Magnetic field induced transition from a vortex liquid to Bose metal in ultrathin a-MoGe thin film

Surajit Dutta, John Jesudasan and Pratap Raychaudhuri*

Tata Institute of Fundamental Research, Homi Bhabha Road, Mumbai 400005, India.

We identify a magnetic field induced transition from a vortex liquid to Bose metal in a 2-dimensional

amorphous superconductor, a-MoGe, using a combination of magnetotransport and scanning tunnelling

spectroscopy (STS). Below the superconducting transition, $T_c \sim 1.36$ K, the magnetoresistance isotherms

cross at a nearly temperature independent magnetic field, $H_c^* \sim 36$ kOe. Above this field, the temperature

coefficient of resistance is weakly negative, but the resistance remains finite as $T \rightarrow 0$, as expected in a bad

metal. From STS conductance maps at 450 mK we observe a very disordered vortex lattice at very low

fields that melts into a vortex liquid above 3 kOe. Up to H_c^* the tunnelling spectra display superconducting

gap and coherence peak over a broad background caused by electron-electron interactions, as expected in

a vortex liquid. However, above H_c^* the tunnelling spectra continue to display the gap but the coherence

peak gets completely suppressed, suggesting that Cooper pairs lose their phase coherence. We conclude

that H_c^* demarcates a transition from a vortex liquid to Bose metal, that eventually transforms to a regular

metal at a higher field H^* where the gap vanishes in the electronic spectrum.

1

The survival of Cooper pairing even after the global phase coherence is destroyed has been a recurring theme in strongly disordered and 2-dimensional superconductors^{1,2,3,4}. In zero field, the zero resistance state can get destroyed due to phase-fluctuations at the superconducting transition temperature T_c , even though Cooper pairs continue to survive up to a much higher temperature^{5,6,7}, T^* . This gives rise to the so called pseudogap state 8,9,10,11,12 between T_c and T^* , where superconductivity survives in nanometer sized puddles^{13,14} that are phase incoherent with respect to each other. On the other hand, when a magnetic field is applied at low temperatures, one observes another intriguing phenomenon, the superconductor (S) to bad-metal/insulator (BM/I) transition 15,16,17,18,19,20 . At a characteristic magnetic field, H_c^* , the magnetoresistance isotherms are observed to intersect giving rise to a state with negative temperature coefficient of resistance (R) above this field. In very strongly disordered superconductors such as InO_x and TiN this results in a strongly insulating state with diverging electrical resistance, sometimes called a superinsulator, which has been the topic of extensive studies²¹. It has been suggested that the superinsulator is the conjugate of the superconductor^{22,23}, where Cooper pairs instead of vortices are localised. On the other hand, when the disorder is more moderate, in several systems such as MoGe, Ta and NbN the resistance increases weakly with decreasing temperature and remains finite even as $T \to 0$; this state is more appropriately classified as a bad metal^{24,25,26,16,27}. Whether Cooper pairs survive in this bad metal is currently an open question. In principle, a metallic state consisting of Cooper pairs is not expected since Cooper pairs are either in eigenstate of phase which gives a superconductor, or in eigenstate of number which gives an insulator. However, in recent years there have been suggestions that a new state called Bose metal²⁸ can arise from 2-dimensional superconductors, where Cooper pairs would exist in a dissipative state 29,30,31,32 , although its existence remains hotly debated 33,34,35 . Therefore, the metallic state above H_c^* , in such systems deserve careful attention.

In this letter, we investigate the field induced S-BM transition in a 2 nm thick amorphous MoGe thin film ($T_c \sim 1.36 \text{ K}$), using a combination of low temperature scanning tunnelling spectroscopy (STS) and magneto-transport measurements. The primary advantage of STS is that it provides direct information

on the local density of states, which cannot be obtained from transport. The central finding of this work is that the field induced dissipative bad metal state shows clear spectroscopic signatures of the existence of phase incoherent Cooper pairs as predicted for a Bose metal.

The *a*-MoGe film was grown by pulsed laser deposition. Details of sample growth and characterisation have been reported elsewhere^{36,37,12}. STS measurements were performed using a homebuilt low-temperature scanning tunnelling microscope³⁸ (STM) operating down to 450 mK and up to a magnetic field of 90 kOe using a Pt-Ir normal metal tip. The tunnelling conductance, $G(V) = \frac{dI}{dV}|_V$, as a function of voltage (V), was measured using standard lock-in technique. To image vortices, spatially resolved G(V) maps were recorded at a fixed voltage close to the coherence peak, where each vortex appears as a local minimum. We used an ultra-high-vacuum suitcase to transport the sample post deposition and transfer in the STM without exposure to air. After completing STS measurements the sample was transported back to the deposition chamber in the same way covered with a 1 nm thick Si protective layer before transport measurements. Magneto-transport measurements were performed in a conventional ³He cryostat. Since the magneto-transport properties of a-MoGe films are extremely susceptible to external electromagnetic radiation³⁹, all electrical feedthrough leading to the sample were fitted with RC filters with a very low cut-off frequency of 100 Hz.

We start with the zero field properties. Fig. 1(a) shows the normalised conductance, $G_N(V) = \frac{G(V)}{G(4\,mV)}$, averaged over 32 × 32 grid over 150 nm × 150 nm area at various temperatures. In STS, superconductivity manifests as a suppression of $G_N(V)$ for voltage, $|V| < \Delta/e$, and the appearance of coherence peaks at the gap edge. Here, in addition to this, we observe a V-shaped background that extends up to high bias. This background, which is routinely observed in tunnelling spectra of disordered superconductors^{40,41,42}, originates from e-e Coulomb interactions and can be accounted for within Altshuler-Aronov (AA) theory^{43,44,45}. In order to fit the data, incorporating both the AA correction and the effect of superconductivity, we adopt a procedure recently developed by Zemlicka et al.⁴⁶ At temperature T the

tunnelling conductance is given in terms of the single particle density of states of the sample, N(E), by the relation⁴⁷,

$$G(V,T) \propto \int_{-\infty}^{\infty} dE \, \frac{1}{kT} \frac{e^{\frac{E+eV}{k_BT}}}{\left(1+e^{\frac{E+eV}{k_BT}}\right)^2} N(E) \quad , \qquad (1)$$

where k_B is the Boltzmann constant. Here we assume the density of states of the Pt-Ir tip to be energy independent, which is a good approximation within 10s of meV from the Fermi level. In a normal metal, AA corrections modify the bare density of states, N_N as⁴⁶,

$$N_N^{AA}(E) = N_N \left(1 + \tilde{\lambda}_0 [f_d(E, \Gamma_0) - \lambda_r \{ f_d(E, \Gamma_1) + f_d(E + E_z, \Gamma_1) + f_d(E - E_z, \Gamma_1) \} \right)$$
(2a)
$$f_d(E, \Gamma_n) = -\frac{1}{2} \int_0^{\frac{\Gamma}{kT}} dx \frac{x}{x^2 + \left(\frac{\Gamma_n}{kT}\right)^2} \frac{Sinh(x)}{Cosh(x) + Cosh\left(\frac{E}{kT}\right)}$$
(2b)

where $\Gamma={}^{h}/_{T}$ where τ is the transport scattering time, $E_z=2\mu_B H$ (μ_B is Bohr magneton) is the Zeeman energy when there is an applied magnetic field H, and Γ_0 and Γ_1 account for the broadening due to energy and spin scattering. We use Γ_0 , Γ_1 , $\tilde{\Lambda}_0$ and λ_T as adjustable parameters. In Fig. 1(a) we can fit the data for $T\geq 3.7$ K using eqn. 1 with $N(E)=N_N^{AA}(E)$; we take $E_z=0$, $\Gamma_0=\Gamma_1=0.2$ meV. It is important to note that the parameters related to AA fitting do not vary more than $\pm 10\%$ from their mean value over the entire range of temperature and magnetic field; the variation does not follow any particular trend and reflects the statistical error from our measurement. The complete set of best fit parameters is given in the Supplementary Material⁴⁸. In principle, Γ is also a fitting parameter which we take as $\Gamma \sim 20$ eV based on $\tau \sim 3 \times 10^{-17} s$ estimated from resistivity. However, for such large value of $\Gamma(\gg \{k_B T, \Gamma_0, \Gamma_1\})$, eqn. (2b) is insensitive to its precise value and practically indistinguishable from setting the integration limit to infinity. For T<3.7 K, we cannot fit the data with AA contributions alone and need to incorporate the effect of superconductivity. In BCS theory where the density of state in the normal metal is assumed to be energy independent, the single particle density of states is given by⁴⁷, $N_S^{BCS}(E)=\left|Re\left\{\frac{E-i\Gamma^D}{\sqrt{(E-i\Gamma^D)^2-\Delta^2}}\right\}\right|$,

where Γ^D is a phenomenological broadening parameter⁴⁹ that accounts for non-thermal sources of broadening. When this correction is applied on the top of AA corrections, the single particle density of states is given by⁴⁶,

$$N(E) = N_S^{BCS}(E)N_N^{AA}(\Omega), \quad (3)$$

where $\Omega = Re\left[\sqrt{(E - i\Gamma^D)^2 - \Delta^2}\right]$; Ω in the second term ensures conservation in the number of states (and charge) above and below the superconducting transition. Using this form for N(E) and Δ , Γ^D as fitting parameters, we can fit the $G_N(V)$ spectra down to 450 mK keeping Γ_0 and Γ_1 same as the normal state value and (Fig. 1(a)). Figure 1(b) shows the temperature variation of Δ and Γ^D along with the temperature variation of the sheet resistance, R_s . $T_c \sim 1.36$ K defined as the temperature where R_s is 0.05% of its normal state value is much lower than $T^* \sim 3.7$ K where Δ vanishes, showing the existence of a large pseudogap state. The zero bias conductance map (inset, Fig. 1(a)) shows large variations, forming puddle like structures consistent with earlier reports¹².

We now turn our attention to the effect of magnetic field. Figure 2(a) shows R_s as a function of H. Below T_c all the R_s -H curves cross close to $H_c^* \sim 36 \, kOe$ which demarcates the S-BM transition. Concentrating first at low temperatures and low fields, we observe finite R_s above 3 kOe (Fig. 2(b)) at 450 mK. We confirm that this R_s indeed corresponds to the linear resistance, by plotting in the same graph $R_{lin} = \frac{dI}{dV}\Big|_{V \to 0}$ calculated from current-voltage (I-V) characteristic measurements (inset Fig. 2(b)). The appearance of a finite linear resistance at subcritical current indicates the formation of VL state⁵⁰. Further evidence of VL is obtained from STS images of the vortex state (Fig. 2(d)). At 1 kOe we can resolve individual vortices even though the spatial configuration is extremely disordered; at 5 kOe some vortices are still visible but at many places we also observe blurred or elongated structures indicating considerable motion of vortices during the acquisition time of the image; at 10 kOe the vortex system is deep into VL and we cannot resolve individual vortices anymore. From R_s vs. T at different H (Fig. 2(c)) we observe that

for $H > H_c^*$, $\frac{dR_s}{dT} < 0$ down to 300 mK, even though the sheet conductance $G_s\left(=\frac{1}{R_s}\right)$ extrapolates to a finite value as $T \to 0$, characteristic of a bad metal.

To understand the evolution of the superconducting state at higher fields, we investigate the $G_N(V)$ vs.V spectra, spatially averaged on a 32×32 grid over 150 $nm \times 150$ nm area (Fig. 3(a)). For H > 60 kOe the tunnelling spectra can be fitted using $N(E) = N_N^{AA}(E)$. We define this field as H^* . Below H^* , we observe two distinct magnetic field regimes (Fig. 3(b)). For $H < H_c^*$ we can fit the tunnelling spectra using N(E) in eqn. 3 using Δ and Γ^D shown in the *inset* of Fig. 3(d). For $H^* \ge H > H_c^*$ this form is no longer adequate; we observe that the fitted value is larger in the voltage range corresponding to the energy where the coherence peaks are expected in $N_s^{BCS}(E)$. This deviation results from a complete suppression of the superconducting coherence peaks above H_c^* . To illustrate this point we modify $N_s^{BCS}(E)$ in the following way: We use the empirical form, $N_s^{Mod}(E) = \alpha_0 - A \exp(-BE^2)$, and adjust α_0 , A and B such that $N_s^{Mod}(E) \approx N_s^{BCS}(E)$ when $N_s^{Mod}(E) \lesssim 0.95$, but asymptotically approaches 1 instead of exhibiting the coherence peak at higher values (Fig. 3(c)). Using $N(E) = N_s^{Mod}(E)N_N^{AA}(\Omega)$ results in an excellent fit of the tunneling curves above H_c^* (Fig. 3(b)). In Fig. 3(d), we plot the coherence peak height (CPH), defined as $max \{N_s^{BCS/Mod}(E)\}$ -1. With increasing field CPH gradually reduces and becomes zero above H_c^* .

To understand the physical implication of these results we note that, while the existence of the superconducting energy gap is a direct manifestation of the pairing of electrons forming Cooper pairs, the superconducting state requires another ingredient, namely, the global phase coherence among Cooper pairs, which is related to the appearance of the coherence peaks at the gap edge⁴⁷. If Cooper pairs lack phase coherence, it is expected that the single particle spectrum will remain gapped, but the coherence peaks will get suppressed^{2,4,7,51}. In magnetic field, the nucleation of vortices complicates this scenario. Here both the gap and the coherence peaks vanish inside the vortex core but appear as one goes further from the vortex centre. In a VL, where vortices are rapidly moving, a slow measurement like STS measures the time averaged tunnelling spectrum which has contribution from both inside and outside the core. This broadens

the spectrum by partially filling the gap and suppressing the coherence peaks. It has been shown⁵² that the average spectrum in the mixed state can be captured by adjusting Γ^D . This accounts for the gradual increase in Γ^D and suppression of CPH below H_c^* . On the other hand, the abrupt disappearance of the CPH for $H^* \geq H > H_c^*$, with no commensurate filling of the gap indicates that the Cooper pairs no longer have phase coherence. We would like to note that the bad metal that we observe here is distinct from the zero field pseudogap state, where as shown before, the spatially averaged spectra do not undergo any qualitative change across T_c . The origin of the pseudogap state lies in the emergence of tens of nanometer sized superconducting puddles separated by insulating regions and thermal fluctuations between these puddles that destroy the zero resistance state^{12,14,53}. Here, even though we observe inhomogeneity in $G_N(0)$, the complete suppression of CPH in the average spectrum suggests that the coherence peak is uniformly suppressed everywhere. This has been further confirmed⁴⁸ by selectively fitting spectra in regions of high and low $G_N(0)$.

In Figure 4 we show the phase boundaries of H_c^* and H^* in the H-T parameter space. The H^* boundary is determined from STS measurement and is defined as the highest magnetic field (at fixed temperature) or highest temperature (at fixed field) where the tunnelling spectra cannot be fitted with the AA contribution alone. The H_c^* boundary on the other hand is defined as the magnetic field at which two magnetoresistance curves intersect. As expected, this boundary is nearly temperature independent till about T_c and then closely follows H^* boundary. Finally, we define the vortex lattice melting boundary, H^m , above which a finite linear resistance appears. The temperature variation of H^m is described very well by the formula for thermal melting 54,48 of the vortex lattice if one substitutes H_c^* for the upper critical field.

We can now place these results in perspective. Based on transport experiments, it is widely believed that the S-I transition corresponds to a quantum critical point²². However, in the case of S-BM, both the states below and above H_c^* are dissipative, and it is important to understand whether H_c^* indeed separates two distinct phases, or is just a percolative cross-over as suggested in some theories. Our STS data answers this crucial question. In the field interval, $H^m < H \le H_c^*$, both transport and tunnelling spectroscopy are

consistent with the formation of a VL. On the other hand, for $H^* \ge H > H_c^*$, we realise a metallic state where the tunnelling spectra show the presence of phase incoherent Cooper pairs, the hallmark of a Bose metal. Our results also put experimental constraints on the wide variety of theories^{55,56,57,58,59,60} that have been proposed to explain the origin of Bose metals. For example, it is difficult to reconcile the abrupt and complete suppression of the coherence peaks in the spatially averaged spectrum, within theories that rely on unusual vortex states such as vortex glass⁵⁵ or vortex liquid⁶¹, or a state where superconducting puddles are immersed in a metallic matrix⁵⁶. The other point to note is that in our experiment the Bose metal is prominent only below T_c (within the error bars of our measurements) even though fragmented superconducting puddles continue to exist up to T^* . Thus, the magnetic field-induced Bose metal is only realised when we have global phase coherent state in zero field.

In summary, we have shown spectroscopic evidence of the existence of a magnetic field induced Bose metal in ultrathin a-MoGe thin film. Our results show that H_c^* is a true critical point demarcating the transition from VL to a Bose metal. This runs in counter to a recent claim from high-frequency conductivity that the true critical point is at a field lower than where the magnetoresistance curves \cos^{62} . Our results are also significant from another standpoint. Several earlier claims of Bose metal based on transport measurements alone have been contested on the ground that the 2-dimensional superconducting state is extremely susceptible to external electromagnetic perturbations 33,39 . Other than the fact that our transport measurements are carried out using electromagnetic filters with very low cut-off, the spectroscopic signature of phase incoherent Cooper pairs provides one of the strongest evidence for the existence of Bose metal. These results have relevance to other systems like High Temperature superconductors 32 where Bose metal states have been reported. We hope that our results will bolster further theoretical investigations on how such a state emerges out of a 2-dimensional superconductor.

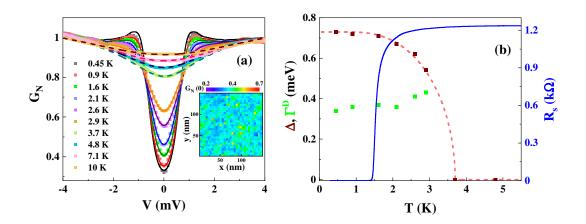

Figure 1I (a) $G_N(V)$ -V tunneling spectra in zero field at different temperatures along with theoretical fit using eqn. 1. At 3.7 K and above the spectra are fitted with AA corrections alone (dashed line) whereas at lower temperatures additional contribution from superconductivity has to be incorporated (solid lines). (*inset*) spatial map of $G_N(0)$ at 450mK. (b) Temperature dependence of superconducting energy gap Δ and Γ^D (left axis) and sheet resistance R_s (right axis) at zero magnetic field; the dashed line is a guide to the eye that mimics the BCS temperature variation of Δ .

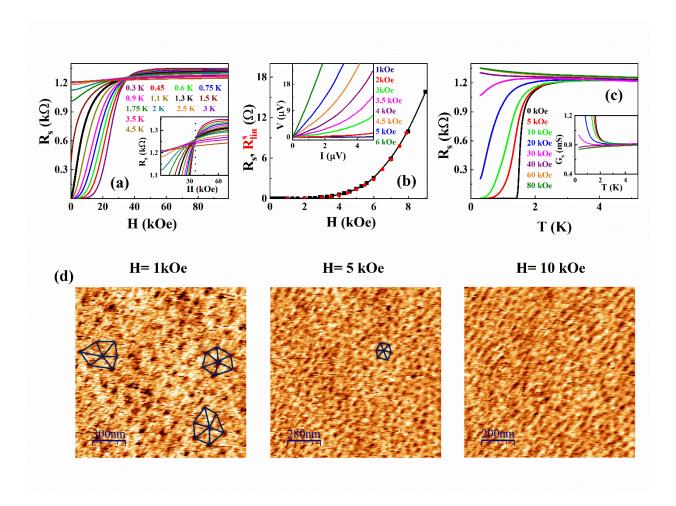

Figure 2I (a) Magnetic field dependence of sheet resistance R_s at different temperatures. (*inset*) expanded view of same plot close to H_c^* (blue dotted line). (b) Plot of R_s (black square) and R_s^{lin} (red circle) vs H at low magnetic fields at 450 mK; (*inset*) I-V characteristics at the same temperatures. (c) Temperature dependence of R_s at various magnetic fields. (*inset*) shows corresponding temperature variation of sheet conductance G_s . (d) Spatial maps of $G_N(V)$ at the coherence peak voltage V = 1.2 mV at 450 mK for H = 1 kOe, 5 kOe, and 10 kOe. At 1 kOe we observe a disordered vortex lattice; at 5 kOe individual vortices can be resolved only at some locations but in the rest of the area individual vortices cannot be identified; at 10 kOe we can no longer resolve individual vortices indicating that the vortex lattice has completely molten. Representative hexagonal coordination are shown at few representative locations 1 kOe and 5 kOe.

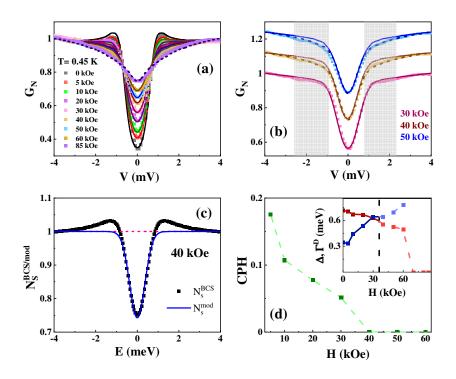

Figure3I (a) $G_N(V)$ vs V in different magnetic fields at 450mK along with theoretical fit using eqn. 1. For H > 60 kOe the spectra are fitted with AA corrections alone (dashed line) whereas at lower temperatures additional contribution from superconductivity has to be incorporated (solid lines). (b) Fit of $G_N(V)$ vs V at H = 30 kOe, 40 kOe and 50 kOe using $N_S^{BCS}(E)$ (solid line) and $N_S^{mod}(E)$ (dashed line) respectively; successive spectra following 30 kOe are shifted upward by 0.12 for clarity. For 40 and 50 kOe ($H > H_c^*$) the fit using $N_S^{BCS}(E)$ deviates significantly in the voltage range where the coherence peak appears (shaded grey region). (c) Plot of $N_S^{BCS}(E)$ (Black dot) and $N_S^{mod}(E)$ (blue solid line), used for the theoretical fit in (b) at 40 kOe. (d) Magnetic field dependence of coherence peak height (CPH). (inset) Variation of superconducting energy gap Δ , Γ^D as a function of magnetic field at 450 mK; for $H > H_c^*$, these values correspond to the values used in $N_S^{BCS}(E)$ from which $N_S^{mod}(E)$ is constructed.

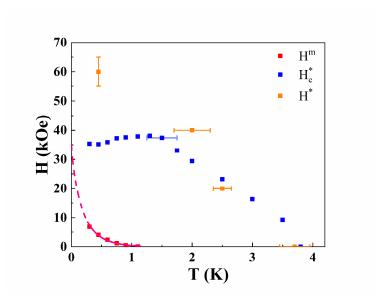

Figure4| Phase diagram showing the temperature evolution of H^* (orange square), H_c^* (blue square), and H^m (red square); the dashed line is the fit to thermal melting line. The Bose metal phase is realized between H_c^* and H^* . In between H^m and H_c^* we have a vortex liquid.

Supplementary Material

I. Spatial variation of tunneling spectra at H = 40 kOe

In this section, we analyze the spatial variation of the tunneling spectra at 40 kOe which is smallest magnetic field at 450 mK at which the coherence peak in the superconducting density of states disappears. As it can be seen from Fig. S1(a) in this field $G_N(0)$ has considerable variation over 10-s of nanometer length scales. We have illustrated the fitting of the selective area tunneling spectra at H= 40 kOe and T= 450mK. We separately analyze the spectra averaged from two kinds of regions: (i) regions where $G_N(0) \ge 0.68$ and (ii) regions where $G_N(0) \le 0.53$. We observe that both kind of spectra can be fitted perfectly using $N_s^{Mod}(E) = \alpha_0 - Aexp(-BE^2)$ as described in the main text (Fig. S1 (b)). The spectrum averaged from region (i) can also be fitted almost equally well using $N_s^{BCS}(E)$ if we take Γ^D to be roughly 2 times Δ , but such large value of Γ^D effectively implies that the coherence peak is completely suppressed. The best fit parameters for the two curves are given in Table S1.

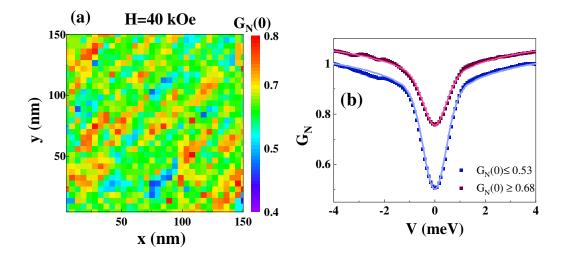

Fig. S1I (a) Spatial map of $G_N(\theta)$ at H= 40 kOe and T= 450 mK. (b) Corresponding G_N -V tunneling spectra at averaged over regions of low $G_N(\theta)$ (blue dot) and high $G_N(\theta)$ (purple dot) along with theoretical fit using eqn. (1).

Table S1: Best fit parameters for the two curves shown in Fig. S1. Δ and Γ^D are the starting values used in $N_s^{BCS}(E)$ from which $N_s^{Mod}(E)$ is constructed.

II. Thermal melting of vortex matter

In fig 4 (main manuscript), we mentioned that the temperature dependence of H_m follows the melting transition line driven by thermal fluctuations. The melting line is theoretically obtained by solving the given equation⁶³,

$$\frac{\sqrt{b_m}}{1 - b_m} \frac{t}{\sqrt{1 - t}} \left[\frac{4(\sqrt{2} - 1)}{\sqrt{1 - b_m}} + 1 \right] = 2\pi \frac{C_L^2}{\sqrt{Gi}}$$

Where, the reduced melting field, $b_m = \frac{H_m}{H_{c2}}$, $t = \frac{T}{T_c}$ is the reduced temperature, C_L is the Lindemann constant and Gi is the Ginzburg-Lenvanyuk number. While fitting, $\frac{C_L^2}{\sqrt{Gi}}$ has been considered as the fitting parameter and the obtained melting line coincides well with the experimental data for $\frac{C_L^2}{\sqrt{Gi}} = 0.065$ (shown in fig. 4). Gi is calculated using the given relation⁶⁴ (for two-dimensional disordered system),

$$Gi = \frac{e^2}{23\hbar} R_s^N = 0.013$$

 $R_s^N (= R_s^{8K})$ is the normal state sheet resistance. Using the value of Gi, we find the Lindemann constant, $C_L \cong 0.09$ which is close to the expected value.
