KROHN–RHODES COMPLEXITY 1 DECIDABLE IMPLIES THAT COMPLEXITY \( n \geq 0 \) IS DECIDABLE

STUART MARGOLIS, JOHN RHODES, AND ANNE SCHILLING

Abstract. When decomposing a finite semigroup into a wreath product of groups and aperiodic semigroups, complexity measures the minimal number of groups that are needed. Determining an algorithm to compute complexity has been an open problem for almost 60 years. The main result of this paper proves that if it is decidable for a finite semigroup or finite automaton to have Krohn–Rhodes complexity 1, then it is decidable if a finite semigroup or finite automaton has complexity \( n \) for all \( n \geq 0 \).

1. Introduction

The concept of complexity has its genesis in the Prime Decomposition Theorem by Krohn and Rhodes [6], which states that every finite semigroup divides an iterated wreath product of its finite simple group divisors and copies of the three element aperiodic monoid consisting of two right zeroes and an identity. When decomposing a finite semigroup into a wreath product of groups and aperiodic semigroups, complexity measures the minimal number of groups which are needed. Determining an algorithm to compute complexity has been an open problem for almost 60 years.

Let \( c \) be the Krohn–Rhodes complexity function for finite semigroups and finite automata [12]. The main result of this paper shows that if \( c = 1 \), then it is decidable if \( c = n \) for all \( n \geq 0 \). This is achieved by a straightforward application of three of the main theorems of Krohn–Rhodes theory, namely the Derived Category Theorem [3, 12], the Fundamental Lemma of Complexity (see Theorem 2.6), and the Presentation Lemma (see Theorem 2.8). See [12] for details and history of all of these important theorems.

The paper is organized as follows. In Section 2, we give a new proof of the Presentation Lemma based on the notion of flows in the Rhodes lattice [9] rather than the proof based on the set-partition lattice in [12]. The direct product decomposition that is a consequence of the Presentation Lemma is crucial for the proof of the main theorem (see Theorem 3.7) that is in Section 3.

2. Complexity and the Presentation Lemma

In this section, we review the basics of transformation semigroups, Green’s relations and the semilocal theory of semigroups. See [5, Chapter 7-8] and [12, Chapter 4] for more details.

We present a new proof of one direction of the Presentation Lemma based on the notion of flows in the Rhodes lattice. We illustrate the Presentation Lemma in the case of inverse semigroups and relate it to classical results in that theory. See [1] and [12] for other formulations and proofs of the
2.1. **Actions and products.** Given a nonempty set $S$ (respectively set $Q$), we denote by $\text{T}(Q)$ (respectively $\text{PT}(Q)$) the monoid of all full (respectively partial) transformations on $Q$, where in the composition $\varphi \circ \psi$ we apply $\varphi$ first (and so we denote by $q \varphi$ the image of $q$ by $\varphi$). In this paper, we use the convention that we treat partial transformations in $\text{PT}(Q)$ as full transformations by adjoining a new element $\varnothing$ to $Q$ and setting $q \varphi = \varnothing$ if $q \varphi$ is not defined and $\varnothing \varphi = \varnothing$.

A **right action** of a semigroup $S$ on a set $Q$ is a semigroup morphism from $S$ to $\text{T}(Q)$. A right action of a semigroup $S$ on a set $Q$ by partial mappings is a semigroup morphism $\alpha$ from $S$ to $\text{PT}(Q)$. If this morphism is injective, the action is **faithful**. We use the notation $(Q, S)$ to express that a semigroup $S$ acts faithfully on the right on a set $Q$ by partial mappings. We call $(Q, S)$ a **transformation semigroup**. Usually, we write $qs$ to denote $q(s \alpha)$.

If $I$ is a right ideal of $S$, then $S$ acts on the right of $I$ by multiplication through the morphism

$$\theta : S \to \text{T}(I)$$

$$s \mapsto \theta_s$$

defined by $a\theta_s = as$ for all $a \in I$.

Let $S^{\text{op}}$ denote the opposite semigroup of $S$. A **left action** of $S$ on $Q$ is a right action $\beta$ of $S^{\text{op}}$ on $Q$. Usually, we write $sq$ to denote $q(s \beta)$. We define left actions by partial mappings, left actions by multiplication and left transformation semigroups $(S, Q)$ in the obvious way.

Let $S$ and $T$ be two semigroups. Let $\beta : T \to \text{T}(S)$ be a left action of $T$ on $S$. The **semidirect product** $S \rtimes_T T$ is the semigroup defined by considering the multiplication $(s, t)(s', t') = (s(ts'), tt')$ on the set $S \times T$. Often, we write just $S \rtimes T$.

Next, we define the **wreath product** $(B, S) \wr (Q, T)$ of the two transformation semigroups $(B, S)$ and $(Q, T)$. The wreath product $(B, S) \wr (Q, T)$ consists of all pairs $(f, t)$, where $t \in T$ and $f : Q \to S \in S^Q$, the semigroup of all functions from $Q$ to $S$ with pointwise multiplication. The action of $(f, t)$ on $(b, q) \in B \times Q$ is

$$(b, q)(f, t) = (b(qf), qt).$$

This defines the product in the semigroup of the wreath product by

$$(f, t)(f', t') = (f(t \circ f'), tt').$$

This defines the wreath product $(B, S) \wr (Q, T)$ as the transformation semigroup $(B \times Q, S^Q \times T)$. The product in the wreath product above gives $S^Q \times T$ the structure of a semidirect product.

2.2. **Actions related to Green’s relations.** We first recall some basic properties of Green’s relations. See [2, 12] for more details. Let $M$ be a finite monoid.

**Green’s relations** $\mathcal{R}$, $\mathcal{L}$ and $\mathcal{J}$ are defined on $M$ by

- $m \mathcal{L} n$ if $Mm = Mn$;
- $m \mathcal{R} n$ if $mm = mm$;
- $m \mathcal{J} n$ if $Mmm = Mnn$.

The $\mathcal{L}$-class of $m \in M$ is denoted by $L_m$ and similar notation is used for $\mathcal{R}$- and $\mathcal{J}$-classes. One defines the $\mathcal{L}$-order on $M$ by $m \preceq_{\mathcal{L}} n$ if $Mm \subseteq Mn$. The quasi-orders $\preceq_{\mathcal{R}}$ and $\preceq_{\mathcal{J}}$ are defined analogously.
The set of idempotents of \( M \) is denoted by \( E(M) \). Regularity of an element \( m \in M \) is equivalent to each of the following: \( L_m \cap E(M) \neq \emptyset \); \( R_m \cap E(M) \neq \emptyset \); and \( J_m \cap E(M) \neq \emptyset \) (the last equivalence uses finiteness). A \( J \)-class is called regular if it contains an idempotent or, equivalently, contains only regular elements. An important fact about finite monoids is that they enjoy a property called stability which states that

\[
xy \mathcal{J} x \Leftrightarrow xy \mathcal{R} x \quad \text{and} \quad xy \mathcal{J} y \Leftrightarrow xy \mathcal{L} y
\]

for \( x, y \in M \) [13, Theorem 1.13]. One consequence of stability is that the intersection of any \( \mathcal{R} \)-class and \( \mathcal{L} \)-class in a \( \mathcal{J} \)-class is non-empty. Another fact about finite semigroups that we shall use is that if \( J \) is a \( \mathcal{J} \)-class such that \( J^2 \cap J \neq \emptyset \), then \( J \) is regular (cf. [13, Corollary 1.24]).

For background on Green’s relations and the Rees Theorem, see [5] and [12, Chapter 4 and Appendix A].

Let \( S \) be a finite semigroup and let \( J \) be a \( \mathcal{J} \)-class of \( S \). We denote by \( L(J) \) the set of all \( \mathcal{L} \)-classes contained in \( J \). We simplify the notation to \( B = L(J) \). The right action of \( S \) on \( B \) is defined by partial maps through

\[
b \cdot s = \begin{cases} bs \\ \text{undefined} \end{cases} \quad \text{if } bs \subseteq J,
\]

for \( b \in B \) and \( s \in S \). In other words, we act on the \( \mathcal{L} \)-class \( b \) by \( S \) if this stays within the \( \mathcal{J} \)-class; otherwise the map is not defined. We denote this action by \( \lambda_J : S \rightarrow \text{PT}(L(J)) \). Note that \( \lambda_J \) is well defined by Green’s Lemma [12, Lemma A.3.1]. We denote the semigroup \( S\lambda_J \) by \( \text{RLM}_J(S) \).

An ideal of \( S \) is called 0-minimal if it is a minimal nonzero ideal; in particular, in a semigroup without zero we count the minimal ideal as a 0-minimal ideal.

We say that \( S \) is right (left) mapping if it contains a 0-minimal ideal \( I \) such that \( S \) acts faithfully on the right (left) of \( I \) by multiplication. If \( S \) is both right and left mapping, then it is called generalized group mapping. Furthermore, if \( I \) is not aperiodic, we say that \( S \) is a group mapping semigroup.

In this section, \((S,X)\) will be a fixed group mapping semigroup with generators \( X \), the \( \mathcal{L} \)-classes of its unique 0-minimal \( \mathcal{J} \)-class denoted by \( B \), and its maximal subgroup denoted by \( G \). Here we view the generators \( X \) as an external set, meaning that \( S \) is generated by \( X \) if there is a surjective morphism from the free semigroup \( X^+ \) to \( S \). The right action on \( B \) is denoted by \( \text{RLM}(S,X) \). So both \((B,\text{RLM}(S,X))\) and \((G \times B,(S,X))\) are faithful right actions. Both \( \text{RLM}(S,X) \) and \((S,X)\) are generated by \( X \). Hence \( X \) acts on the right on \( B \) and \( G \times B \). See also Lemma 2.4.

**Proposition 2.1.** [12, Proposition 4.6.22] Every right or left mapping semigroup has a unique 0-minimal ideal, which is necessarily regular.

Given a right (left) mapping semigroup \( S \), we denote by \( I \) this unique 0-minimal ideal. Write \( J = I \setminus \{0\} \). For all \( u, v \in J \), it follows that \( S^1 u S^1 \) and \( S^1 v S^1 \) are nonzero ideals contained in \( I \). By minimality of \( I \), we have \( S^1 u S^1 = I = S^1 v S^1 \) and so \( uJv \). Conversely, \( uJv \in J \) implies \( u \in J \), hence \( J \) is a \( \mathcal{J} \)-class of \( S \), called the distinguished \( \mathcal{J} \)-class of \( S \).

**Proposition 2.2.** [12, Proposition 4.6.35] Let \( J \) be a regular \( \mathcal{J} \)-class of a finite semigroup \( S \). Then \( \text{RLM}_J(S) \) is a right mapping semigroup with distinguished \( \mathcal{J} \)-class \( J\lambda_J \). Furthermore, \( J\lambda_J \) is aperiodic.
Assume now that $S$ is a right mapping semigroup. It is routine to check that the right action by multiplication

$$
\theta: S \to T(I)
$$

$$
s \mapsto \theta_s
$$

induces a right action by partial mappings (by multiplication)

$$
\theta': S \to PT(J)
$$

$$
s \mapsto \theta'_s,
$$

where $\theta'_s$ is the restriction of $\theta_s$ with domain $J \setminus 0\theta_s^{-1}$. Since $\theta$ is faithful, $\theta'$ is faithful as well.

Assume now that $R$ is an $R$-class contained in $J$. Let $\theta^R_s$ be the restriction of $\theta'_s$ with domain $R$. We claim that

$$
\theta^R: S \to PT(R)
$$

$$
s \mapsto \theta^R_s
$$

is still a faithful right action by partial mappings by multiplication.

First, we note that $\theta^R_s$ is well defined. If $u \in R \cap \text{dom}(\theta'_s)$, then $u\theta^R_s = us \leq_R u$ and $u\theta^R_s \cap u$. Since $S$, being a finite semigroup, is stable, we obtain $u\theta^R_s \in R$. Thus $\theta^R_s$ is well defined. We refer to [12, Appendix A.2] for basic definitions and properties of stability.

Since each $\theta^R_s$ is obtained from $\theta'_s$ by restriction, it is still a right action. Suppose now that $\theta^R_s = \theta^R_t$ for some $s, t \in S$. We claim that $\theta'_s = \theta'_t$. Indeed, let $u \in J$. Then there exists some $v \in R \cap L_u$, hence $u = xv$ for some $x \in S^1$. It follows that

$$
u\theta'_s = xvs = x(v\theta^R_s) = x(v\theta^R_t) = xvt = u\theta'_t.
$$

Thus $\theta'_s = \theta'_t$. Since $\theta'$ is faithful, this yields $s = t$. Therefore $\theta^R$ is also faithful.

**Remark 2.3.** We remarked before that $S^1uS^1 = I$ for every $u \in J$. Since $J$ is regular, $u$ has an inverse $u'$ also in $J$, hence

$$
I = S^1uS^1 = S^1uu'uS^1 \subseteq I^1uI^1 \subseteq I
$$

and so $I$ is 0-simple. Since $S$ is finite, it follows from the Rees Theorem that $I$ is up to isomorphism a Rees matrix semigroup of the form $M^0[G, A, B, C]$. We may assume that

- $G$ is a group isomorphic to one of the group $H$-classes in $J$
- $A$ is the set of $R$-classes in $J$
- $B$ is the set of $L$-classes in $J$
- $C = (c_{ba})$ is a $B \times A$ matrix with entries in $G \cup \{0\}$

Since $I$ is regular, each row or column of $C$ contains nonzero entries.

To understand the right action of $S$ on $I$, we must understand the corresponding right action of $S$ on $M^0[G, A, B, C]$. Of course, $0s = 0$ for every $s \in S$. And we have seen that $(a, g, b)s \neq 0$ implies $(a, g, b)sR(a, g, b)$, so the first coordinate will not change. Hence it is all about the action on $G$ and $B$.

**Lemma 2.4.** [5, Proposition 2.17] Let $S$ be a generalized group mapping semigroup acting on the $R$-class $G \times B$ of its distinguished $J$-class $J$ isomorphic to $M^0[G, A, B, C]$. Then $(G \times B, S)$ embeds into $(G, G) \wr (B, RLM_J(S))$. 
Given Lemma 2.4, if \((a, g, b) \in J\) and \(s \in S\), if \((a, g, b)s \neq 0\) then we can write
\[
(a, g, b)s = (a, g(b)s, bs),
\]
where \(bs\) is the image of \(b\) under \(RLM(s)\) and \(r\) is a function \(\text{dom}(RLM(s)) \to G\). We will use this notation throughout the rest of the paper.

Let \(\mu: B \to G\) be a partial function and let \(s \in S\). Define the partial function \(\mu^s: Bs \to G\) by
\[
(bs)\mu^s = ((b\mu)s) \quad \text{for} \quad b \in \text{dom}\mu \cap \text{doms}.
\]
Note that \(\mu^s\) defines a partial function if and only if
\[
bs = b's \implies b\mu(b)s = b'\mu(b')s.
\]
This is called the cross section condition.

2.3. Subsets, partitions, cross-sections. Let \(G\) be a finite group and \(B\) a finite set. A partial partition of \(B\) is a partition of a subset \(W\) of \(B\) (including the empty set). Given \(W \subseteq B\), we denote by \(GW\) the collection of all functions \(f: W \to G\). The group \(G\) acts on the left of \(GW\) by \((g\mu)(x) = g(\mu(x))\) for \(\mu \in GW, g \in G, x \in W\). Then the element \(G\mu\) of the set of orbits \(GW/G\) is called a cross section with domain \(W\). An SPC (Subset, Partition, Cross Section) over \(G\) is a triple \((W, \pi, C)\), where \(W\) is a subset of \(B\), \(\pi\) is a partition of \(W\) and \(C\) is a collection of \(k\) cross sections with domains \(\pi_1, \ldots, \pi_k\), where \(\pi_1, \ldots, \pi_k\) denote the blocks of \(\pi\). We denote by \(SPC(B, G)\) the set of all such triples.

We describe next an alternative formalism. Given a partition \(\pi\) of \(W \subseteq B\) and \(\mu, \mu' \in GW\), we write
\[
\mu \sim_{\pi} \mu' \quad \text{if} \quad \mu|_{\pi_i} \in G(\mu'|_{\pi_i}) \quad \text{for each block} \quad \pi_i \quad \text{of} \quad \pi.
\]
Then \(\sim_{\pi}\) is an equivalence relation on \(GW\). If we denote by \([\mu]|_{\pi}\) the equivalence class of \(\mu \in GW\), then we can view \(SPC(B, G)\) as the set of triples of the form \((W, \pi, [\mu]|_{\pi})\), where \(W \subseteq B\), \(\pi\) is a partition of \(W\) and \(\mu \in GW\).

We consider a partial order on \(SPC(B, G)\) based on containment of sets and partitions:
\[
(W, \pi, [\mu]|_{\pi}) \leq (W', \pi', [\mu']|_{\pi'}) \quad \text{if}:
\]
\begin{enumerate}
  \item \(W \subseteq W'\),
  \item every block of \(\pi\) is contained in a (necessarily unique) block of \(\pi'\),
  \item \([\mu']|_{\pi}|_{\pi} = [\mu]|_{\pi}.
\end{enumerate}

With this partial order, \(SPC(B, G)\) becomes a \(^\land\) semilattice. It is a lattice if and only if \(G\) is trivial. Assume now that \(G\) is nontrivial. By adding a top element \(\hat{1}\) to \(SPC(B, G)\), we obtain the Rhodes lattice \(R_{B}(G)\). This new element will be the join of any two elements of \(SPC(B, G)\) not admitting a common upper bound. See [9] for more details and connections between Rhodes lattices and Dowling lattices.

2.4. Flows on automata. An \((\text{deterministic partial})\) automaton is a structure of the form \(A = (Q, X, \delta)\), where \(Q\) and \(X\) are finite nonempty sets and \(\delta: Q \times X \to Q\) is a partial function. We write \(qx\) instead of \((q, x)\delta\). Thus each \(x \in X\) defines a partial function on \(Q\) and we have the corresponding morphism from the free semigroup \(X^+\) to \(\text{PT}(Q)\). Let \(T_A\) denote its transition monoid. Recall that \(T_A\) is the subsemigroup of the monoid of all partial functions on \(Q\) generated by the functions in \(X\). We say that \(A\) is \(\text{aperiodic}\) if \(T_A\) is aperiodic. Recall that an aperiodic finite semigroup is one in which each subgroup is trivial.
Let $A = (Q, X, \delta)$ be an automaton and let $S$ be a group mapping $X$-semigroup. We assume that $I = M^0[G, A, B, C]$ is the 0-minimal ideal of $S$ using the notation of Remark 2.3. Recall the operator $\mu \mapsto \mu'$ defined by (2.2).

A flow on the automaton $A$ relative to $S$ is a map $\xi : Q \to \text{SPC}(B, G)$ satisfying the following condition: if $(q, x)\delta = q' = q \cdot x$, $q\xi = (W_q, \pi_q, [\mu_q]_{\pi_q})$ and $(qx)\xi = (W_{qx}, \pi_{qx}, [\mu_{qx}]_{\pi_{qx}})$, then
\begin{equation}
\begin{aligned}
& (F1) \quad W_q x \subseteq W_{qx}; \\
& (F2) \quad \text{if } (\pi_q)_i \text{ is a block of } \pi_q, \text{ then } (\pi_q)_i x \subseteq (\pi_{qx})_j \text{ for some necessarily unique block } (\pi_{qx})_j \text{ of } \pi_{qx}; \\
& (F3) \quad (\pi_q)_i \to (\pi_{qx})_i x \text{ is a partial one-to-one function between } W_q/\pi_q \text{ and } W_{qx}/\pi_{qx}; \\
& (F4) \quad \mu_q^x \text{ as in (2.2) is well defined;} \\
& (F5) \quad \mu_q^x|_{(\pi_q)_i x} \in G(\mu_{qx}|_{(\pi_q)_i x}) \text{ for each block } (\pi_q)_i \text{ of } \pi_q.
\end{aligned}
\end{equation}

We also denote such a flow by
\begin{equation}
\text{spc} = (W_q, \pi_q, [\mu_q]_{\pi_q}) \xrightarrow{x} (W_{qx}, \pi_{qx}, [\mu_{qx}]_{\pi_{qx}}) = \text{spc}'.
\end{equation}

To show that the concept is well defined, we have to show that whenever $[\nu]_{\pi_q} = [\mu]_{\pi_q}$, conditions (F4) and (F5) hold for $\nu$ if and only if they hold for $\mu$.

Write $\pi_q = \{(\pi_q)_1, \ldots, (\pi_q)_m\}$. Since $[\nu]_{\pi_q} = [\mu]_{\pi_q}$, for each $i = 1, \ldots, m$ there exists some $g_i \in G$ such that $\nu|_{(\pi_q)_i} = g_i\mu|_{(\pi_q)_i}$.

Assume that $\mu_q^x$ is well defined. Then by (2.3) we have that $bx = b'x$ implies $(b\mu_q)((b)x) = (b'\mu_q)((b')x)$.

If $bx = b'x$, it follows from (F3) that $b, b' \in (\pi_q)_i$ for some $i \in \{1, \ldots, m\}$. Hence
\begin{equation}
(b\mu_q)((b)x) = g_i(b\mu_q)((b)x) = g_i(b'\mu_q)((b')x) = (b'\nu)((b')x).
\end{equation}

Thus (2.3) implies that $\mu_q^x$ is well defined. The reverse implication follows by symmetry.

Assume now that for each $i = 1, \ldots, m$, there exists some $h_i \in G$ such that $\mu_q^x|_{(\pi_q)_i x} = h_i(\mu_{qx}|_{(\pi_q)_i x}) x$.

For every $b \in \text{dom}\nu_q \cap (\pi_q)_i = \text{dom}\mu_q \cap (\pi_q)_i$, we have
\begin{equation}
(bx)\nu_q^x = (b\nu_q)(((b)x) = g_i(b\mu_q)(((b)x) = g_i(bx)\mu_q^x = g_i(h_i(bx)(\mu_{qx}) x).
\end{equation}

Hence $\nu_q^x|_{(\pi_q)_i x} = g_i h_i(\nu_{qx}|_{(\pi_q)_i x})$. The reverse implication follows by symmetry and so the concept of flow is well defined.

2.5. **Complexity.** Given two pseudovarieties $V$ and $W$ of finite semigroups, we denote by $V \ast W$ the pseudovariety of finite semigroups generated by all semidirect products $S \times T$, with $S \in V$ and $T \in W$. The semidirect product is an associative operation on pseudovarieties.

Let $S$, $A$ and $G$ denote respectively the pseudovarieties of all finite semigroups, aperiodic finite semigroups and finite groups. The complexity pseudovarieties are defined inductively by
\[ C_0 = A, \quad C_{n+1} = A \ast G \ast C_n \quad (n \geq 0). \]

The Prime Decomposition Theorem, also known as the Krohn–Rhodes Theorem, is given as follows.

**Theorem 2.5.** (Prime Decomposition Theorem) $S = \bigcup_{n \geq 0} C_n$.

The complexity function $c : S \to \mathbb{N}$ is defined by $Sc = \min \{n \in \mathbb{N} \mid S \in C_n\}$. 

Theorem 2.6. (Fundamental Lemma of Complexity) Let \( \varphi : S \to T \) be a surjective homomorphism of finite semigroups. If \( \varphi \) is injective on every subgroup of \( S \), then \( Tc = Sc \).

Assume that \( J \) is a regular \( J \)-class of a finite semigroup containing a nontrivial subgroup. We define a congruence \( \equiv_J \) on \( S \) by
\[
s \equiv_J t \quad \text{if } \forall x, y \in J \ (x sy \in J \iff xty \in J), \quad \text{and in this case } x sy = xty.
\]
The quotient \( S/\equiv_J \) is denoted by \( GM_J(S) \). Note that \( GM_J(S) \) is a group mapping semigroup.

If \( G \) is a subgroup of \( S \) with identity \( e \), then the restriction of the projection \( \gamma_K : S \to GM_{J_K}(S) \) to \( G \) is injective. Indeed, if \( g, h \in G \) satisfy \( g \equiv_J ehe \) and consequently \( g = h \).

Theorem 2.7. Let \( S \) be a finite subgroup and let \( J_1, \ldots, J_n \) be the \( J \)-classes of \( S \) containing a nontrivial subgroup. Then \( Sc = \sum_{i=1}^{n} (GM_{J_i}(S))c \).

Proof. Let \( \gamma : S \to \prod_{i=1}^{n} GM_{J_i}(S) \) be the homomorphism defined by \( s \gamma = (s \gamma_{J_1}, \ldots, s \gamma_{J_n}) \). In view of the previous comment, \( \gamma \) is injective on every subgroup of \( S \). It follows from Theorem 2.6 that \( Sc = \gamma c \).

Now
\[
S \gamma c \leq (\prod_{i=1}^{n} GM_{J_i}(S))c \leq \max\{(GM_{J_1}(S))c, \ldots, (GM_{J_n}(S))c\}.
\]
On the other hand, \( GM_{J_i}(S) \leq S \gamma \) yields \( (GM_{J_i}(S))c \leq S \gamma c \) for \( i = 1, \ldots, n \). Thus
\[
\max\{(GM_{J_1}(S))c, \ldots, (GM_{J_n}(S))c\} \leq S \gamma c
\]
and so \( Sc = \max\{(GM_{J_1}(S))c, \ldots, (GM_{J_n}(S))c\} \).

We define a group mapping semigroup to be pure if \( GMc = RLMc + 1 \). Theorem 2.7 implies that every semigroup \( S \) has complexity equal to at least one of its group mapping images. It follows by induction on the order of \( S \) that we can reduce the problem of computing complexity to that of deciding if a group mapping semigroup is pure or not.

Given \( n \geq 1 \), we denote by \( \text{Sym}_n \) the symmetric group on an \( n \)-set. We give a version of the Presentation Lemma based on flows as in [4]. For other versions see [12] and [1]. See Section 2.6 for further details and history on the Presentation Lemma.

Theorem 2.8. (Presentation Lemma) Let \( S \) be a group mapping semigroup generated by \( X \) acting by multiplication on the right on its 0-minimal ideal \( I = M^0[\text{G, A, B, C}] \). Write \( J = I \setminus \{0\} \) and assume that \( (RLM_J(S))c = n \geq 1 \). Then \( Sc = n \) if and only if there exists some flow on an automaton \( A = (Q, X, \delta) \) relative to \( S \) with transition semigroup \( T_A \) of the automaton \( A \) with \( T_{AC} = n - 1 \). In this case \( S \) divides \( (G \setminus \text{Sym}_{|B|} \setminus T_A) \times RLM_J(S) \).

Proof. We only provide the forward direction of the proof. The converse can be found in [1].

For the forward direction we restrict to the case \( n = 1 \). The case \( n > 1 \) is the obvious generalization.

Let \( (S, X) \) be a group mapping semigroup acting on \( G \times B \) with \( RLM(S, X)c \leq 1 \). Suppose there exists a flow \( \xi \) for an aperiodic automaton \( A = (Q, X, \delta) \). We need to show that \( S \prec (G \setminus \text{Sym}_{|B|} \setminus T_A) \times RLM_J(S) \).

We use \( \xi \) to define a new group mapping semigroup \( (S^\xi, X) \) generated by \( X \). For \( q \in Q \), consider the SPC \( q^\xi = (W_q, \pi_q, [\mu_q \pi_q]) \). The right action by \( x \in X \) is given by \( (qx)^\xi = (W_q x, \pi_q x, [\mu_q x \pi_q]) \).

We need to show that a direct product decomposition exists as implied by the statement of the
presentation lemma. When we write \( q\xi = (W_q, \pi_q, [\mu_q]_{\pi_q}) \), we pick a fixed arbitrary representative in the orbit of \([\mu_q]\) under left multiplication of \( G \), which is fixed throughout this proof.

\( S^\xi \) will be a group mapping semigroup of total maps. Hence its minimal ideal, which is a Rees matrix semigroup, has no zeros in its matrix. \( S^\xi \) acts on \( G \times [\bar{b}] \times Q \), where \([\bar{b}] = \{1, 2, \ldots, b\} \) with \( b \) the maximal number of blocks in any of the partitions \( \pi \) in the flow \( q\xi \). We consider \( \pi_q \) always to have \( b \) blocks by adding empty blocks. We number the blocks in some arbitrary but fixed order, fixed throughout this proof. Then by (F3) in Section 2.4, we extend the map \((\pi_q)_i \mapsto ((\pi_q)_i \cdot x) \) to a permutation of \([\bar{b}]\), denoted by \( p_{q,qx} \). This permutation is fixed throughout this proof.

Now we define the right action of \( S^\xi \) on \([\bar{b}] \times Q \) by the generator \( x \in X \) as follows

\[
(j,q)x = ((j)p_{q,qx},qx) = (jx,qx).
\]

The permutation \( p_{q,qx} \) maps blocks of \( \pi_q \) onto blocks of \( \pi_{qx} \). This action of \( S^\xi \) on \([\bar{b}] \times Q \) is clearly in \( \text{Sym}_{\pi}(Q,T_A) \).

To compute the action of \( X \) on \( G \times [\bar{b}] \times Q \) define

\[
(g,j,q) \cdot x = (g \cdot \tilde{g}(j,q,x),jx,qx),
\]

where \( \tilde{g}(j,q,x) \) is defined as follows. Let \( c_j \) be the cross section of the \( j \)-th block of \( q\xi \) given by the fixed representative of the \( j \)-th block of \([\mu_q]_{\pi_q}\). If this \( j \)-th block is empty, \( \tilde{g}(j,q,x) \) is arbitrary but fixed throughout this proof. Similarly, let \( c_{j'} \) be the cross section of \((q\xi)\xi\), where \( j' = (j)p_{q,qx} \). Then by (F4) and (F5) there exists \( \tilde{g}(j,q,x) \) such that

\[
c_j \mu^x \leq \tilde{g}(j,q,x)c_{j'}
\]

with \( \mu^x \) as defined in (2.2). Altogether this defines the action

\[
(2.5) \quad (g,j,q)x = (g\tilde{g}(j,q,x),jx,qx).
\]

Hence \( X \) generates a semigroup acting faithfully on the right on \( G \times [\bar{b}] \times Q \), which is a subsemigroup of \( G \wr \text{Sym}_{\pi}(Q,T_A) \) and which is the group mapping with all total maps. More precisely, this is a right group mapping semigroup of total maps. We define \( S^\xi \) to be the group mapping image of this semigroup. Its minimal ideal is a Rees matrix semigroup without zero.

Let \( \bar{Q} = G \times [\bar{b}] \times Q \) and consider \((\bar{Q},S^\xi, X) \times (B + 0, \text{RLM}(S), X)\). We define a subset \( \bar{Q} \) of \( \bar{Q} \times (B + 0) \) as follows:

1. \( \tilde{q} \times 0 \) is in \( \bar{Q} \) for all \( \tilde{q} \in \bar{Q} \);
2. \( ((g,j,q),b) \) is in \( \bar{Q} \), where \( b \in (\pi_q)_j \neq \emptyset \).

Define the map \( \rho: \bar{Q} \to G \times B \) by \( \tilde{q} \times 0 \mapsto 0 \) and \( ((g,j,q),b) \mapsto (g \cdot (b)c_j,b) \). This provides a morphism of transformation semigroups

\[
(\bar{Q},(S^\xi, X) \times (\text{RLM}(S), X)) \longrightarrow (G \times B + 0, (S, X)).
\]

Namely, if \( bx \) is not defined, then the morphism condition is satisfied trivially. If \( bx \) is defined, then (2.5) shows that it is a morphism.

This proves the forward direction of the Presentation Lemma. \( \square \)
2.6. Historical remarks on the Presentation Lemma and its uses. The first use of crosssections and implicitly of the Presentation Lemma (Theorem 2.8) appeared in Tilson’s paper [14]. This paper proved that complexity is decidable for semigroups with at most 2 non-zero \( J \)-classes. In the early 1970s, Rhodes formalized the notion of cross-sections and proved a version of the Presentation Lemma. He used it to give improved lower bounds for complexity in [10]. A number of non-trivial examples that require the Presentation Lemma to compute their complexity are also given in this paper. This has been one of the most important uses of the Presentation Lemma. See [12, Sections 4.14-4.16] and [8] for many illuminating examples.

The first published proof of the Presentation Lemma appeared in the important paper [1]. Rhodes developed the notion of flows on automata in [11]. This was presented in [12, Section 4.14] and with much more detail in [4]. Our treatment of the Presentation Lemma is based on these latter references with a very important difference. The treatment in [12] and [4] is based on flows in the set-partition lattice referred to as \( \text{SP}(M,X) \) in [4], while our treatment in this paper is based on flows in the Rhodes lattice \( R_B(G) \).

In our notation, the set-partition lattice is \( R_{G \times B}(1) \), the Rhodes lattice on the set \( G \times B \) relative to the trivial group. There are important differences between \( R_{G \times B}(1) \) and \( R_B(G) \) that were noted in our text and appear in [8, Section 4.1]. In particular, \( R_{G \times B}(1) \) is a lattice and \( R_B(G) \) is a quotient lattice. The maximal elements of these two lattices differ. The maximal element of \( R_B(G) \) has the intended meaning of having arrived at a contradiction to the existence of a flow and plays a crucial role in this paper. There is no such notion in \( R_{G \times B}(1) \). We strongly prefer the use of \( R_B(G) \) and cross-sections to describe and prove the results of this paper.

2.7. The Presentation Lemma for inverse semigroups. A group-mapping (GM) inverse semigroup is an inverse subsemigroup of a wreath product of partial transformation monoids of the form \( G \wr (B, \text{SIM}_B) \), where \( G \) is a finite group and \( B \) is a finite set; \( \text{SIM}_B \) is the symmetric inverse monoid on \( B \).

It is convenient to represent the semigroup \( G \wr (B, \text{SIM}_B) \) by partial monomial matrices over \( G \). We assume \( B = \{1, \ldots, n\} \) for some \( n \geq 1 \). An \( n \times n \) partial monomial matrix over a group \( G \) is an \( n \times n \) matrix with entries in \( G \cup \{0\} \) such that each row and each column has at most one non-zero entry. We identify an element \((g, i) \in G \times B \) with the \( n \)-dimensional row vector that has \( g \) in position \( i \) and 0 in all other positions. We identify the collection of all such vectors with \( G \times B \). The usual multiplication of a vector by a matrix then gives the completion (i.e., a transformation semigroup of total functions) of the wreath product \( G \wr (B, \text{SIM}_B) \), with the all-0 vector acting as the sink state.

Clearly the group of units of \( G \wr (B, \text{SIM}_B) \) is the usual monomial group \( G \wr (B, \text{Sym}_{[B]}(\text{Sym}_B)) \), where \( \text{Sym}_{[B]} \) denotes the symmetric group on the set \( B \). The monomial group consists of the monomial matrices over \( G \), i.e., the \( n \times n \) matrices with entries in \( G \cup \{0\} \) with exactly one non-zero entry in each row and each column. \( G \wr (B, \text{SIM}_B) \) is a generalized group mapping (GGM) semigroup. When \( G \) is trivial, we identify it with \( (B, \text{SIM}_B) \). If \( G \) is non-trivial, then it is a GM semigroup.

It is not difficult to see that \( G \wr (B, \text{SIM}_B) \) has a unique 0-minimal ideal which consists of those partial monomial matrices that have at most one non-zero entry in the matrix. Hence, this 0-minimal ideal is isomorphic to the \( n \times n \) Brandt semigroup \( B_n(G) \) over \( G \). Thus, a GM inverse semigroup is an inverse subsemigroup of \( G \wr (B, \text{SIM}_B) \) that contains all the matrices in \( B_n(G) \), for some non-trivial group \( G \). Furthermore, for inverse semigroups, elementary facts from the semilocal theory of finite semigroups (see [5, Chapters 7-8] and [12, Chapter 4]) show that an
inverse semigroup \( S \) is right letter mapping (RLM) as outlined above if and only if \( S \) is GGM over the trivial group, if and only if \( S \) is a subsemigroup of some \( \text{SIM}_B \) containing all partial constant functions.

If \( S \subseteq G \wr (B, \text{SIM}_B) \) is a GM inverse semigroup, then the map which replaces each non-zero entry in a matrix \( s \in S \) by the identity element gives the map \( \text{RLM}: S \rightarrow \text{RLM}(S) \). If \( s \) is a partial monomial matrix over \( G \) we define \( \text{dom}(s) \subseteq B \) to be the set of non-zero rows of \( s \). Thus \( \text{dom}(s) = B \) if and only if \( s \in G \wr (B, \text{Sym}_B) \), and thus every element \( s \) of \( G \wr (B, \text{SIM}_B) \) is the restriction to \( \text{dom}(s) \) of some element of the group of units. It follows that the semigroup

\[
T(S) = \{ (s, \tau) \mid \tau \in G \wr (B, \text{Sym}_B), \tau|_{\text{dom}(s)} = s \}
\]

is a subdirect product of \( S \) and \( G \wr (B, \text{Sym}_B) \). Furthermore it is easy to see, via the functorial properties of the \( \text{RLM}(\cdot) \) map, that \( \text{RLM}(T(S)) = \text{RLM}(S) \) (see \cite[Chapter 4.6]{note1}). It follows that the function

\[
(\tau, \text{RLM}(s)) \in G \wr (B, \text{Sym}_B) \times \text{RLM}(S) \text{ such that } (s, \tau) \in T(S) \mapsto s \in S
\]

is a well defined surjective morphism. Therefore, we have the following theorem, which is the Presentation Lemma for inverse semigroups; \( \prec \) denotes division of semigroups.

**Theorem 2.9.** Let \( S \subseteq G \wr (B, \text{SIM}_B) \) be a GM inverse semigroup. Then

\[ S \prec G \wr (B, \text{Sym}_B) \times \text{RLM}(S). \]

We note that a proof of this result follows from the general Presentation Lemma. Since a GM inverse semigroup \( S \) generated by \( X \) acts by partial bijections on \( G \times B \), it follows that the automaton with one state, with trivial semigroup, and one loop for each generator \( x \in X \), gives a flow. We send the single state to the SPC whose set is \( B \), and whose partitions blocks are all singletons with the trivial cross-section on each block. The reader can check that this is a flow, and the proof of the Presentation Lemma gives the decomposition in the previous theorem.

For readers familiar with the theory of inverse semigroups, the Presentation Lemma for inverse semigroups is intimately related to the theory of \( E \)-unitary semigroups. Indeed by a theorem of McAlister and Reilly \cite{note2}, every \( E \)-unitary inverse semigroup is a subdirect product of a group and a fundamental inverse semigroup. A GGM finite inverse semigroup \( S \) is fundamental if and only if \( S \) is RLM. Indeed the maximal fundamental image of a GM inverse semigroup is its RLM image. See \cite{note2} for the theory of \( E \)-unitary semigroups.

Let us look more closely at the direct product decomposition given by this theorem. According to the proof of the Presentation Lemma, the subsemigroup of \( G \wr (B, \text{Sym}_B) \times \text{RLM}(S) \) that maps onto \( S \) is

\[
T = \{ (M, \text{RLM}(s)) \mid s \in S \text{ and } M \text{ is an } n \times n \text{ monomial matrix over } G \text{ whose restriction to the non-zero rows of a partial monomial matrix } s \text{ is equal to } s \};
\]

that is, the matrix \( M \) as it appears in \( T \) is a monomial matrix that extends the partial monomial matrix \( s \).

As a specific example we can take the small monoid \( S \) consisting of the group of units \( G \wr (B, \text{SIM}_B) \) and the 0-minimal ideal \( B_n(G) \). A small monoid is by definition a monoid consisting of its group of units and a unique 0-simple ideal. As noted above, \( B_n(G) \) consists of all partial monomial matrices that have at most one non-zero entry in the whole matrix. Such a matrix is either the 0-matrix, or
it can be encoded by the triple \((i, g, j)\), where \(g \in G\) is the unique non-zero entry located in row \(i\) and column \(j\). This gives the connection to the usual definition of \(B_n(G)\).

RLM(S) is obtained by changing all non-zero entries of elements of \(S\) to 1. By identifying the symmetric inverse monoid on \(B\) with the monoid of all partial permutation matrices (i.e., matrices over \(\{0, 1\}\) with at most one non-zero entry in each row and column), we find that RLM(S) is a small monoid whose group of units is the symmetric group \(\text{Sym}_{|B|}\) (in the guise of all \(n \times n\) permutation matrices), and whose 0-minimum ideal is the set of all partial permutation matrices with at most one non-zero entry (also known as the “matrix units”). Clearly, this 0-minimal ideal is isomorphic to the Brandt semigroup \(B_n(\{1\})\).

The semigroup \(T\), lifting \(S\) to the subdirect product, consists of three \(J\)-classes: \(J_0, J_1, J_2\). The class \(J_0\) is the minimal ideal, and is equal to \(\{(M, 0) \mid M \in G \times G(\{1, \ldots, n - 1\}; \text{Sym}_{|B|})\}\). Thus \(J_0\) is isomorphic to \(G \times G(\{1, \ldots, n - 1\}; \text{Sym}_{|B|})\). The class \(J_2 = \{(M, \text{RLM}(M)) \mid M \in G \times G(\{1, \ldots, n - 1\}; \text{Sym}_{|B|})\}\) is the group of units of \(T\) and consists of all pairs of a monomial matrix and its permutation matrix image. Clearly, \(J_2\) is isomorphic to \(G \times G(\{1, \ldots, n - 1\}; \text{Sym}_{|B|})\).

The class \(J_1\) is the inverse image of \(B_n(G)\) under the morphism from \(T\) to \(S\). Since the congruence of this morphism is contained in \(H\) (by the general theory), \(J_1 \approx B_n(H)\) for some group \(H\), which we now determine. As the unit of \(H\) we take an idempotent \(e = (I_n, e_1) \in J_1\), where \(I_n\) is the identity matrix and \(e_1\) is the \(n \times n\) matrix with 1 in position \((1, 1)\) and 0 elsewhere. The idempotent \(e_1\) can also be considered to be an element of \(S\), and then the group \(G \times G(\{1, \ldots, n - 1\}; \text{Sym}_{|B|})\) consists of all partial monomial matrices whose \((1, 1)\) position contains an element of \(G\) and all other elements are 0. Thus, \(H_e = \{(M, e_1) \mid M\) is a monomial matrix that is non-zero in position \((1, 1)\}\). Such a monomial matrix \(M\) over \(G\) consists of two diagonal blocks: a \(1 \times 1\) block consisting of an element of \(G\), and an arbitrary \((n - 1) \times (n - 1)\) monomial matrix over \(G\). Therefore, \(H \approx G \times G(\{1, \ldots, n - 1\}; \text{Sym}_{n-1})\).

The morphism from \(T\) to \(S\) is as follows: it sends \((M, \text{RLM}(M)) \in J_2\) to \(M\); it sends \((M, \text{RLM}(M)) \in J_1\) to \(\psi(M_1)\), where \(\psi\) is the morphism from \(B_n(G \times G(\{1, \ldots, n - 1\}; \text{Sym}_{|B|}))\) to \(B_n(G)\), induced by the projection from \(G \times G(\{1, \ldots, n - 1\}; \text{Sym}_{n-1})\) to \(G\); and it sends all elements of \(J_0\) to 0.

As a generalization we look at \(S_r\), which is the rank-\(r\) small monoid consisting of the group of units \(G \times G(\{1, \ldots, n - 1\}; \text{Sym}_{|B|})\) and the \(J^0\)-class of all partial monomial matrices of rank \(r\). It is easy to see that the 0-minimal ideal is isomorphic to the Brandt semigroup \(B_{n-r}(G \times G(\{1, \ldots, n - 1\}; \text{Sym}_{|B|}))\). An analysis as above shows that the lift \(T\) consists of three \(J\)-classes: the group of units is \(G \times G(\{1, \ldots, n - 1\}; \text{Sym}_{|B|})\), as is the minimal ideal; and the lift of \(B_{n-r}(G \times G(\{1, \ldots, n - 1\}; \text{Sym}_{|B|}))\) is \(B_{n-r}(G \times G(\{1, \ldots, n - 1\}; \text{Sym}_{|B|}))\). This latter group is the analogue of the Young subgroup on a two-block partition in \(G \times G(\{1, \ldots, n - 1\}; \text{Sym}_{|B|}))\), and is intimately connected to the representation theory of \(G \times \text{Sim}_B\).

3. \(c = 1\) DECIDABLE IMPLIES \(c = n\) DECIDABLE

In this section, we prove the main result of the paper, namely that if complexity 1 is decidable, then complexity \(n \geq 0\) is decidable. We show that given a group mapping semigroup \(S\) of complexity \(n\), we can find a computable relational morphism \(\rho: S \to T\) to a semigroup \(T\) of complexity \(n - 1\) such that the derived semigroup \(D(\rho)\) has complexity 1.

We begin with the following well-known technical lemma whose proof we include for purposes of completeness.
Lemma 3.1. Let \((Q, S), (Q', S'), (P, T), (P', T')\) be transformation semigroups. Then
\[
(Q, S) \triangleright (P, T) \times (Q', S') \triangleright (P', T')
\]
eMBEDS into \(((Q, S) \times (Q', S')) \triangleright ((P, T) \times (P', T'))

Proof. Let \(f : P \to S\) and \(f' : P' \to S'\). Define \(F : P \times P' \to S \times S'\) by \((p, p') = (pf, pf')\). Then for all \(q \in Q, p \in P, q' \in Q', p' \in P'\), we have \((q, p, q', p')((f, t), (f', t')) = (q(pf), pt, q'(pf'), p't') = (q, q', p, p')(F, (t, t'))\). The assertion follows easily.

Corollary 3.2. Let \((Q, S), (Q', S'), (P', T')\) be transformation semigroups. Then
\[
(Q, S) \times ((Q', S') \triangleright (P', T'))
\]
embeds into \(((Q, S) \times (Q', S')) \triangleright (P', T')\).

Proof. This is a special case of Lemma 3.1 with \((P, T) = (1, 1)\), the trivial transformation semigroup.

The consolidation of a category \(\mathcal{C}\) is the semigroup on the set \(\text{Mor}(\mathcal{C}) \cup \{0\}\) obtained by defining the product of all non-composable morphisms to be 0, which is the zero element of the consolidation. In the next theorem, by derived semigroup of a relational morphism we mean the consolidation of the derived category of the relational morphism. We assume knowledge of the derived category theorem. We also need the following result, which is part of the proof of the Derived Category Theorem of Complexity. See [3, 12] for these results and a definition of the Rhodes expansion \(\hat{S}\) of a semigroup \(S\). The next lemma is well known.

Lemma 3.3. Let \(\phi : S \to T\) and \(\psi : T \to U\). Then \(D(\phi \psi) \prec D(\phi) \triangleright D(\psi)\).

Proof. By the Derived Category Theorem, \(T \prec D(\psi) \triangleright U\) and \(S \prec D(\phi) \triangleright T\). Therefore, \(S \prec (D(\phi) \triangleright D(\psi)) \triangleright U\). The Derived Category Theorem then implies that \(D(\phi \psi) \prec D(\phi) \triangleright D(\psi)\).

The next theorem summarizes some important properties of the Rhodes expansion. See [3, Chapter XII] and [12, Chapter 4] for the proof of the following theorem.

Theorem 3.4. Let \(\rho : S \to T\) be an aperiodic relational morphism and let \(\hat{\rho} : S \to \hat{T}\) be the induced relation to the Rhodes expansion of \(T\). Then the derived semigroup \(D(\hat{\rho})\) is aperiodic. Therefore, \(S \prec D(\hat{\rho}) \triangleright \hat{T}\), that is, \(S\) divides the wreath product of an aperiodic semigroup and \(\hat{T}\). Furthermore, for any semigroup \(S\), \(\hat{S}c = Sc\).

The following is an easy consequence of the derived semigroup theorem.

Theorem 3.5. Let \(n \geq 1\). A semigroup \(S\) has \(Sc \leq n\) if and only if there is a relational morphism \(\theta : S \to T\), where \(Tc \leq n - 1\) such that the derived semigroup \(D(\rho)\) satisfies \(Dc \leq 1\).

Proof. If \(Sc \leq n\), then \(S \prec A \ast G \ast A' \ast T\) for some aperiodic semigroups \(A, A'\), group \(G\) and \(T\) satisfying \(Tc \leq n - 1\). Therefore there is a division, that is, an injective relational morphism (see [12]) \(\delta : S \to A \ast G \ast A' \ast T\). Let \(\pi : A \ast G \ast A' \ast T \to T\) and \(\rho = \delta \pi : S \to T\). It follows from the Derived Category Theorem that \(D(\rho) \prec A \ast G \ast A'\) and thus \(D(\rho)c \leq 1\).

Conversely, if there is a relational morphism \(\theta : S \to T\), where \(Tc \leq n - 1\) such that the derived semigroup \(D(\rho)\) satisfies \(Dc \leq 1\), then \(S \prec D(\rho) \triangleright T\) and therefore, \(Sc \leq n\).
Now we prove that we can bound the search space to check that if \( S \) is a group mapping semigroup satisfying \( Sc \leq n \), then there is a relational morphism \( \rho: S \rightarrow T \) with \( Tc \leq n - 1 \) and \( D(\rho) \leq 1 \).

**Theorem 3.6.** Let \( S \) be a group mapping semigroup. There exists a computable function \( f_n: \mathbb{N} \rightarrow \mathbb{N} \) such that if there is a relational morphism \( \rho: S \rightarrow T \) with \( Tc \leq n - 1 \) and \( D(\rho)c \leq 1 \), then we can find such a \( T \) with \( |T| \leq f_n(|S|) \).

**Proof.** We prove this by induction on \( n > 0 \) and \( |S| \). If \( n = 1 \), we take \( T \) to be the trivial semigroup, \( \rho: S \rightarrow T \) to be the trivial morphism. Then \( D(\rho) = S \), so the result is true in this case.

In order that there be such a semigroup \( T \) it is necessary and sufficient that \( Sc \leq n \) by Theorem 3.5. Assume then that \( n > 1 \), \( Sc \leq n \) and the assertion is proved for \( n - 1 \). If \( Sc \leq n - 1 \), we take \( T = S \), \( \rho \) the identity morphism, so that \( D(\rho)c = 0 \). So we can assume that \( Sc = n \). If \( RLM(S)c = n - 1 \), that is, if \( S \) is pure-GM, then \( S \prec G \cap RLM(S) \), where \( G \) is the maximal subgroup of the distinguished ideal \( I(S) \) and the derived semigroup of the morphism from \( S \) to \( RLM(S) \) is easily seen to divide a Brandt semigroup over \( G \) and thus has complexity 1. We can thus take \( T = RLM(S) \).

So we can assume that \( Sc = RLM(S)c = n \). By the Presentation Lemma (see Theorem 2.8), \( S \prec H \cap A \times RLM(S) \) for some group \( H \) and aperiodic semigroup \( A \). Recall from Section 2 that the map \( \phi: RLM(S) \rightarrow RLM(S)^{GM} \) is aperiodic. Let \( J_1, \ldots, J_k \) be the regular non-aperiodic \( J \)-classes of \( RLM(S) \). Let \( S_i \) for \( i = 1, \ldots, k \) be the GM image of \( RLM(S) \) relative to \( J_i \). Then \( RLM(S)^{GM} \) is a subdirect product of \( S_i \) (with \( i = 1, \ldots, k \)) [5, Fact 8.6].

Since \( |S_i| < |S| \), by induction, there is a relational morphism from \( \rho_i: S_i \rightarrow T_i \) onto a semigroup \( T_i \) of complexity at most \( n - 1 \) such that \( D_i = D(\rho_i) \) has complexity at most 1 and \( |T_i| \leq f_n(|S_i|) \) for some computable function \( f_n \). It follows from Lemma 3.1 that \( RLM(S)^{GM} \prec (\prod_{i=1}^k (D_i)) \times \prod_{i=1}^k (T_i) \). The derived semigroup theorem implies that the derived semigroup \( D(\hat{\psi}) \) of the morphism \( \hat{\psi}: RLM(S)^{GM} \rightarrow \prod_{i=1}^k (T_i) \) satisfies \( D(\hat{\psi})c \leq 1 \).

Let \( U = \prod_{i=1}^k (T_i) \) and \( T = \hat{U} \). Let \( \rho = \hat{\phi} \hat{\psi}: RLM(S) \rightarrow T \). Then by Lemma 3.3, \( D(\rho) \prec D(\hat{\phi}) \times D(\hat{\psi}) \). By Theorem 3.4, \( D(\hat{\phi})c = 0 \) and by construction, \( D(\hat{\psi})c \leq 1 \). Therefore, \( D(\rho)c \leq 1 \). We have \( RLM(S) \prec D(\rho) \times T \) and by the use of the Presentation Lemma indicated above, \( S \prec (H \cap A) \times (D(\rho)) \times T \). By Corollary 3.2, it follows that \( S \prec ((H \cap A) \times D(\rho)) \times T \). By Theorem 3.4, \( \hat{T}c = Tc \leq n - 1 \). Let \( \theta: S \rightarrow T \) be the composition of \( RLM: S \rightarrow RLM(S) \) with \( \rho \). By the Derived Category Theorem, \( D(\theta) \prec ((H \cap A) \times D(\rho)) \) and thus \( D(\theta)c \leq 1 \).

The semigroup \( T \) is clearly computable and its order is a computable function of the maximal values of the values of \( f_n \) on the orders of GM semigroups with order strictly less than that of \( S \). Therefore, we can define \( f_n(|S|) \) to be this maximal value. This completes the proof.

We can now prove the main result of this paper, namely that if complexity 1 is computable for all finite semigroups, then so is complexity \( n \) for all \( n > 1 \).

**Theorem 3.7.** The complexity of a finite semigroup is computable if complexity 1 is computable.

**Proof.** Let \( Sc = n \). We proceed by induction on \( n \). By assumption and the aperiodic case for \( n = 0 \), the assertion is true if \( n \leq 1 \).

Assume that \( n > 1 \) and that by induction it is decidable if \( Sc = k \) for \( k \leq n - 1 \). Now let \( S \) be a finite semigroup. If \( Sc = n - 1 \), we are done by induction. Therefore, we can assume that \( Sc \geq n \) and by induction on \( |S| \), that \( S \) is a GM semigroup. By induction if we have \( RLM(S)c \leq n - 1 \,
then it follows that $S$ is a pure-GM semigroup of complexity $n$. By induction on cardinality, we can decide if $\text{RLM}(S)c \leq n$. If not, then $Sc \geq \text{RLM}(S)c \geq n + 1$. So we can assume that $\text{RLM}(S)c = n$.

By Theorem 3.6, we need to look at all relational morphisms $S \to T$, where $|T| \leq f_n(|S|)$ and $Tc \leq n - 1$, and check if any has derived semigroup with complexity at most 1. By induction we can list all the (finite number) of semigroups of order at most $f_n(|S|)$ and complexity $n - 1$. Since we have an algorithm to check if a semigroup has complexity 1, we can check all the derived semigroups in our list. If some derived semigroup of some relational morphism has complexity 1, then $Sc = n$ and if none exists, then $Sc = n + 1$. Therefore we can decide if any semigroup has complexity at most $n$. \hfill \Box

**Remark 3.8.** The proofs in this section are related to the results in Chapter 9 of [5], especially related to computing complexity by chains of GM and RLM semigroups.
