the Haar-measure random bit-strings than the classical random bit-strings. Our results imply that random matrices and the Wasserstein distance could be new tools for analyzing the performance of quantum computers.

Quantum computers could simulate nature better than classical computers, as Feynman initiated the idea of quantum computing [1]. Quantum supremacy [2, 3] that a quantum computer could perform certain computational tasks exponentially faster than a classical computer, is one of key milestones in developing practical quantum computers. The power of a quantum computer is believed to stem from its quantum nature such as interference, entanglement, and a large Hilbert space growing exponentially with the number of qubits. The speed-up of quantum algorithms such as Shor’s factoring algorithm [4] or the Harrow-Hassidim-Lloyd algorithm for solving linear systems of equations [5] requires a large-scale and error-corrected quantum computer. With noisy-intermediate scale quantum computers available these days, quantum sampling algorithms are considered good candidates to demonstrate quantum supremacy or quantum advantage [6].

Recently, the achievements of quantum supremacy for quantum sampling algorithms on noisy intermediate scale quantum computers have been reported. In 2019, Google team [7] claimed the first quantum supremacy by implementing random quantum circuits on 53 superconducting qubits. More recently, Wu *et al.* performed the random quantum circuits with 56 superconducting qubits [8]. In 2020, Zhong *et al.* [9] reported the quantum advantage in the Gaussian boson sampling on linear optical quantum computers. The boson sampling task is to sample bit strings from the probability distribution of bosons, given by the permanent of a unitary operator [10, 11].

Google’s quantum supremacy benchmark task is to generate random bit-strings by applying random quantum circuits on qubits followed by the measurement. The probability distribution of random bit-strings generated by random quantum circuits is not given by a

uniform random distribution, but obeys the eigenvector distribution of a circular unitary ensemble [12, 13]. Google’s Sycamore quantum processor could generate millions of these random bit-strings of size $n = 53$ in about 200 seconds, while a supercomputer with the currently known efficient classical algorithms would take much longer time [14, 15]. To verify that a quantum computer implements random quantum circuits correctly, the linear cross-entropy benchmark was introduced [7, 16]. The linear cross-entropy fidelity is calculated using a probability distribution obtained from a classical computer and output bit-strings of a quantum computer. Its value was slightly greater than the theoretical threshold. However, there are important questions unexplored whether Google’s quantum random bit-strings are truly random, or how far away Google’s random bit-strings are from classical random bit-strings or from the Haar-measure sampling. A rigorous analysis is needed to quantify the performance of quantum random circuits because random unitary dynamics is essential in chaotic scattering [17–21], quantum information processing [22], randomized benchmarking of noisy quantum gates [23–25], scrambling of information in black holes and quantum many-body systems [26, 27], and hydrodynamic simulation [28] in addition to the quantum supremacy benchmark test.

In this paper, we analyze the randomness of output bit-strings of random quantum circuits using the random matrix theory [21, 29, 30], the NIST random number test code [31], and the Wasserstein distance [32]. To compare with the dataset of Google’s quantum supremacy experiment, classical random bit-strings and the Haar-measure random bit-strings are generated. The heat map patterns of random bit-strings and the NIST random number tests will show the non-randomness of Google’s random bit-strings and uncover errors of Google’s random quantum circuits. The difference between Google’s and classical random bit-strings is illustrated by the positions of outliers of random matrices of random bit-strings. Finally, we’ll calculate the Wasserstein distance between various

data sets of random bit-strings. It will be shown that Google's random bit strings are farther away from the Haar-measure random-bit strings than the classical random bit-strings

Random Quantum Circuits

Let us start with a brief introduction to the random quantum circuit benchmark and how to verify its faithful implementation. The random quantum circuit benchmark starts with sampling a random unitary operator $U(2^n)$, then applying it on an input state $|0^n\rangle$ of n qubits and measuring the output state $|\psi\rangle = U|0^n\rangle$ in the computational basis $\{|x\rangle\}$ to generate the random bit string $x = a_0a_1\cdots a_{n-1}$ with $a_i \in \{0,1\}$. The probability of getting a random bit string x is given by $p_x \equiv |\langle x|\psi\rangle|^2 = |\langle x|U|0^n\rangle|^2$. By repeating this process M times, a $M \times n$ random-bit array is obtained.

The first key element of the random quantum circuit is how to draw unitary operators uniformly and randomly. Mathematically, this could be done with the Haar invariant measure on a $U(2^n)$ unitary group. The collection of these random unitary operators is called a circular unitary ensemble (CUE) introduced by Dyson [12]. The Haar-measure sampling of a unitary operator out of the unitary group is challenging. A unitary operator $U(2^n)$ can be decomposed into the $(2^n - 1)!$ product of 2-dimensional unitary transformations, called the Hurwitz decomposition [33, 34]. However, this decomposition requires a huge amount of gate operations: the number of 1 or 2-qubit gates is $n^2 \times 2^{2n}$ and the number of parameters is 2^{2n} . Emerson *et al.* [22] proposed a method of generating pseudo-random unitary operators: the quantum circuit of n random unitary rotations on single qubits with $3n$ parameters followed by the simultaneous two-body interactions on n qubits are repeated m times. On a classical computer, random unitary matrices can be generated by the QR decomposition of matrices with Gaussian random complex elements [35]. The QR algorithm needs $O((2^n)^3)$ floating point operations.

The second key element of the random quantum circuit is the statistical property of the probability p_x finding a qubit state in $|x\rangle$. Random unitary operators make qubit states distributed uniformly in a 2^n dimensional Hilbert space. So amplitudes c_x of $|\psi\rangle = \sum_x c_x |x\rangle$ may have the Gaussian distribution on the surface of a 2×2^n dimensional sphere. This leads to calculate the probability distribution $P(p)$ for the random variable p (dropping the subscript x of p_x)

$$P(p) = (N-1)(1-p)^{N-2}. \quad (1)$$

This is the chi-square distribution with 2 degrees of freedom $\chi_2^2(p)$, and known as the eigenvector distribution of a circular unitary ensemble [13, 17, 20]. For large N , it becomes $P(p) = Ne^{-Np}/(1-e^{-N}) \approx Ne^{-Np}$. Note that this should not be confused with the Porter-Thomas distribution $P_{PT}(q) = \frac{1}{\sqrt{2\pi Nq}}e^{-Nq/2}$ that is the eigenvector distribution of an orthogonal circular ensemble [7, 16, 20, 36, 37]. The expectation value of finding p

with respect to $P(p)$ is given by $1/N$. This is consistent with our intuition that classically the probability p_x of finding a bit string x out of N possible bit strings is $1/N$.

The last key element is to verify the faithful implementation of random quantum circuits. To this end, one has to estimate the empirical probability p_x of finding a random quantum state in $|x\rangle$ with $x = 0, \dots, 2^n - 1$ from the output data, a $M \times n$ random binary array. Then one has to construct an empirical probability $P_{em}(p)$ of probabilities p to compare it to the ideal probability $P(p)$ given by Eq. (1). For a small number of qubits, the Kullback-Leibler divergence or the cross entropy of $P_{em}(p)$ from $P(p)$ were used to measure how the probability distribution $P_{em}(p)$ is close to the ideal distribution $P(p)$ [16, 37].

However, in Google's quantum supremacy experiment with $n = 53$ qubits, the reconstruction of P_{em} was impossible because a few millions of random bit-strings is too small to estimate $p(x)$ with $x = 0 \sim 9 \times 10^{15}$. Instead, the linear cross-entropy fidelity $F_{XEB} = 2^n \cdot \frac{1}{M} \sum_{i=1}^M p(x_i) - 1$ is introduced [6, 7, 37–39]. Here, x_i are the observed bit strings and the probability $p(x)$ is calculated using the Schrödinger-Feynman simulation of a single random unitary operator for $n = 53$ on a supercomputer. A tricky point is that Google's experiment applied the same single random unitary operator, rather than the CUE, to get a few millions of random bit-strings and to calculate $p(x)$ on a supercomputer. If the CUE were used, $p(x)$ would be random and the linear cross-entropy would not be applied. Google obtained $F_{XEB} = 0.00224$ for $n = 53$ qubits.

Non-randomness of Google's Random Bit Strings

Google's measurement data sets [40] are the text files of $M \times n$ random-bit arrays labeled by five parameters: **n** the number of qubits from 12 to 53, **m** the number of cycles from 12 to 20, **s** a seed for the pseudo-random number generator, **e** the elided gate number, and the two types of coupler activation patterns (EFGH or ABCDCDAB). The numbers of measurements are $M = 500000, 250000$, or 3000000 . One example of Google's data file is `measurements_n53_m20_s0_e0_pABCDAB.txt`.

The measurement data, $M \times n$ random bit-strings, are the only information to tell whether the random quantum circuit benchmark was implemented properly on Google sycamore qubits. For comparison with Google's random bit-strings, we generate (i) random bit-strings sampled from a circular unitary ensemble, called the CUE random bit-strings or the Haar measure random bit-strings, and (ii) classical random bit-strings. The CUE random bit-strings are generated by the QR decomposition algorithm [35]. A random matrix A with complex elements sampled from the normal distribution is factored as $A = QR$, and then Q is a Haar measure unitary matrix. Due to the limited computing power of a personal computer, the CUE random-bit strings for $n = 12$ are generated using Python or Julia random matrix library [41]. The classical random bit-strings from $n = 12$ to $n = 53$ are sampled using the pseudo-random number

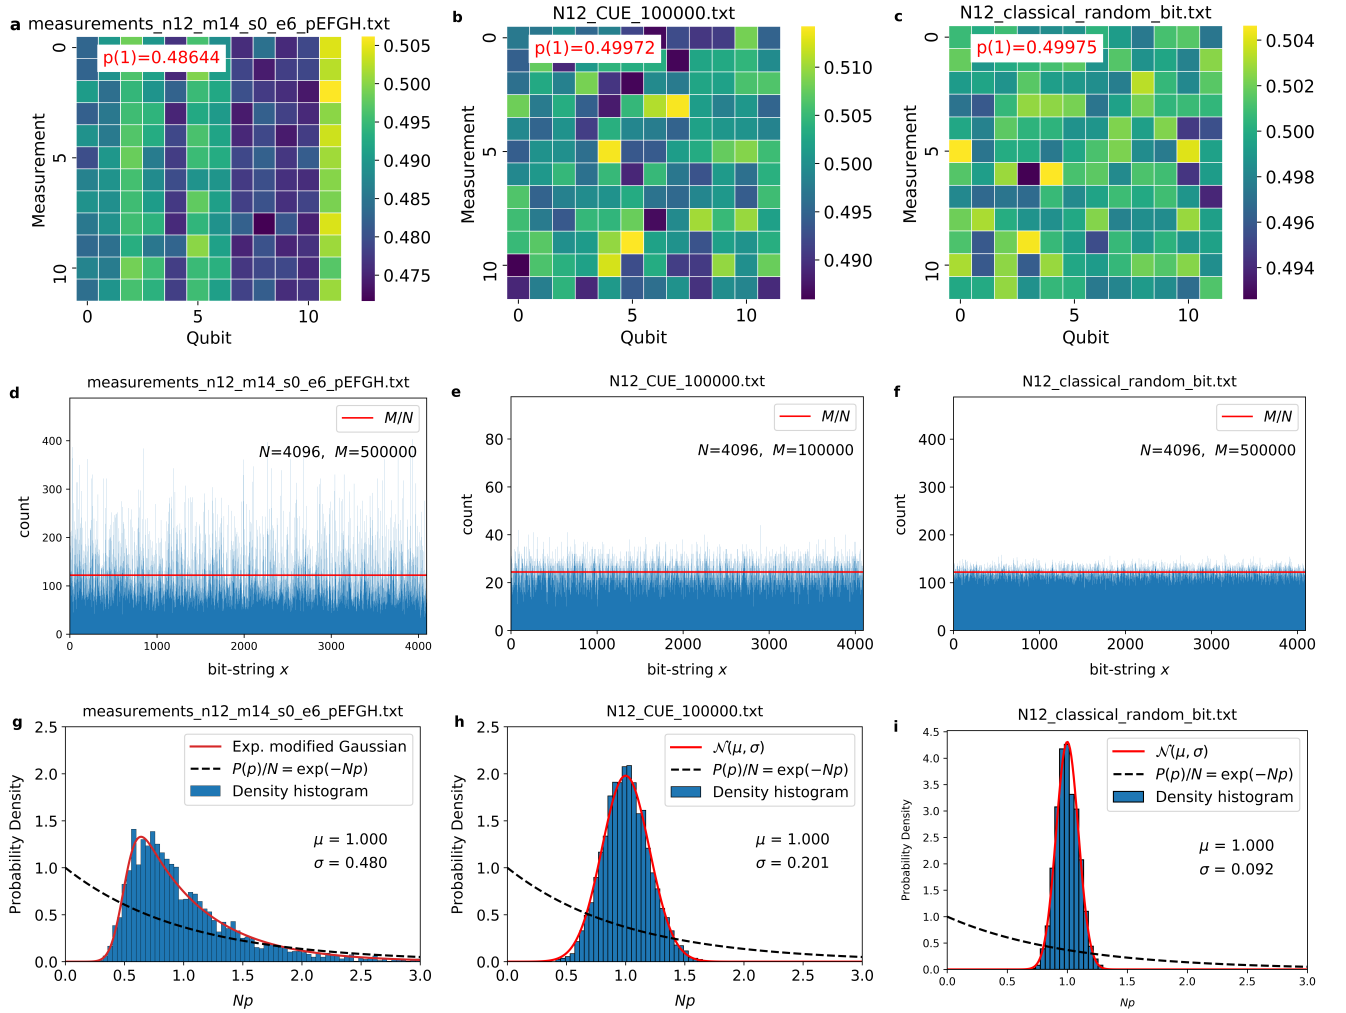

Figure 1. **Three kinds of random-bit strings.** The first, the second, and the third columns are figures for Google's random bit-strings circuits for $n = 12$ qubits and $M = 500000$, the CUE random bit-strings for $n = 12$ and $M = 100000$, classical random bit-strings for $n = 12$ and $M = 500000$, respectively. **a**, **b**, and **c** plot the heat maps for random bit strings. $p(1)$ represents the average of getting bit 1. **d**, **e**, and **f** are the histograms of bit-strings x as a function of x where $0 \leq x \leq N - 1$. Here the red lines are the average of p_x , $\bar{p} = M/N$. **g**, **h** and **i** plot the empirical probability density as a function of Np constructed from **d**, **e**, and **f**. The black lines plot Eq. (1), $P(p)$. The red lines are fitting curves. The exponentially modified Gaussian distribution has three parameters for location, scale, and shape. The normal distribution is denoted by $\mathcal{N}(\mu, \sigma)$ with the mean μ and the standard deviation σ .

generator on a personal computer. The Python scripts generating the CUE and classical random bit-strings are attached in Supplementary.

First, we plot the heat maps of random bit-strings as shown in Fig. 1. By slicing a $M \times n$ rectangular array of random bit-strings, $D = (x_1, x_2, \dots, x_M)^T$, the ensemble of $n \times n$ square random binary matrices $\{X_k = (x_{nk+1}, x_{nk+2}, \dots, x_{nk+n})^T\}$ is constructed. Here $x_i = a_1 a_2 \dots a_n$ is the i -th row of the random bit array D and $k = 0, 1, \dots, M/n - 1$. Figs. 1 (a), (b), and (c) show the heat maps of the average density matrix, $\mathbf{X} = \frac{n}{M} \sum_{k=0}^{M/n} X_k$ with $n = 12$ for Google, CUE, and classical random bit-strings, respectively. The heat maps for other Google samples from $n = 12$ to $n = 53$

and classical random bit-strings for $n = 53$ are shown in Figs. S2, S3, S4 in Supplementary. Surprisingly, all the heat maps of Google's data show the stripe patterns at some qubit indices, while the CUE and classical samples do not. As depicted Figs. S2, S3, and S4 in Supplementary, the two coupler activation types, EFGH and ABCDCDAB give rise to the different the bright and dark stripe patterns. For $n = 53$ and ABCDCDAB activation, the stripe patterns become more clear as the cycle number m increases. The total number of bit 1 of D is counted to calculate the average of finding bit 1, $p(1)$. As shown in Figs. 1 (a), (b), and (c), Google's random bit-strings show the value $p(1) \approx 0.486$, that is less than the expected value 0.5, while the CUE and classical random bit-strings have $p(1) \approx 0.499$ very close to 0.5. As shown in Figs. S2,

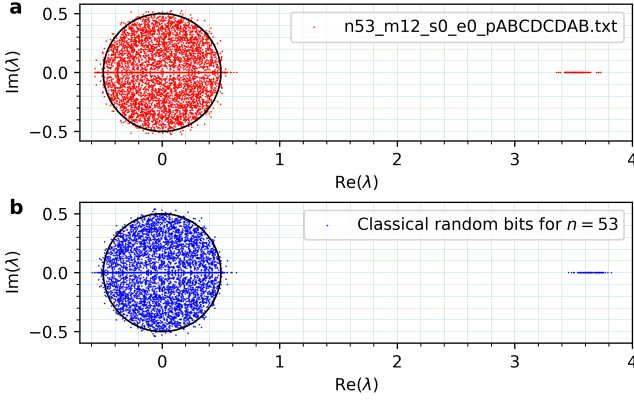

Figure 2. **Circle law of random matrices of random bit-strings.** The eigenvalue distributions of the $n \times n$ random bit matrices $\{X_k\}$ are shown for Google's random bit-strings **a** and for the classical random bit-strings **b** for $n = 53$. Only eigenvalues of 100 X_k samples are shown. The black circle is known as the Girko circle of the non-Hermitian Ginibre ensemble. The outliers far away from the circle are the real eigenvalues located between 3 and 4.

S3, S4, $p(1)$ for Google's random bit strings ranges from 0.483 to 0.489. The non-randomness of Google's random bit-strings can also be checked with a random number test, as well as the stripe patterns. We perform the NIST statistical random number tests [31, 42]. As shown in Table S1 in Supplementary, Google's quantum random bit-strings fail to pass some NIST random number tests, while the CUE and classical random bit strings pass. The failure of the NIST frequency test means Google's data has too many 0's. Also Google's data fail to pass some NIST tests. Thus, we demonstrate that Google's random bit-strings are not truly random in contrast to the CUE or classical random bit-strings.

Next, we calculate the empirical distributions $p_x = b_x/M$ for $n = 12$, where b_x counts the number of bit-strings with the value x and $0 \leq x \leq N - 1$ in decimal notation. As illustrated in Figs. 1 (d), (e), and (f), Google's random bit-strings fluctuate widely and the classical random bit-strings fluctuate a little. Using the empirical distribution $p(x)$, one can construct the three empirical probability distributions $P_{\text{Google}}(p)$, $P_{\text{CUE}}(p)$, and $Q_{\text{cl}}(p)$ to see they follow Eq. (1), the eigenvector distribution of the circular unitary ensemble, as shown in Fig. 1 (g), (h), and (i). All three distributions are different from the eigenvector distribution $P(p)$ of the CUE, Eq. (1). We leave the study of these discrepancies as an open question.

The difference between Google random bit-strings and the CUE or classical random bit-strings is further illustrated using the random matrix theory of the random binary matrices. The collection $\{X_k\}$ of $n \times n$ matrices X_k of random bit-strings can be regarded as a real Ginibre ensemble. It is well known that for random matrices with identically-and-independently matrix elements and zero

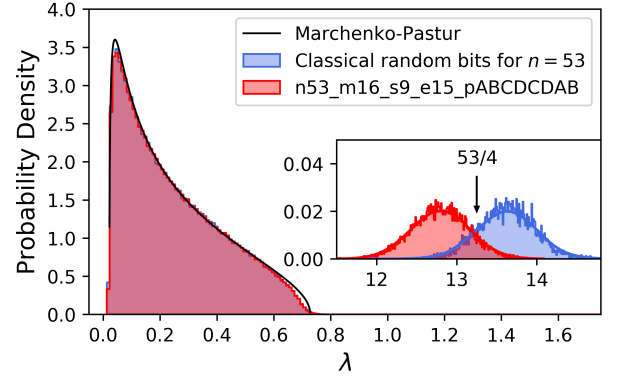

Figure 3. **Marchenko-Pastur distribution of the Wishart ensemble of random bit-strings.** The Marchenko-Pastur distribution of eigenvalues of Wishart ensembles for Google's random bit strings and classical random bit strings.

mean, the distribution of complex eigenvalues of random matrices follows the Girko circular law [30, 43]. However, random matrices formed by random bit strings here have the matrix element $x_{ij} \in \{0, 1\}$, so the mean of a matrix X is not zero. If x_{ij} are sampled identically and independently from the Bernoulli distribution, the mean of X could be $1/2$. We are interested in whether the mean of X generated by quantum random circuits is identical to $1/2$ or not.

The distribution of the complex eigenvalues of random matrices $\{\frac{1}{\sqrt{n}}X^{(k)}\}$ with $k = 1, \dots, 100$ are plotted in Fig. 2. Most eigenvalues of both Google and classical random matrices are distributed inside of the circle with radius $1/2$ and some outliers with large real eigenvalues are located outside the circle. As shown in Fig. 2 closely, the positions of outliers with large real eigenvalues of Google's random bit-strings are different from that of the classical random bit-strings. The radius $1/2$ and the outliers can be explained as follows. The matrix X with nonzero mean can be transformed to Z with zero mean by

$$Z = 2X - J, \quad (2)$$

where J is an all-one matrix. The ensemble of $n \times n$ real random square matrices (Z_k) with the matrix elements z_{ij} sampled identically and independently from the Bernoulli distribution with zero mean and unit variance. The complex eigenvalues of $\frac{1}{\sqrt{n}}Z$ are distributed uniformly in the unit circle. So the radius of the circle of the eigenvalue distribution of X is $1/2$. The Saturn-ring effect along the real line and the outliers shown in Fig. 2 are due to the fact that X and J are non-commutative.

Let us slice the $M \times n$ random bit-string array D into $p \times n$ rectangular binary matrices X where $p > n$. Then, the collection of $n \times n$ symmetric matrices $W = \frac{1}{p}X^t \cdot X$ is called the Wishart ensemble. It is known that if the elements of X are sampled identically and independently

from the normal distribution $\mathcal{N}(\mu, \sigma)$ with zero mean $\mu = 0$ and the variance σ^2 , the distribution of real eigenvalues of W is given by the Marchenko-Pastur distribution [44]

$$\rho(\lambda) = \frac{1}{2\pi\gamma\sigma^2} \frac{\sqrt{(\lambda_+ - \lambda)(\lambda - \lambda_-)}}{\lambda}, \quad (3)$$

where $\lambda_{\pm} = \sigma^2(1 \pm \sqrt{\gamma})^2$ are the upper and lower bounds and $\gamma = n/p$ is the rectangular ratio. Here we take $p = 1/2$. Fig. 3 plots the Marchenko-Pastur distributions of Google's and classical random-bit strings for $n = 53$. As shown in Fig. 3, the outliers outside the Marchenko-Pastur distribution distinguish Google's random bit-strings from the classical random bit-strings. With Eq. (2), W can be expressed as

$$W = \frac{1}{4p} (Z^t \cdot Z + Z^t \cdot J + J^t \cdot Z + J^t J). \quad (4)$$

Here the first term of Eq. (4) is be written as $\frac{1}{p} \frac{Z^t}{2} \cdot \frac{Z}{2}$, so $\frac{Z}{2}$ has zero mean and variance $\sigma^2 = 1/4$ while the variance of X is $\sigma^2 = 1/2$. This gives the upper and lower bounds, $\lambda_+ = 0.728$ and $\lambda_- = 0.021$, respectively. The last term of Eq. (4) becomes $\frac{1}{4p} (J^t)_{n \times p} \cdot (J)_{p \times n} = 1/4 (J)_{n \times n}$ where an all-one matrix J has the eigenvalue 0 and n . So the outliers are located around $53/4$.

How far away are they? – Wasserstein Distances

Up to now, we have shown (i) the non-randomness of Google's random bit-strings using the heat maps and (ii) the random matrix theory of random bit-strings can distinguish Google's data from the classical random samples. The final question we would like to address is how much Google random bit-strings are different from the CUE or classical random bit-strings. In Google's experiment, the cross entropy fidelity was used to measure how the real distribution is close to the ideal distribution. The disadvantage of the cross entropy is that it is not symmetric and gives rise to zero or diverge if there is no overlap between two distributions. To overcome these, we employ the Wasserstein distance of order 1, $W(p, q)$ between two discrete probability distributions, p_i and q_i ,

$$W(p, q) = \inf_{\lambda_{ij}} \sum_{i,j} \lambda_{i,j} |x_i - y_j|, \quad (5)$$

where λ_{ij} is the joint probability of x_i and y_j such that $\sum_i \lambda_{i,j} = q_j$, $\sum_j \lambda_{i,j} = p_i$, and $\lambda_{i,j} \geq 0$. Given two samples, $\{x_1, x_2, \dots, x_M\}$ and $\{y_1, y_2, \dots, y_M\}$, $W(p, q)$ can be obtained directly without calculating the empirical distributions p and q . We use the Python optimal transport library [45] for calculating the Wasserstein distance between two samples. Fig. 4 (a) plots the Wasserstein distances, normalized by N , between Google and classical random bit-strings as a function of n . For $n = 53$, Google samples with the activation pattern with EFGH are closer to the classical random bits than that with ABCDCDAB. For $n = 12$, we calculate the Wasserstein distance among all

Wasserstein distances b.t. classical and quantum random bit strings

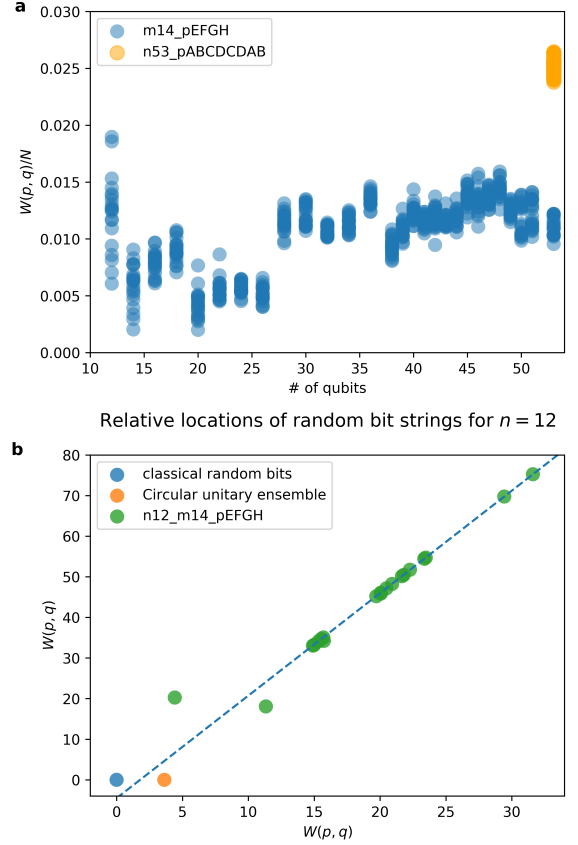

Figure 4. **Wasserstein Distances.** **a** The Wasserstein distances, divided by N , between Google's quantum random bit-strings and the classical random bit-strings are plotted as a function of the number of qubits, n . The blue and orange dots represent the activation patterns EFGH and ABCDCDAB, respectively. **b** For $n = 12$, All pairs of Wasserstein distances among Google, CUE, and classical random bit samples are calculated and their relative locations are plotted. For each sample, $M = 500,000$ is taken.

pairs of Google, CUE, and classical random bit-strings so their relative locations in the 2-dimension are displayed in Fig. 4 (b). It shows that Google random samples are farther away from the CUE random bit sample than the classical random bit sample. Also, all Google samples except 2 samples are fit to a straight line passing between the CUE and classical random bit samples.

Summary

In conclusion, we analyzed the randomness of Google's quantum random bit-strings generated by random quantum circuits. It is found that the heat maps of Google's data have the stripe patterns at specific qubit sites and contain more bit 0 than bit 1. This led to Google's data failing to pass the NIST random number tests. These non-randomness signatures of Google bit strings do not occur in the Haar-measure random sample or in the classical random bit-strings. The non-randomness of Google's data is caused by the errors of quantum gates

or by the readout errors. The random matrices of random bit-strings distinguish Google data from the classical random bit-strings. The calculation of the Wasserstein distance shows that Google random bits are farther away from the Haar measure sample than the classical random bit sample. The Wasserstein distance between two samples would be a simple and powerful tool of measuring the fidelity of quantum gates. The two activation patterns of Google's Sycamore qubits give rise to quite different results in the heat map of the bit strings and in the Wasserstein distances. Our findings imply that the random matrix analysis and the Wasserstein distance may be used as benchmark tools to measure the performance of intermediate scale quantum computers. The linear cross-entropy used in Google's supremacy experiment needs the classical simulation to calculate the probability $p(x)$ of finding a bit-string x . As the number of qubits increases, this classical simulation is very difficult. So one faces the dilemma of how to verify the performance of quantum computers using the linear cross-entropy [46]. The calculation of the Wasserstein distance requires only two data sets of bit-strings and do not need to estimate probability

distributions from the two data sets. Classical random bit-strings for one hundred qubits can be easily generated and the Wasserstein distance between the classical random bit-strings and the random bit-strings of random quantum circuits could be calculated.

SUPPLEMENTARY MATERIALS FOR “NON-RANDOMNESS OF GOOGLE’S QUANTUM SUPREMACY BENCHMARK”

A. Preparation of the data and the script files

The three kinds of random bit strings used in this study are prepared as follows.

- Google’s data for quantum supremacy benchmark test [40] is downloaded from the Dryad Digital Repository, <https://datadryad.org/stash/dataset/doi:10.5061/dryad.k6t1rj8>.
- The QR algorithm is used to perform the Haar measure sampling of unitary operators from $U(N)$. The Python script and the Julia script, `Haar.py` and `Haar.jl` were written. Due to the limit of the computational power of the PC (Intel Core i7-4790 CPU @ 3.60 GHz and 24 GB memory), it took about 7 days to sample 60000 random unitary operators using the QR algorithm for $n = 12$.
- The classical random bit strings are generated using a simple Python script, `Randbit.py`. The classical random bit array of the size $n = 53$ by $M = 500000$ is produced quickly within a few minutes on the PC.

B. Eigenvalue distributions of the Haar measure samples

Fig. S1 shows the eigenvalue distributions of $M = 1000$ Haar measure samples of $U(2^{12})$ generated by the QR algorithm.

Figure S1. Eigenvalue distribution of circular unitary ensembles

C. Heat maps of Google random bit-strings

Figs. S2 and S3 show the heat maps of Google’s data from $n = 12$ to $n = 53$ with the activation pattern EGGH. Figs. S4 depicts the heat maps of Google’s data for $n = 53$, the cycles $m = 12, 14, 16, 20$, and the activation pattern ABCDCDAB. The pictures are plotted by running the Python script, `Heatmap.py`, as follows

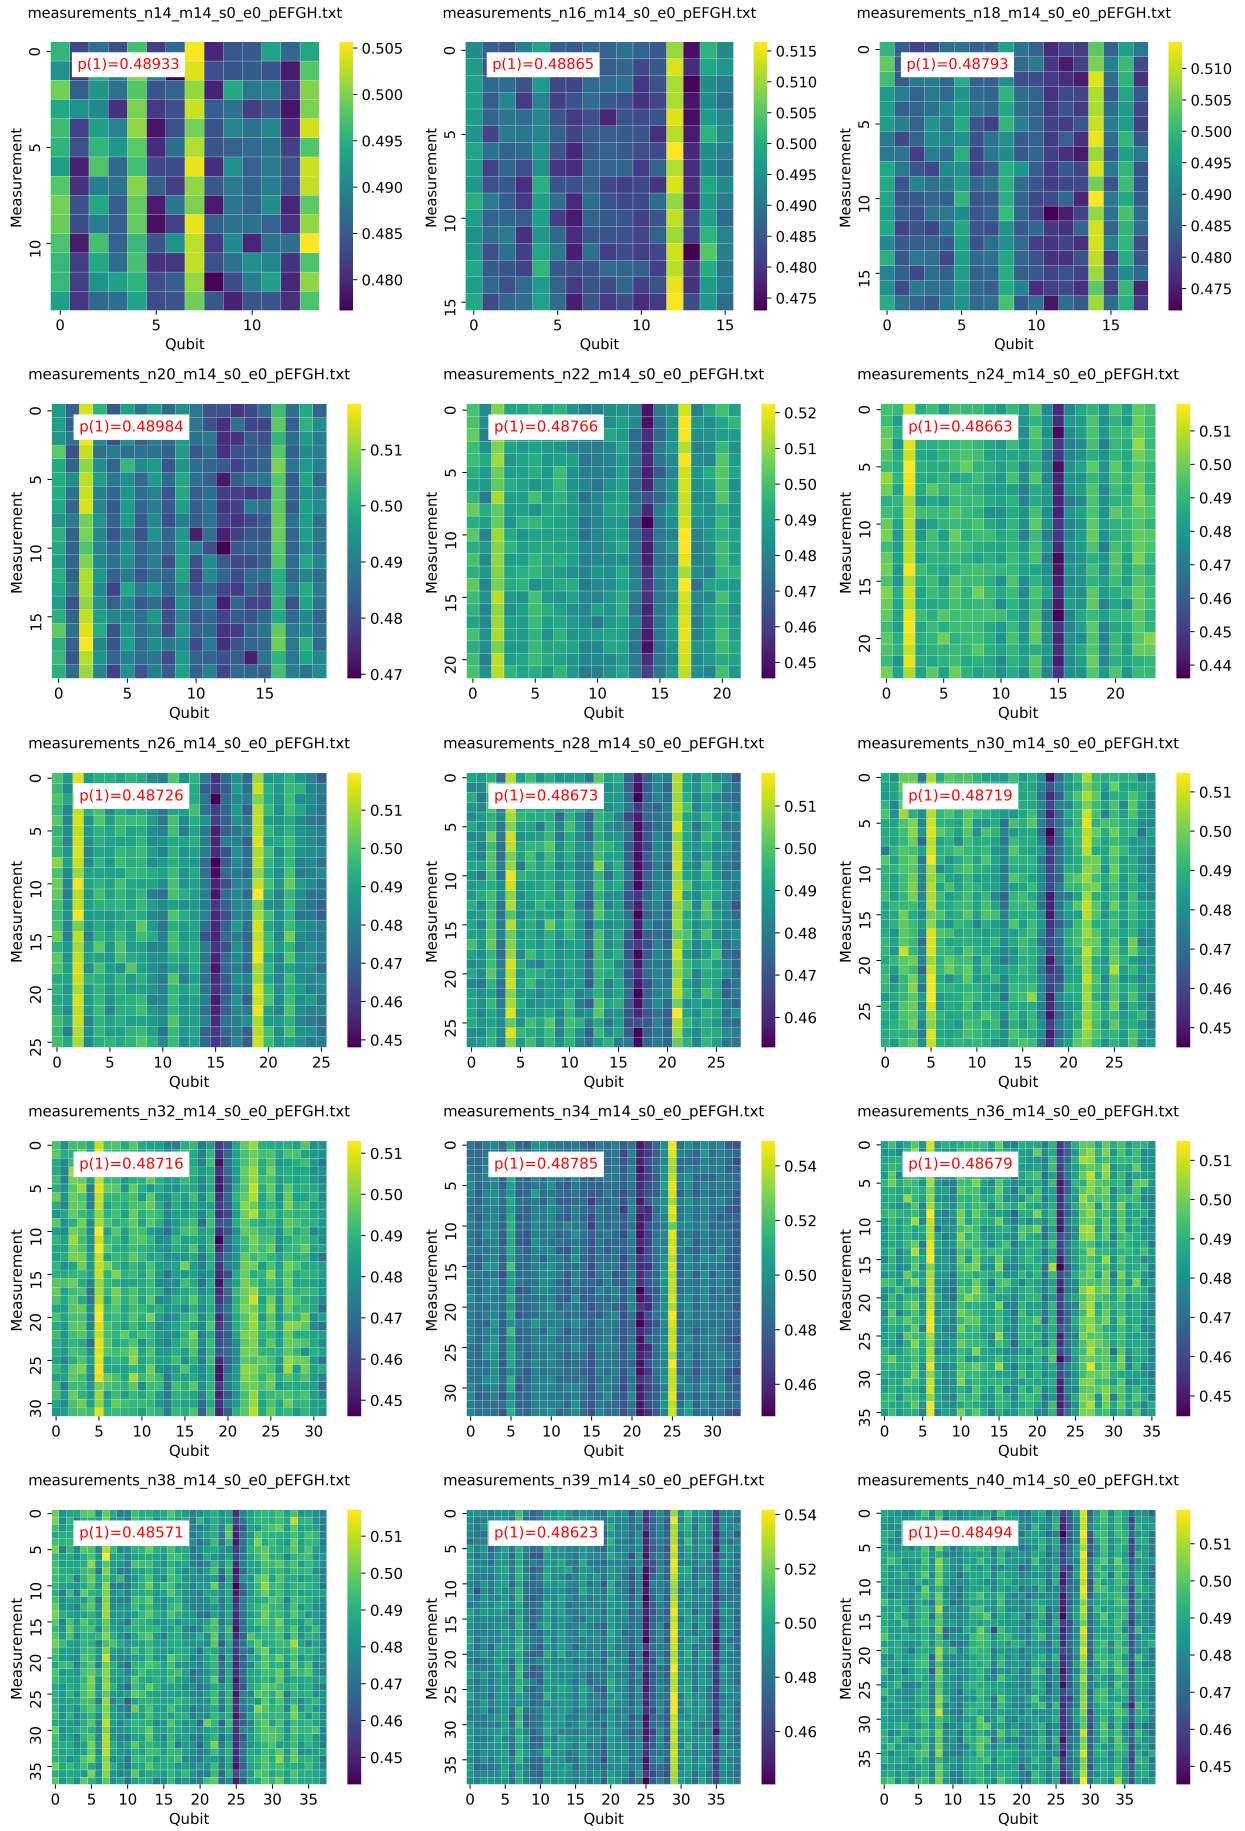

Figure S2. Heat maps of Google's random bit strings for $n = 14, 16, 18, 20, 22, 24, 26, 28, 30, 32, 34, 36, 38, 39, 40$ and EFGH activation pattern.

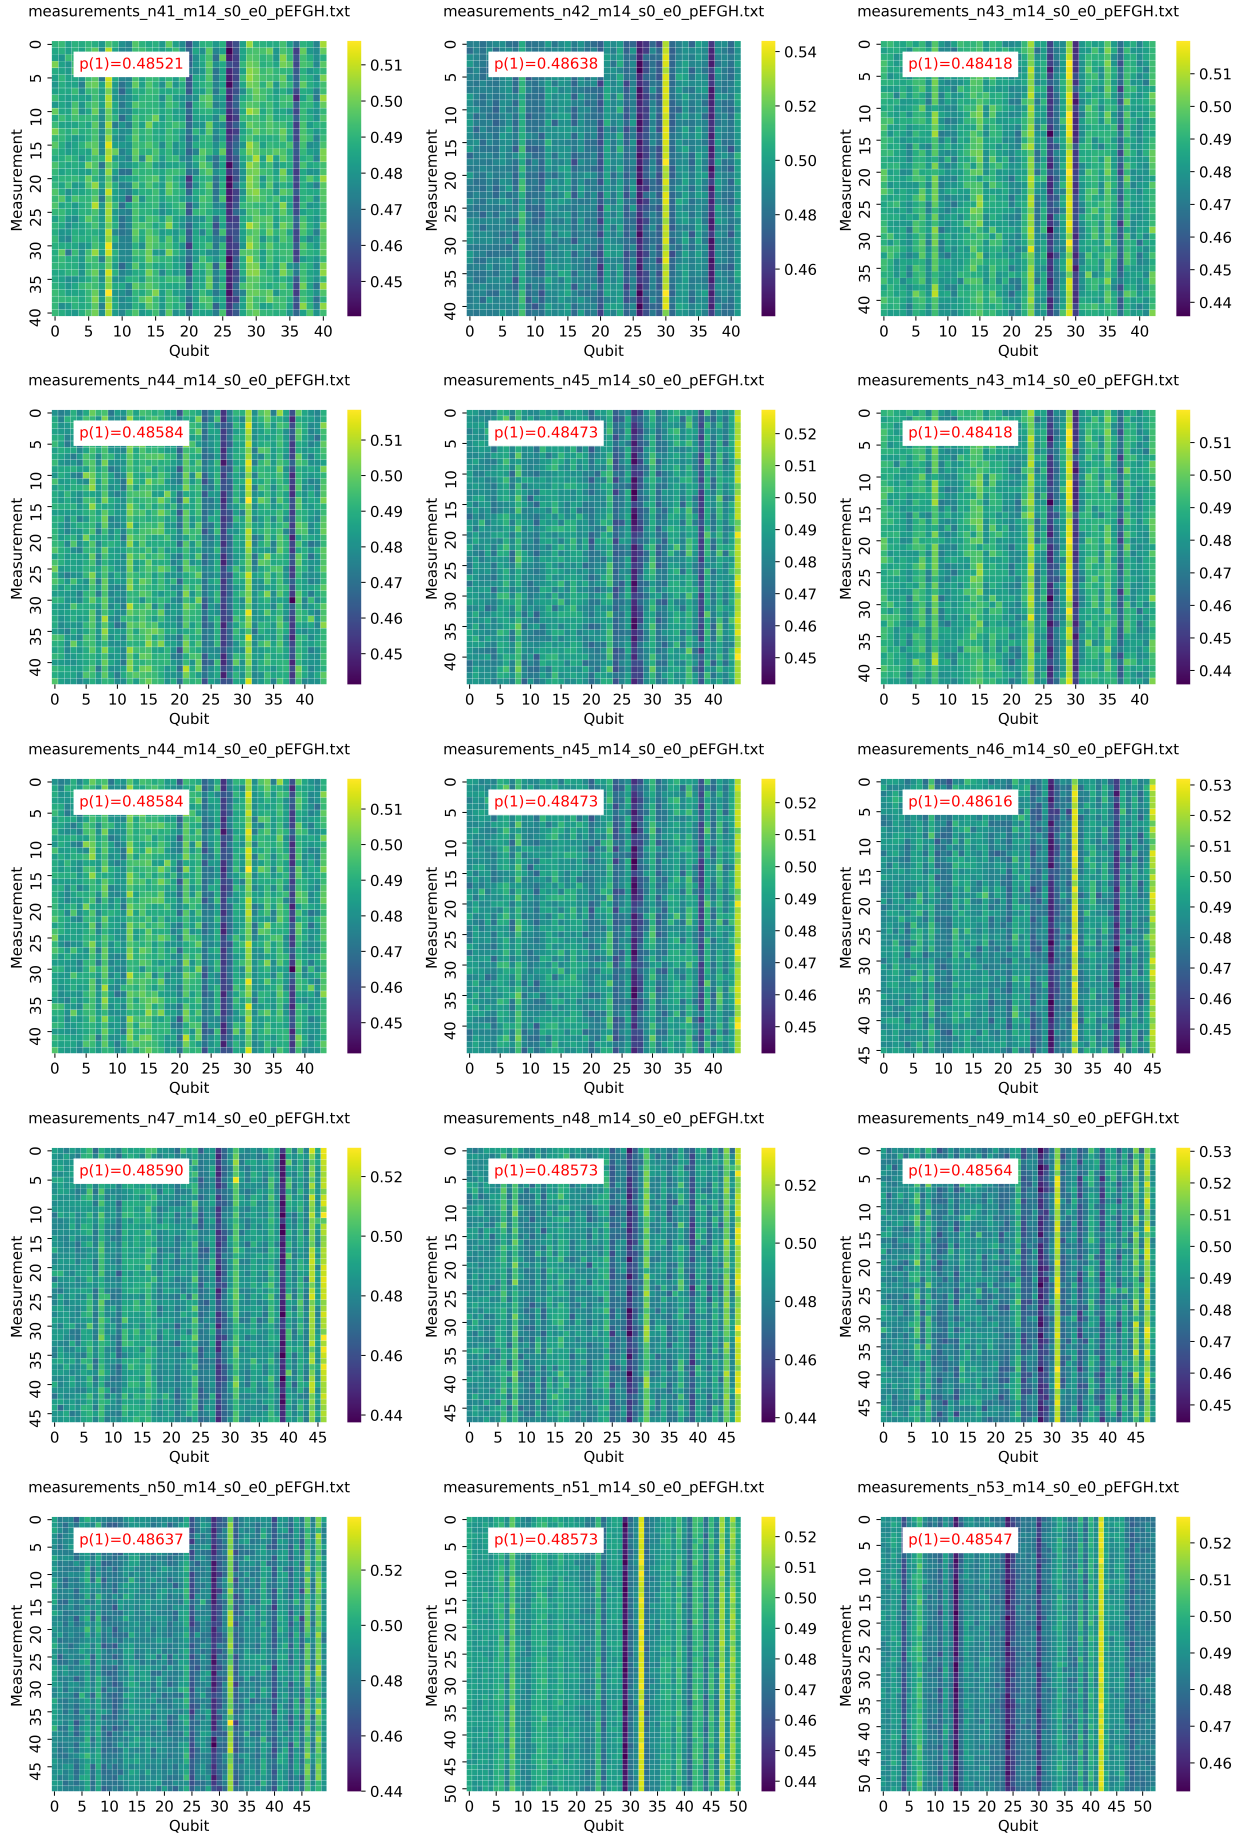

Figure S3. Heat maps of Google's random bit strings for 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 53 and EFGH activation pattern.

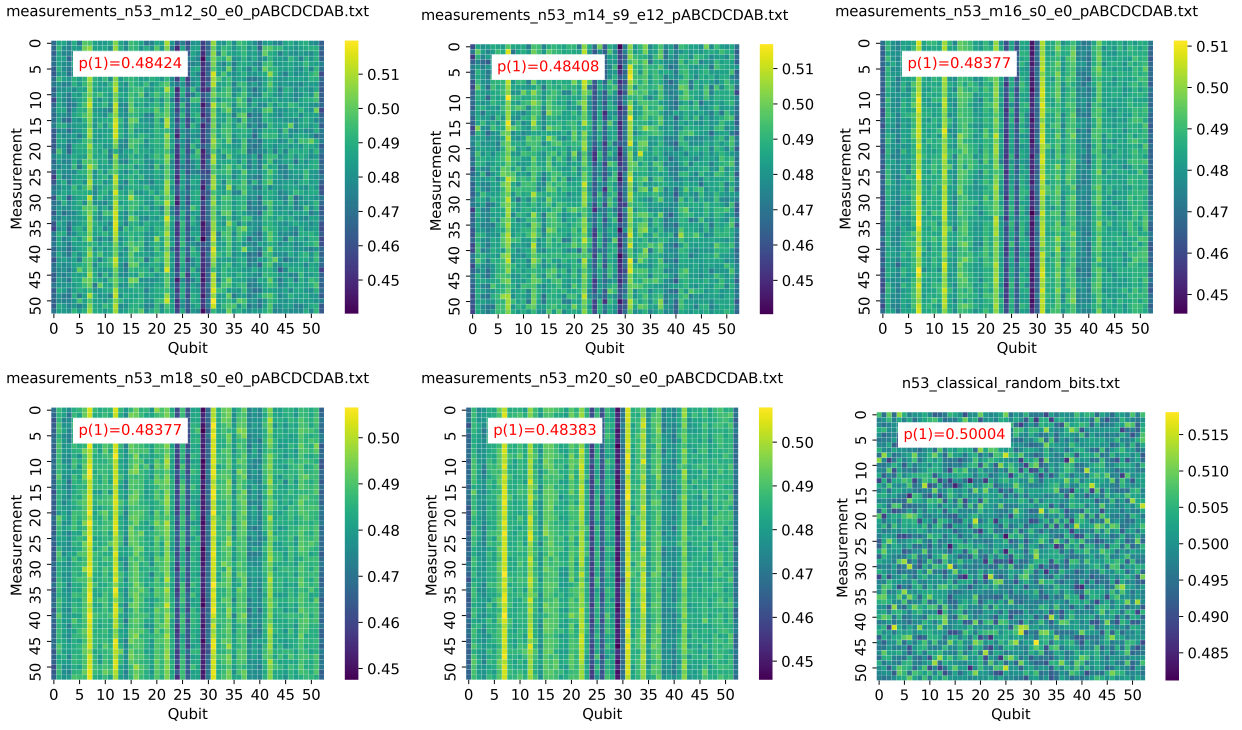

Figure S4. Heat maps of Google's random bit strings for $n = 53$, ABCDCDAB activation pattern, and cycle $m = 12, 14, 16, 18, 20$.

D. NIST Statistical Test for Random Numbers

The randomness of Google’s random bit-strings are tested using the NIST statistical test suite for random and pseudo-random number generators for cryptographic applications [31]. Instead of the NIST C code, NIST SP 800-22, the Python implementation of the NIST statistical test suite developed by Ang [42] is used because of the easy graphic user-interface, as shown in Fig. S5. Table S1 shows the results of the NIST random number tests for classical random bits for $n = 53$, Qiskit random circuits for $n = 12$, the Haar measure sample for $n = 12$, and Google’s data from $n = 12$ to $n = 53$. Most Google’s data do not pass the frequency test, run test, and overlapping template matching, approximate entropy test, and cumulative sum tests. We performed the NIST statistical test for all Google data and the result files `Random_test.zip` are attached.

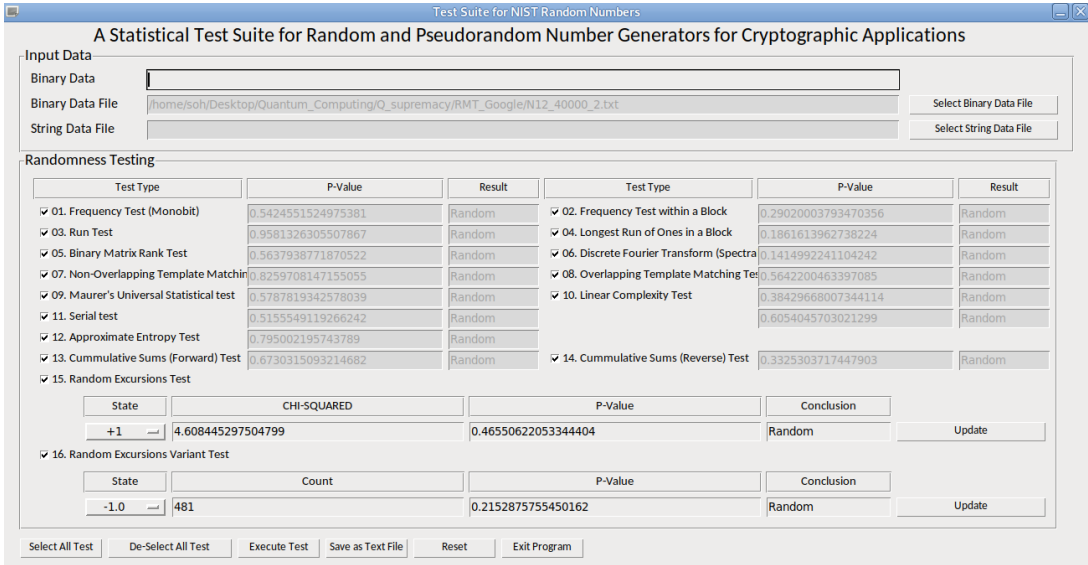

Figure S5. The screen shot of a python implementation of the NIST statistical test suite [42].

	01. Frequency test (mono-bit)	02. Frequency test within a block	03. Run test	04. Longest run of ones in a block	05. Binary matrix rank test	06. Discrete Fourier transform	07. Table S1. NIST random number tests on the Haar measure sampling for $n = 12$, classical random bit sampling for $n = 53$, random quantum circuit sampling with Qiskit for $n = 12$ and Google's random quantum circuit data. The letter 'R' stands for random and 'N' for non-random. The letter 'U' stands for some sub-tests that are random and the others non-random. The other results of the NIST random number tests on Google's random quantum circuits are found in the Supplementary Data.
