(Received xx; revised xx; accepted xx)

Solvent exchange is a process involving mixing between a solute-containing good solvent and a poor one. The process creates local oversaturation which causes the nucleation of minute solute droplets. Such ternary systems on a macro-scale have remained unexplored in the turbulent regime. We experimentally study the solvent exchange process by injecting mixtures of ethanol and trans-anethole into water, forming a turbulent buoyant jet in upward direction. Locally, turbulent mixing causes oversaturation of the trans-anethole following turbulent entrainment. We optically measure the concentration of the nucleated droplets using a light attenuation technique and find that the radial concentration profile is sub-Gaussian. In contrast to the entrainment-based models, the spatial evolution of the oversaturation reveals continuous droplet nucleation downstream and radially across the jet, which we attribute to the limited mixing capacity of the jet. Though we are far from a full quantitative understanding, this work extends the knowledge on solvent exchange into the turbulent regime, and brings in a novel type of flow, broadening the scope of multicomponent, multiphase turbulent jets with phase transition.

1. Introduction

Solvent exchange can be employed to extract specific components from mixtures. The process finds various industrial applications, such as liquid-liquid extraction (Lohse 2016), drug delivery (Lepeltier et al. 2014), resource recycling (Zimmermann et al. 2014), and oil recovery (Sun et al. 2017). Such solvent exchange processes consist of a ternary liquid system, where mixing between a good solvent and a poor one takes place, leading to oversaturation of the solute originally dissolved in the good solvent. This in turn triggers nucleation of the solute droplets. Such droplet nucleation is called spontaneous emulsification, or is known by its popular name ‘ouzo effect’. In this process metastable droplets are formed in the liquid, creating a milky appearance due to Mie scattering for the case of watered-down ouzo beverage. In recent decades, numerous efforts have been made to understand such a complex multicomponent and multiphase flow, see the review by Lohse & Zhang (2020), Vitale & Katz (2003) and Sitnikova et al. (2005) were among the earliest studies of the ouzo effect, using divinylbenzene and trans-anethole as...
the solute, respectively. They both located the position of the metastable region in the ternary phase diagram, and experimentally revealed the diffusive growth process of the droplets and their size distribution.

To quantitatively study the diffusion dynamics of the multicomponent droplets, Su & Needham (2013) extended the classic work of Epstein & Plesset (1950) on the dissolution and growth of gas bubble in surrounding liquid to the case of a droplet. Chu & Prosperetti (2016) further analytically investigated the droplet growth and dissolution of the multicomponent droplets, broadening the theoretical framework of droplet diffusion dynamics, making it more applicable to the real-world applications, such as liquid-liquid extraction. Corresponding molecular dynamics simulation was done by Maheshwari et al. (2017). Tan et al. (2019) studied the micro-droplet nucleation of the water-ethanol drop in host anise oil. They combined the multicomponent diffusion model, thermodynamic equilibrium, and a scaling analysis of Marangoni and buoyancy forces. With this they could successfully predict the spontaneous emulsification by the convection-enhanced diffusion process.

While the aforementioned cases are homogeneous nucleation in the bulk, the ouzo effect has also been widely investigated on the surface of microfluidic channels, so-called surface droplet formation via heterogeneous nucleation. Hajian & Hardt (2015) studied the droplet nucleation and its radial migration in a micro-channel, measuring the concentration field formed by the solvent exchange and the following diffusive mass transfer. For controlled solvent exchange in a microfluidic setups, Zhang et al. (2015) found that the volume of the nucleated droplets scales as $Pe^{3/4}$, with Peclet number $Pe = \frac{Q}{wD}$, where $Q$ is the volume flow rate, $w$ the channel width, $D$ the diffusion coefficient. Following this finding, the universality of the phenomena has been demonstrated, including the effect of the solution composition (Lu et al. 2015, 2016), confining the flow geometry (Lu et al. 2017; Zeng et al. 2019), and formation (Li et al. 2018) and growth (Dyett et al. 2018) of the surface nanodroplets. For related work, Li et al. (2021) implemented a Hele-Shaw like thin cell with a porous section to better collect the nucleated droplets. For this geometry, they formulated a theoretical model based on the ternary diagram and the diffusion equation, and found and explained the scaling of the volume of the nucleated droplets in the oversaturation front to be proportional to $Pe^{1/2}$.

While solvent exchange is thus reasonably and in part even quantitatively understood, the scope of quantitative studies has up to now been limited to small scales and the laminar flow regime. For industrial-scale applications such as liquid-liquid extraction, however, processes on larger scales are generally less controlled than those in microfluidic devices due to turbulence. It is therefore highly desirable to unveil the diffusion dynamics of the ternary liquid system in turbulent environments, where intense mixing and nucleation appear. The turbulent jet is one of the most fundamental and well-studied form of turbulent shear flow (see e.g. Pope (2000)), which makes it an ideal candidate to bridge the field of solvent exchange and turbulence.

Built upon the classic single phase studies for turbulent jets and plumes (List 1982; Morton et al. 1956; Fischer et al. 1979; Turner 1986; Pope 2000), the case of multiphase flow has drawn extensive interest due to its common occurrence in environmental fluid mechanics (Woods 2010) and combustion applications (Raman & Fox 2016). The Deepwater Horizon Oil Spill further triggered a series of investigations into such types of multiphase flow (K.McNutt et al. 2012; Reddy et al. 2012; Ryerson et al. 2012). With turbulent entrainment, bubbles or droplets can grow and dissolve in a jet, inducing significant buoyancy variation in the flow. Chu & Prosperetti (2019) analytically identified key parameters for the multiphase plume dynamics, including the droplet dissolution
The present experimental study aims to investigate the solvent exchange process in a multiphase turbulent buoyant jet in the upward direction, bridging the gap between the ouzo effect and turbulent shear flow. We will employ trans-anethole and refer to it as oil throughout the paper as it is the oil phase in the ternary liquids system. We will use a vertical ethanol-oil jet being injected in a quiescent water bath, creating an ‘ouzo’ mixture close to the needle. We utilize a novel method to construct the averaged oversaturation (concentration) field for the ouzo solution using titration, light attenuation technique, and minimization using an axisymmetric discretization. We compare the ouzo case with the nucleation-free case of injecting only dyed ethanol, revealing the distinct features of the ouzo case in the radial concentration profile, the centerline evolution, and the oversaturation flow rate. Adapting the mixing-limited arguments for the prolonged depletion of the reacting plume of Mingotti & Cardoso (2019), the extended lifetime of the droplet-laden respiratory puff of Chong et al. (2021) and of the evaporating spray of de Rivas & Villermaux (2016) and Villermaux et al. (2017), we provide a qualitative explanation for the continuous nucleation downstream and the wide-spread location of the micro-droplet nucleation across the jet.

The paper is structured as follow: In §2 we detail the experimental setup and the methods to measure the velocity field and the concentration field, and to resolve the nucleated droplets. The concentration fields can be reconstructed by combining the information from two cameras, as presented in §3. The results extracted from the
concentration fields are presented in §4, with supporting discussion and qualitative analysis in §5. Conclusions and future prospects are presented in §6.

2. Experimental method

2.1. Setup

We have conducted several experiments to study the solvent exchange process in a turbulent buoyant jet (ouzo jet). The jet experiments were operated in a glass tank with dimensions 25 cm × 25 cm × 50 cm (W × L × H) as in Fig. 1. The tank was filled with decalcified water before each run of experiments. The injected fluid consisted of mixtures of ethanol (Boom, 100%) and trans-anethole (Sigma Aldrich, ≥99%) with varying weight ratio, and the fluid was injected by a Harvard 2000 syringe pump at selected flow rates, forming an upwards turbulent buoyant jet through a round needle with inner diameter 0.51 mm, outer diameter 0.82 mm, and length 12.7 mm. Reference cases were also conducted by injection of dyed ethanol, offering comparison between the common passive scalar jet and the ouzo jet. The water and the injected liquid were kept at room temperature (20 ± 1) °C for all the experiments to minimize the effect of the temperature-dependence of the solubility in the ternary liquids system. The experimental conditions are listed in Table 1.

To measure the local concentration we use a light attenuation technique. For this we use a LED back lighting with diffuser and recorded using two Photron FASTCAM Mini AX200 high speed cameras with 1024×1024 pixels resolution at 50 fps, one from afar with a Sigma 50 mm objective to capture the entire jet evolution, and the other with a Zeiss 100 mm objective placed closer to the tank and zoomed in to the region right above the injection needle. The injection and the recording lasted for 40-50 s, providing 2000-2500 frames for each experiment. To obtain the velocity field of the turbulent buoyant jets, we relied on particle image velocimetry (PIV) with laser activation and using different cameras, which will be detailed in §2.5.

2.2. Titration and oversaturation

To study the nucleation and the solvent exchange process quantitatively, knowledge of oversaturation of the nucleated component is required (Li et al. 2018, 2021). This means that the first step is to obtain the binodal curve, namely the saturation curve by titration. Normally, the titration results of such ternary system are determined visually by checking the change of appearance. However, this is extremely difficult since we operated in the regime with extremely small amounts of oil. We therefore opted for cameras for accurate determination of the point of saturation. The camera-assisted titration was conducted by step-wise adding water into the oil-ethanol solution, followed by taking 100 frames to obtain the averaged light intensity of the mixture. The water-adding process lasted until the solution turned opaque enough, after which we obtained the intensity-to-concentration graph, see the black points in Fig. 2a. Based on the data points we performed a 2nd order polynomial curve fitting to obtain the titration curve, from which we define the 1% drop of the light intensity as the point of saturation. We repeated such titration procedure for 25 different initial compositions of the ethanol-oil mixture, with weight ratios $w_e : w_o$ ranging from 10 : 1 to 300 : 1, forming the binodal curve as shown in Fig. 2b.

Together with the diffusion path, the acquired binodal curve as in Fig. 2b was then used to quantify the amount of oversaturation, see Fig. 2c Ruschak & Miller (1972) first formulated the diffusion path theory, which was later applied to the study of nanodroplets

formation on surfaces [Lu et al. 2017; Li et al. 2021]. When the ethanol-oil mixture mixed with the water, only the oil phase nucleated out, and the water-ethanol ratio in the fluid parcel remained unchanged, following the diffusion path. As in Li et al. (2021), we assume the diffusion coefficient of water and oil to be the same, meaning that the diffusion path becomes a straight line in the ternary diagram, see Fig. 2c. The diffusion path depends solely on the initial ethanol-oil ratio. For a specific water concentration (wt), the oversaturation was obtained by connecting the corresponding point on the binodal curve to the end point of the oil phase, from which we can extract the segment length between the diffusion path and the binodal curve as the oversaturation, see Fig. 2c.

Then the oil oversaturation is related to the water concentration as in Fig. 2d. Fig. 2d not only displays the significant dependence of the oversaturation on the initial composition, $w_e/w_o$, but also reveals the existence of an upper bound for the oversaturation, which is later confirmed by the recorded intensity in the concentration calibration as shown in Fig. 3. The water concentration $C_{\text{water}}$ is the selected value used in the concentration calibration, which will be described below.

2.3. Light attenuation technique and calibration

To characterize the concentration of the nucleated oil in the flow, we implemented a light attenuation technique. Unlike the passive scalar studies, the droplet nucleation makes the flow almost opaque, causing the commonly used laser induced fluorescence (LIF) not feasible. We therefore use a light attenuation technique to measure the local concentration. This technique has been widely adapted in turbulent jet and plume studies based on the pioneer work of Cenedese & Dalziel (1998), from single phase cases.
Table 1: Experimental conditions. Each experiment was repeated three times to confirm the repeatability of the data. Experiments 1–4 correspond to the ouzo jets with empty dye column, and experiments 5–6 correspond to the dyed ethanol jets with empty \(w_c/w_o\) column. \(w_c/w_o\) denotes the weight ratio between ethanol and the oil in the injected fluid. Q is the volume flow rate regulated by the syringe pump, leading to different characteristic length \(L_m\), initial velocity \(u_0\), and initial Reynolds number \(Re_0 = Qd/(\frac{1}{4} \pi d^2 \nu)\), where \(d = 0.51\ mm\) is the inner diameter of the needle. Here, \(L_m = M^{3/4}/B^{1/2}\), where \(M = Q^2/(\frac{1}{4} \pi d^2)\) is the initial momentum flux, and \(B = Qg(\rho_{jet} - \rho_{amb})/\rho_{amb}\) is the initial buoyancy flux. \(B = 1.635 \times 10^{-7} \ m^4/s^3\) is constant throughout our experiments as the density of the oil is ignored, i.e., we consider the jet density \(\rho_{jet}\) to be solely determined by the ethanol. The viscosity of the oil was also neglected, leading to a constant viscosity \(\nu = \nu_e = 1.5 \times 10^{-6} \ m^2/s\), which is used to calculate \(Re_0\).

with dye as in Kikkert et al. (2007), Allgayer & Hunt (2012), Van Sommenen & Woods (2012), and Mingotti & Cardoso (2019), to multiphase ones as in Leppinen (2001), and Mingotti & Woods (2015). The method is based on the Lambert-Beer law, relating the recorded depth-integrated intensity to the concentration field, namely

\[
\log\left(\frac{I}{I_{ref}}\right) = -2\gamma Cd, \tag{2.1}
\]

where \(I\) is the recorded intensity of the averaged images, \(I_{ref}\) the reference intensity of the background, \(\gamma\) the light absorption property of the dye determined from calibration, \(d\) the depth of the substance in the line-of-sight, and \(C\) the desired line-of-sight average concentration. The line-of-sight averaged concentration used in the aforementioned papers, however, is not a solution for the nonlinear response we see here. In a pioneering work, Sutherland et al. (2012) analyzed the averaged image based on the axisymmetric discretization, converting the depth-integrated recorded image to the concentration field as a function of radius and height, which serves as a very good strategy for our interests to obtain the oversaturation field as a function of radius and height in the domain.

We performed our calibration in a 10 mm thick cell as shown in Fig. 3a. As the reference case, the calibration curve for the dyed ethanol is shown in Fig. 3b, which was used to calculate the concentration field for the dyed ethanol jet. Red food dye (JO-LA) was added step-by-step followed by taking 200 frames to obtain the averaged light intensity for every 5×5 pixels working window. The blue curve indicates the linear relation within a certain range, and the slope of the blue curve is the constant \(\gamma\) in eq. (2.1).

On the other hand, for the ouzo cases, the cell was first filled with a mixture of ethanol and oil at the specific \(w_c/w_o\) ratio, and water was then added gradually. Averaging the intensity over 200 frames for every 5×5 pixels working window, the calibration curves as
Figure 2: (a) Camera assisted titration to determine the saturation point for a specific $w_e/w_o$. The black data points are obtained by averaging the light intensity of the entire domain, and the error bar denotes the standard deviation of the light intensity within the domain. The star marks water concentration ($C_{\text{water}}$) causing 1% drop of the light intensity, which is used to calculate the saturation concentration. Combining multiple titration results, namely the saturation concentration with 25 different $w_e/w_o$ ratios, the binodal curve in the ternary diagram as in (b) can be built. (c) show the binodal curve and the theoretical diffusion path for the case $w_e/w_o = 33$. While there is only one binodal curve for all the different compositions, the diffusion path varies with the composition $w_e/w_o$. The length of the line segment between the diffusion path and the binodal curve represents the oversaturation of the oil. Such line segment is determined by the line connecting the corresponding point on the binodal curve and the pure oil phase at coordinate (0,1), see Li et al. (2021). (d) The relation between the water concentration and oil oversaturation can then be built from (c) for the following calibration.

in Fig. 3c and Fig. 3d were built for every working window locally in the entire domain, which, however, reveals a nonlinear relation between the unit depth attenuation and the concentration. The $x$-axis in these two figures, namely the oil oversaturation, were derived from Fig. 2d. Although the reason behind such nonlinear optical response is
Figure 3: (a) Calibration cell. The yellow dot \((x = 0 \text{ cm}, z = 10 \text{ cm})\) is the selected point whose calibration curves are shown in (b)–(e). (b) Calibration curve for the reference dye case. \(\Phi\) denotes the degree of light attenuation per unit depth, \(\log(I_{\text{ref}}/I)/d\), where \(d\) is the cell thickness. The linear section can be used to convert the recorded intensity to a concentration field. Note that for the dye case in (b), the jet concentration needs to be carefully selected to operate in the linear regime. (c,d) The calibration curve for the two ouzo cases, which have a different optical characteristic from the dye case studied here and in the literature. The abscissa \(C_{\text{oil,sat}}\) is the oversaturation of the oil. The upper bounds for the ouzo calibration curve in (c,d) are imposed by the theoretical maximum oversaturation shown in Fig. 2d, namely 0.0023 for \(w_e/w_o = 100\), and 0.0087 for \(w_e/w_o = 33\). Such theoretical upper bounds are only valid if the diffusion path does not deviate too much from the straight line assumption as in Fig. 2c. For (b)–(d) the black error bar represents the standard error of the mean \(\Phi\), which is very small throughout the calibration. (e) The rescaled calibration curves as in (c), (d). The abscissa \(\tilde{C}_{\text{oil,sat}}\) is the rescaled oversaturation, which is obtained from \(\tilde{C}_{\text{oil,sat}} = (C_{\text{oil,sat}} - C_{\text{thresh}})/(C_{\text{max}} - C_{\text{thresh}})\), where \(C_{\text{thresh}}\) is the oversaturation where the attenuation reaches 0.1% of the highest attenuation as indicated by the black star in (c), (d), and \(C_{\text{max}}\) is the theoretical upper bound we just mentioned above.

Beyond the scope of this research and remains unclear, it is not seen for the first time. Van Sommeren & Woods (2012) also observed a nonlinear response in their experiment, which they fitted with polynomials, confirming that in-situ calibration also functions well when the optical response is nonlinear.
For the case of ouzo, the combination of a logistic function and a linear function fits our calibration data well, written as

$$\Phi(C) = \frac{\log \left( \frac{I_{\text{ref}}}{I} \right)}{d} = \frac{a_0}{1 + a_1 e^{a_2 (C - a_3)}} + \frac{a_4 (C - a_5)}{1 + a_1 e^{a_2 (C - a_3)}},$$  

(2.2)

where $a_0, a_1, a_2, a_3, a_4,$ and $a_5$ are the fitting parameters, and $C$ is the oil oversaturation, equivalent to the $O_{\text{oil}, \text{sat}}$ in Fig. 3c. Note that other fits are possible, but for our purpose we simply need a good approximation of the experimental curve $\Phi(C)$. To compare the calibration curve for the two $w/e/w_o$ ratios, the oversaturation and the attenuation were both rescaled, showing a reasonable collapse, see Fig. 3e. The rescaled oversaturation also eliminates the flat section of the logistic function for low oversaturation, creating a one-to-one injective map for the calibration.

Fig. 4a shows a snapshot of the turbulent jet with oil droplet nucleation, while Fig. 4b is the averaged image over 2000-2500 frames as that in Fig. 4a. The averaged image contains the upstream section only with $z < 35 \text{ cm}$ since the jet descended quickly after reaching the surface, interfering with the ascending jet. Fig. 4c shows a horizontal cross-section of the jet, illustrating the discretization scheme similar to Sutherland et al. (2012), where $dy_{mn}$ can be directly obtained as a function of $dr$ solely based on geometric relations, where $m$ denotes $x$ position on the recorded images, and $n$ the axisymmetric elements in $r$ direction. Note that $m \leq n$ always holds, and we calculate the left half ($x < 0$) and right half ($x > 0$) of the jet separately, that is $C_n \neq C'_n$. While the concentrations $C_n$ remain as unknowns, the recorded intensity $I_m$ at a specific location from Fig. 4b can then be expressed as the integration of the converted intensity calculated from the calibration curve over every discretization element on the light path. For the reference dye case with linear calibration curve as eq. (2.1), the concentration can be obtained as

$$C_n = \frac{1}{2\gamma} \sum_{n=0}^{N-1} \log \left( \frac{I_{\text{ref}}}{I_m} \right) dy_{mn}^{-1},$$

(2.3)

while for the ouzo cases with the nonlinear calibration curve as eq. (2.2), the problem requires minimization of $m$ equations with $n$ variables, written as

$$\log \left( \frac{I_{\text{ref}}}{I_m} \right) = \sum_{n=0}^{N-1} dy_{mn} \left( \frac{a_0}{1 + a_1 e^{a_2 (C_n - a_3)}} + \frac{a_4 (C_n - a_5)}{1 + a_1 e^{a_2 (C_n - a_3)}} \right).$$

(2.4)

The calculation can be done for every height, leading to the oversaturation fields as in Fig. 7, which will be discussed in §3.

### 2.4. Droplet size detection

The nucleated droplets through solvent exchange are generally referred to as micro- or even nano-sized droplets. However, experimentally measured sizes are based on cases with no flow (Tan et al. 2019) or laminar flow (Hajian & Hardt 2015; Lu et al. 2015). To measure the sizes of the nucleated droplets in the case of a turbulent jet, we utilize a Navitar 12× objective on a Photron FASTCAM Mini AX200 camera, achieving a resolution of 3 $\mu$m/pixel, see Fig. 5. Fig. 5a clearly shows the nucleated droplets in the plume after the injection stopped, which is similar to the laminar flow scenario in the aforementioned literature. Comparing Figs. 5b and 5c, we see that the droplets were indeed micro-sized ($O(10 \mu m)$) for both turbulent cases. The droplets for $w_e/w_o = 33$ are larger and thus easier to identify, which is in line with the findings of Vitale & Katz (2003).
Figure 4: (a) The instantaneous image obtained by dividing the recorded frame by the background frame. (b) The mean image derived by averaging the frames as in (a) over time. (c) An horizontal cross-section of the axisymmetric discretization, similar to that in Sutherland et al. (2012). Here we do not impose symmetry for the left half ($x < 0$) and the right half ($x > 0$) of the jet. The averaged image in (b) can be converted to a concentration field by the calibration curve in Fig. 3 for every $5 \times 5$ pixels, together with the optimization algorithm constructed based on the scheme in (c).
Figure 5: Identification of nucleated droplets. From all three figures it can be seen that the nucleated droplets are indeed micro-sized. For comparison, we show a droplet of 25 μm diameter in all three cases. (a) The nucleated droplets for $w_e/w_o = 100$ when the injection just stopped (i.e., $u_z$ approached 0). (a) serves as a reference laminar case where the droplet nucleation can be easily identified. (b) The nucleated drops of a jet with $w_e/w_o = 100$ in the turbulent regime for $Re_0 = 555$. The black thin sheets are the fluid interfaces due to refraction, while the black dots in the inset are the nucleated droplets with $17 \times$ magnification, which are obviously smaller than 25 μm. (c) The nucleated droplets for $Re_0 = 555$ and $w_e/w_o = 33$, which are larger and easier to identify.

2.5. PIV

While the light attenuation technique resolved the mean oversaturation field, we relied on particle image velocimetry (PIV) to measure the velocity field. Ethanol seeded with $20 - 50$ μm fluorescent particles was injected into the water-filled tank, which was also seeded with the same particles in order to prevent measuring a velocity that is solely based on entrained or injected liquid. Note that we used the obtained velocity field of the ethanol jet to represent that of the ouzo jet, assuming that the micro-sized nucleated oil droplets can be considered as tracer particles which barely affect the velocity field. The Photron cameras were replaced with LaVision Imagers sCMOS cameras with resolution $2560 \times 2160$ pixels, capturing the image pairs on the 1 mm thick laser sheet created by a dual cavity laser (Quantel Evergreen 145 laser, 532 nm). The velocity fields are calculated using the multi-pass method with a starting window size $64 \times 64$ pixel to a final size $16 \times 16$ pixel with 25% overlap.

Considering that the velocity decreases drastically as the jet travels downstream, the experiments were performed with two different time intervals $dt$ between image-pairs to resolve both the far field and the near field, see Figs. 6a and 6b. Fig. 6c shows the measured centerline velocity in $z$-direction, $u_m$, obtained by averaging 100 fields as that in Fig. 6a and 6b. Here $u_m$ matched well with the theoretical model prediction for a pure jet and a pure plume [Fischer et al. 1979; List 1982]:

$$u_{m,jet} = 7M^{1/2}z^{-1},$$
$$u_{m,plume} = 3.7B^{1/3}z^{-1/3}. \quad (2.5)$$

We fit a 4th order polynomial to the experimental data, obtaining the velocity in the jet-to-plume transition region, which is otherwise difficult to handle with theoretical models. Fig. 6d shows the radial flow profile of the streamwise velocity $u_z$ with Gaussian distribution, which is later used to calculate the oversaturation flow rate as in Fig. 12.
Figure 6: The velocity field of $Re_0 = 555$ measured by PIV. (a) and (b) shows an instantaneous velocity field recorded for the far and near field, respectively. The background color represents the magnitude of the velocity vector. (c) The centerline velocity in $z$-direction, $u_m$, is obtained from the theoretical model, the measurements, and the polynomial fit of the measured data. From (c) we can infer that the near field results match well with the pure jet model, and thus the pure jet model and the far field data are combined for curve-fitting to construct the centerline profile, see the red curve. (d) The radial profile of the streamwise velocity $u_z$. 
3. Oversaturation field

3.1. Contour map

Following the procedure detailed in §2.3, the optimization problem was solved to construct the oversaturation field, Fig. 7. The calculated results in Fig. 7 justify the assumption of a straight diffusion path and the theoretical upper bound, showing $\tilde{C}_{\text{oil, oversat}} \leq 1$ across the jet except for the region very close to the needle. We thus attribute the local oversaturation exceeding the theoretical upper bound, namely $\tilde{C}_{\text{oil, oversat}} > 1$ close to the injection point, to the violation of our straight diffusion path assumption at that location. This violation results from the intense cross-component diffusion and nucleation and the turbulent entrainment effect in that region.

Considering the opaque nature of the ouzo jet flow, the calculated results cannot be verified by other concentration detection methods such as LIF. However, by comparing the results from two different cameras (Fig. 7(a)–(c) and (b)–(d)), the highly consistent results demonstrate the reliability of our data. Note that the turbulence started to develop after a certain laminar length (Hassanzadeh et al. (2021)), which is subtracted to obtain the virtual origin in z-direction for the analysis in §4. Figs. 7(c) and (d) also reveal the initial stage where nucleation dominates over dilution, causing the oversaturation exceeding the upper bound. This is where the oil droplets nucleate intensely, which might result in a significant deviation of the straight diffusion path assumption. Note that the concentration fields for the dyed-ethanol injection were also obtained by the same method, which are not shown here but will be exploited as reference cases in the analysis in §4.
Figure 7: Calculated rescaled oversaturation field at $Re_0 = 1387$, with $w_e/w_o = 100$ in (a), (c), and with $w_e/w_o = 33$ in (b), (d). Panels (a) and (b) show the results derived from the far-view camera, while (c) and (d) exhibit the results obtained from the zoomed-in camera, which correspond to the black square in (a) and (b), respectively. The white spots in the contour map are caused by the local minima found during optimization, which poses little effect on the analysis. The oversaturation values mostly lie within the theoretical upper bounds as discussed in Fig. 3, which is 0.0023(wt) and 0.0087(wt) for $w_e/w_o = 100$ and $w_e/w_o = 33$, respectively, leading to the rescaled oversaturation smaller than 1, except for the region close to the needle. Note that the abscissa is converted to $r$ from $x$ after calibration.
4. Results

4.1. Generalized normal distribution

To better capture the radial profile of oversaturation field in Fig. 7, we fitted the results by a generalization of a normal distribution,

\[ C(r) = C_m e^{-\frac{|r - \mu|^\kappa}{\kappa \sigma \kappa}} + C_0, \]  

where \( C_m \) is the centerline oversaturation, \( \mu \) the offset of the centerline, which is or very close to zero for most of the fits, \( \sigma \) the width of the jet, \( \kappa \) the parameter to characterize the potential non-Gaussian profile, and \( C_0 \) the offset of the oversaturation, which is also very close to zero. When \( \kappa = 2 \) the profile becomes the standard Gaussian case. Fig. 8 showcases the quality of the fitting, where the center received less weight than the outer region based on the amount of information contained, that is, the area of the corresponding discretized annulus region in Fig. 4c. The fitted variables and the fitted profile are then used in the following sections to analyze the evolution of the centerline oversaturation and the jet profile.

4.2. Radial profile

In the classic jet and plume studies, the jet width of the concentration field \( b_T(z) \) is usually determined by the position where the value drops to \( 1/e \) of the centerline value. For a self-similar flow, \( b_T(z)/z \) is a constant at around 0.127 for pure jet, and 0.12 for pure plume (Fischer et al. 1979). When the radial flow profile is Gaussian, jet width determined from the definition above, \( b_T(z) \), and \( \sigma \) obtained from eq. (4.1) are the same. However, from Fig. 9 we can tell the radial profile is non-Gaussian for the ouzo cases, therefore we implemented the traditional definition of \( b_T(z) \) to characterize the jet width.
and plot the evolution of $b_T(z)/z$ in Figs. 9a and 9b. While the reference dye cases match well with the constant value reported in the literature (Fischer et al. 1979), the ouzo cases exhibit a continuously decreasing trend, starting with twice the value of the reference case and approaching the reference value as the jet evolved downstream. The larger jet width suggests a wider spread of the oversaturation, revealing that the nucleation was not restricted to the centerline, but occurred radially across the jet following the turbulent entrainment at the interface between the jet and the ambient water. As the oil, originally dissolved in the injected fluid, nucleates and gradually gets consumed with increasing $z$, the ratio $b_T(z)/z$ also approaches the reference dye case. Note that the spatial evolution of $b_T(z)/z$ is nearly independent of $Re_0$ and $w_e/w_o$, suggesting a potentially universal characteristic for the ouzo jets.

As the ratio $b_T(z)/z$ for the ouzo jet is larger than the dye case, we wonder how the nucleation changes the radial profile. To characterize the radial profile, we calculate the spatial evolution of the kurtosis from the fitted parameter $\kappa$ of Fig. 8, see Figs. 9c and 9d for the results. The kurtosis is calculated by

$$kurtosis = \frac{\Gamma(1/\kappa)\Gamma(5/\kappa)}{[\Gamma(3/\kappa)]^2},$$

(4.2)

where $\Gamma$ is the gamma function. While the kurtosis for the dye cases is around 3 as expected for a Gaussian distribution, for the ouzo cases it is smaller than 3 and only gradually approaches 3 as the flow develops. The radial profile for the upstream ouzo jet can thus be characterized as sub-Gaussian, resulting from the nucleation across the jet. The spatial evolutions of the jet width and of the kurtosis reveal the radially spread nucleation in the ouzo jets, whose effect becomes weaker downstream with the consumption of the dissolved oil.

4.3. Centerline scaling

The centerline evolution of the concentration has always been the focus of turbulent jet and plume studies, as the scaling between the dilution and streamwise length is crucial to the self-similarity of the flow. In Fig. 10 we present the centerline evolution for the dyed ethanol jet and the ouzo jet for different $Re_0$. As the dye concentration dropped monotonically due to dilution, the oversaturation of the ouzo jets experienced several stages, from increasing sharply right above the needle, tightly followed by a sudden decrease, and finally entering a mild dilution regime. Here we normalized the height $z$ with the characteristic length scale for the jet-plume transition, $L_m = M^{3/4}/B^{1/2}$, where $M, B$ are the initial momentum and buoyancy flux, respectively (Fischer et al. 1979). For $z/L_m < 1$, the flow is characterized as momentum dominated jet, followed by a gradual transition to the buoyancy-dominated plume as the flow reaches $z/L_m = 5$. Fig. 10a and Fig. 10b display the centerline evolution for $Re_0 = 555$ and $Re_0 = 1387$. For the ouzo cases, we can clearly identify three different regimes: (1st) a fast nucleation stage where the concentration climbs up quickly. (2nd) a fast dilution stage, which is only absent for the $Re_0 = 555, w_e/w_o = 100$ case, and (3rd) the mild dilution stage in the downstream location, where the nucleation is competing with the dilution.

The results for the two different Reynolds number shown in figs. 10a and 10b are almost identical, except for the abscissa value. Despite the difference of the normalized length in $z$-direction, $z/L_m$, figs. 10a and 10b actually cover the same physical length $z$. $Re_0$ determines the momentum-buoyancy competition, and in turn the regime where different stages occurs, that is for $Re_0 = 555$ the jet develops into a pure plume regime quickly ($z > 5L_m$), while the initial momentum plays a major role for $Re_0 = 1387$. We can therefore conclude that the evolution of the centerline oversaturation is
Figure 9: The radial oversaturation profile of the buoyant jets. The errorbars represent the uncertainty of the curve fitting discussed in §4.1. Panels (a) and (b) show the spatial evolution of the jet width \( b_T(z) \) divided by the vertical distance \( z \) by probing the radial position where the concentration reach 1/e of the fitted peak. For each parameter set we show the results of two repeated experiments, denoted by subscripts a, and b. Compared to the reference dye cases, ouzo jets exhibited broader \((2\times)\) jet width upstream, while they become narrower as the jet develops and approaches the value for the dye case downstream. (c,d) display the kurtosis calculated from the fitted parameter \( \kappa \). While the reference dye cases exhibit a value close to 3, the ouzo cases show a value around 2, revealing that the ouzo jet has a sub-Gaussian nature.

nearly independent of \( Re_0 \). Furthermore, as \( Re_0 \) determines the momentum-buoyancy competition which affects the strength of turbulent entrainment, it seems that the centerline evolution is nearly independent of the turbulent entrainment effect. Such finding is somehow counter-intuitive as one might consider the turbulent entrainment as the dominant mechanism for the micro-droplet nucleation. In §4.4 we will show that
Figure 10: Normalized centerline evolution of the rescaled oversaturation for dyed ethanol, ouzo $w_e/w_o = 100$, and ouzo $w_e/w_o = 33$. The errorbars represent the uncertainty of the curve fitting discussed in §4.1. (a) and (b) shows results for $Re_0 = 555$ and $Re_0 = 1387$, respectively. $C_{\text{max}}$ is the initial dye concentration for dye case and the theoretical peak for ouzo cases. For the ouzo cases, we can clearly identify three different regimes: (1)\textsuperscript{st} fast nucleation stage where the concentration climbs up quickly, (2)\textsuperscript{nd} fast dilution stage, which is absent for the case of $Re_0 = 555$ and $w_e/w_o = 100$, and (3)\textsuperscript{rd} the mild dilution stage in the downstream location, where the nucleation is competing with dilution by turbulent entrainment. The results from two different compositions collapse well in the 3\textsuperscript{rd} regime for both $Re_0$.

the effect of the turbulent entrainment on the nucleation indeed exists, but only appears in the overall oversaturation flow rate.

To retrieve quantitative information from the centerline evolution, it is crucial to know how the oversaturation scales with the height $z$. Therefore the curves with different conditions in Fig. 10 are separated, while repeated experiments with the same control parameters are ensemble-averaged, leading to Figs. 11a through 11f which are then fitted locally using a moving window to derive the local scaling exponent $\beta$ as $C_m(z)/C_{\text{max}} \propto$
Micro-droplet nucleation through solvent exchange in a turbulent buoyant jet

$$(z/L_m)\beta.$$ Figs. [11g] and [11h] show that the dye cases match the value in the literature, starting with $\beta = -1$ for the pure jet and then gradually approached the pure plume value $\beta = -1.66$. For the ouzo jets, the multiple stages mentioned above are clearly visible, with $\beta > 0$ in (1st) initial production stage, then (2nd) a sharp drop to $\beta < -2$ in a short range, in the end (3rd) reaching a mild dilution regime with $\beta$ slightly below 0. These transitions reveal the competition between the nucleation and the dilution. We note that the drastic change and the extreme values in the 1st and 2nd stages might not be accurate, as they are located in the intense nucleation region shown in Fig. [7], indicating the violation from the straight diffusion path assumption.

### 4.4. Oversaturation flow rate

To make use of the oversaturation data in the entire domain (see Fig. [7]), we calculated the rescaled oversaturation flow rate by multiplying the oversaturation field, the velocity field from Fig. [6] and the corresponding area within the discretized annulus region, namely the rescaled oversaturation flow rate

$$\dot{Q}_{oil}(z) = \sum_{r=0}^{(n-1)dr} \dot{C}_{oil,sat}(r, z)u_z(r, z)A_{annu}(r)$$

Similarly, we can obtain the mass flow rate for the dye reference cases,

$$Q_{dye}(z) = \sum_{r=0}^{(n-1)dr} C_{dye}(r, z)u_z(r, z)A_{annu}(r)$$

Here $\dot{C}_{oil,sat}$ is the rescaled oversaturation from Fig. [4] (dimensionless) for the ouzo cases and $C_{dye}$ is the concentration field for dye cases, $u_z(z)$ the streamwise velocity measured by PIV as in Fig. [6] and $A_{annu}(r)$ the area of the axisymmetric elements as in Fig. [4c].

For the standard scenario without any nucleation or depletion, the mass flow rate should be conserved in the streamwise $(z)$ direction, $Q(z) = const$, which is confirmed for our reference dyed ethanol case in Fig. [12a]. Fig. [12b] on the other hand, shows the continuous increase of the oversaturation flow rate before reaching the peak. This very nicely demonstrates and quantifies the nucleation. The repeatability of the results across different trials is good, firmly indicating that the nucleation from the solvent exchange process outperformed the dilution within the domain, as both effects resulted from turbulent entrainment. Such finding contrasts the behavior of the centerline scaling exponent $\beta(z)$ in Fig. [11] as $\beta(z)$ did not become larger than 0 downstream. The increasing oversaturation flow rate evolution is consistent with the finding of sub-Gaussian flow profile and thus the wide-spread nucleation across the jet. Also, although the $Re_0$ (and thus the entrainment) has little effect on the centerline evolution, a significant dependence of the $\dot{Q}_{oil}(z)$ on $Re_0$ demonstrates the crucial role of the entrainment in the solvent exchange in the jet.

For $z/L_m \leq 5$, that is, before the buoyancy dominates over the momentum, the experimental data for the two employed compositions $w_e/w_o$ for both $Re_0$ almost collapse, suggesting a potentially universal evolution for the solvent exchange process in this regime. Despite the collapse in the jet regime, the $w_e/w_o = 100$ cases deviate from the $w_e/w_o = 33$ ones in the plume regime, reaching a peak, and even start to decline somewhere downstream for $Re_0 = 555$. The peak signals the end of nucleation, and the later decline of the curve reflects that the dissolution takes over from nucleation. This is consistent with the discussion of the upper bound of the oversaturation in §2.2 and in Fig. [2d].
Figure 11: Centerline evolution of the oversaturation. Panels (a)–(f) present the centerline evolution in all cases in Fig. 10. The curve in each plot is then locally fitted with moving window to deliver the best fitting results. The length of the fitting window is defined as $h_{\text{fit}}$, which starts with $h_{\text{fit}} = 0.1 z/L_m$ in the fast nucleation regime, changing to $h_{\text{fit}} = z/L_m$ between the peak and $z = 5 L_m$, then ending with $h_{\text{fit}} = 3 z/L_m$ for $z > 5 L_m$. The results of the fitting are shown in (g) and (h). $\beta$ denotes the local scaling exponent of $C_m/C_{\text{max}} \propto z^\beta$. The ouzo cases can be segmented into three stages as detailed in the caption of Fig. 10. In the dilution stage, the exponent $\beta$ ($\beta < 0$ there, representing decaying) is identical for both $w_e/w_o$, and is significantly smaller (i.e., less decaying) than the reference dye case. The fluctuation in the end (large $z$) were probably caused by insufficient averaged frames downstream as described in §2.3.
Figure 12: Mass flow rate evolution along the height. The errorbars show the propagated uncertainty originating from the concentration field. (a) shows the mass flow rate $Q_{dye}(z)$ of reference dye case calculated using eq. (4.4), which is reasonably conserved within our domain. (b) displays the rescaled oversaturation flow rate for the ouzo cases with two different $w_e/w_o$ and two different $Re_0$, calculated using eq. (4.3). The height $z$ is normalized by $L_m$ to show the variation with jet-plume transition. Each legend represents the case with 2 repeating experiments. The results are reproducible while the dependence on $Re_0$ is significant. For $z/L_m \leq 5$ we see the curves between the two compositions are very close, while the composition makes a difference downstream, especially for $Re_0 = 555$.

5. Discussion

With the experimental results above, we aim to build up a theoretical framework to capture the observed features, or at least to enable a qualitative explanation of the findings. In the buoyant jet, the turbulent entrainment of water into ethanol-oil mixture is a crucial mechanism for the solvent exchange process, as the nucleation will be activated once the entrained water starts to mix with the injected fluid, forming the ternary system
You-An Lee, Chao Sun, Sander G. Huisman, Detlef Lohse

consisting of water, ethanol, and trans-anethole. Incorporating the established turbulent entrainment model, the z-direction evolution of the compositions of the elements in the ternary system can easily be obtained. The volume flow rate for a jet \((i = j)\) or a plume \((i = p)\) is obtained by

\[
q_i(z) = \pi u_{m,i}(z)(b_{w,i}(z))^2,
\]

where \(b_{w,i} = 0.125z\) is the jet width for the velocity field from the PIV measurements, and \(u_{m,j}(z) = 7M^{1/2}z^{-1}\) for the jet, and \(u_{m,p}(z) = 3.7B^{1/3}z^{-1/3}\) for the plume from eq. (2.5). This results in the volume flow rates

\[
q_j(z) = 0.34M^{1/2}z,
q_p(z) = 0.18B^{1/3}z^{5/3},
\]

for the jet and plume, respectively. Here \(M\) and \(B\) are the initial momentum flux and buoyancy flux, respectively. Note that we directly combined the two models in the middle of the transitional range, \(z/L_m = 3\). This procedure is far from perfect but sufficient for a qualitative investigation. With the volume flow rate of the entrained water \(q_i(z)\), \(i = j, p\), and the volume flow rate of the injected ethanol-oil mixture \(q_0\), the oversaturation \(C_{oil,sat}(z)\) can be calculated as

\[
C_w(z) = (q_i(z) - q_0)/(q_i(z) - q_0 + \rho_e q_0),
C_o(z) = \frac{1 - C_w(z)}{1 + w_e/w_o},
C_{oil,sat}(z) = C_o(z) - C_{o,binodal}(z),
\]

where \(C_w(z)\) is the weight fraction of water in the three phase mixture during the process, \(C_o(z)\) is the weight fraction of oil in the mixture, and \(C_{o,binodal}(z)\) denotes the saturation concentration of the oil from the binodal curve shown in Fig. 2c Fig. 13a shows the spatial evolution of the oil oversaturation. Although the sharp variation upstream also appeared in the experimental results in Fig. 10, the variation here is more pronounced. Also, the oversaturation shows a continuous sharp decrease throughout the entire domain, reflecting that the so-called mild dilution stage in the experimental data is absent in our simplified model. Multiplying the results in Fig. 13a with the corresponding volume flow rate, as the procedure in eq. (4.3), the overall oversaturation flow rate as in Fig. 12b can be examined from a theoretical perspective, which is shown in Fig. 13. Unlike the (nearly) monotonic increase in Fig. 12b, the modelled cases here exhibit extremely intense nucleation right above the needle, and the oversaturation flow rate is nearly conserved for almost the entire domain, which indicates the absence of either nucleation or dissolution.

As the entrainment is the only mechanism we include in the model, the significant deviation from the experimental results unveils that additional factors must contribute to the observed phenomena. Mingotti & Cardoso (2019) considered mixing as the bottleneck for the fast reactive plume, which led to the prolonged depletion of the injected liquid before reaching stoichiometric level. Mingotti & Cardoso (2019) pointed out that mixing was constrained within the Batchelor scale located at the rim of the eddies in the reactive plume, causing the incomplete reaction for those entrained fluid. Despite the simplicity of our model lacking the mixing effect for the solvent exchange process, we argue that the weak dilution stage in Fig. 10 and the monotonic increase in Fig. 12b are direct consequences of the mixing limitation, considering that the time scale for the fast reaction in Mingotti & Cardoso (2019) and the micro-droplet nucleation in our study are both extremely short (Tan et al. 2019). We note that the mixing-limited phenomena not only appeared in a fast reactive plume, but also in other types of multiphase flow, for
Figure 13: Analytical results obtained using the entrainment-only model. (a) is determined by the scale analysis, while (b) is obtained by multiplying results of (a) with the volume flow rate, and thus sharing the same plot legend. (a) can be a reference case to the centerline evolution in Fig. 10. If the entrained water mixed fully with the jet fluid, the nucleation would complete not far from the needle, which is not observed in the experimental findings. Note that the sharp drop in the figure results from the direct bridging of the volume flow rates for a jet and a plume as mentioned earlier, see eq. (5.2). On the other hand, (b) can be compared with Fig. 12b, showing the plateau instead of the monotonic increase using the entrainment-only model.

example the evaporation of droplets in dense sprays [de Rivas & Villermaux (2016), Villermaux et al. (2017)] and in a respiratory puff [Chong et al. (2021)], where the lifetime of the droplets were controlled by the mixing in the ambient humidity field. In our experiments, the limited mixing prevented the oil in the injected fluid from completely nucleating in a short range above the virtual origin, allowing the dissolved oil to be widely distributed by the eddies before nucleation, leading to the wide-spread nucleation across the jet, which has been identified and emphasized throughout our experimental results.

6. Conclusions and Outlook

We have experimentally studied the solvent exchange process in a turbulent buoyant jet. We calculate the oversaturation field from the recorded images using a light attenuation technique, which consists of titration, calibration, axisymmetric discretization, and an optimization algorithm. These experimental procedures involve the background knowledge in the solvent exchange process and the turbulent buoyant jet. The fundamental assumption we made is the straight diffusion path, which leads to the evaluation of the oversaturation, and in turn the nonlinear calibration curve. Except for the region right above the needle, the constructed oversaturation fields gave values below the theoretical upper bound for the oversaturation, consistent with the diffusion path assumption. In addition, the very similar results between the two cameras further support the validity of the assumption, the implemented methods, and hence the calculated oversaturation fields.

Analyzing the rescaled oversaturation fields, the ouzo jets exhibited wider jet spreading $b_T(z)/z$ and a sub-Gaussian radial profile, reflecting enhanced nucleation in the entrain-
In the streamwise direction, the centerline oversaturation demonstrated a three-stage evolution, consisting of fast nucleation, sharp dilution, and finally mild dilution, with the scaling exponent $\beta$ of the centerline oversaturation being almost independent of $Re_0$ and the initial compositions of the ethanol-oil mixture, $w_e/w_o$, in the final stage. In contrast, integrating the velocity field, the oversaturation flow rates in the entire domain show monotonic increase before reaching the peak, again reflecting the wide-spread nucleation of the oil droplets across the jet in the entrainment region.

In addition to the experimental findings, we have formulated a simplified model, only considering the turbulent entrainment. It serves as the first step to build the theoretical framework for the ouzo jet. The differences between the experimental results and the model suggest the existence of other mechanisms, which we attributed mainly to the rate-limiting mixing constraint within the Batchelor scale. The entrainment rate exceeded the mixing rate, leading to the prolonged nucleation downstream and across the jet.

To the authors’ knowledge, this work is the first attempt to experimentally and theoretically tackle the ouzo jet, a complex fluid mechanics problem combining solvent exchange and turbulent shear flow. The approach to quantify the concentration of the nucleated droplets, namely the oversaturation, seems a promising way for future efforts in this line of research. In future work, jets with different initial composition $w_e/w_o$ and higher $Re_0$ should be studied to test whether the observed collapse is universal. Moreover, an analytical framework including the mixing rate would be highly valuable towards a thorough understanding of the topic.
