A Heavy Traffic Theory of Two-Sided Queues

SUSHIL MAHAVIR VARMA and SIVA THEJA MAGULURI, Georgia Institute of Technology, USA

Motivated by emerging applications in online matching platforms and marketplaces, we study a two-sided queue. Customers and servers that arrive into a two-sided queue depart as soon as they are matched. It is known that a state-dependent control is needed to ensure the stability of a two-sided queue. However, analytically studying the steady-state behaviour of a two-sided queue, in general, is challenging. Therefore, inspired by the heavy-traffic regime in classical queueing theory, we study a two-sided queue in an asymptotic regime where the control decreases to zero. It turns out that there are two different ways the control can be sent to zero, and we model these using two parameters viz., \( \epsilon \) that goes to zero and \( \tau \) that goes to infinity. Intuitively, \( \epsilon \) modulates the magnitude of the control and \( \tau \) is the threshold after which we modulate the control.

We show that depending on the relative rates of \( \epsilon \) and \( \tau \), there is a phase transition in the limiting regime. We christen the regime when \( \epsilon \tau \to 0 \), the quality-driven regime, and the limiting behaviour is a Laplace distribution. The phase transition starts in the regime when, \( \epsilon \tau \) goes to a nonzero constant when the limiting distribution is a Gibbs distribution, and so we call it the critical regime. When \( \epsilon \tau \to \infty \), we conjecture that the limiting distribution is uniform and prove that in a special case. We call this the profit-driven regime. These results are established using two related proof techniques. The first one is a generalization of the characteristic function method, and the second is a novel inverse Fourier transform method.

1 INTRODUCTION
Since the work of Erlang [10] in the context of telecommunication systems, more than a century ago, queueing theory has emerged as a well-established discipline that has had an impact on a large number of applications including wired and wireless networks, cloud computing, manufacturing systems, transportation systems etc. The central building block of queueing theory is a single server queue, which has a fixed server, customers that wait until their service and then depart immediately thereafter. In addition, there is a queue or a waiting space for the customers to wait, and a stochastic model of the arrivals and services. While the single server queue is well-understood when the arrivals and service are memory-less, there is no closed-form expression for the stationary distribution of the queue length for general distributions. Therefore, queueing systems are studied in various asymptotic regimes, including the heavy-traffic regime, where the arrival rate approaches the service rate.

More precisely, suppose \( \epsilon \) denotes the difference of the service rate and arrival rate, in heavy-traffic one studies the queue in the limit when \( \epsilon \downarrow 0 \). Clearly, when \( \epsilon = 0 \), the queue becomes unstable (null-recurrent). However, it is known [27] that the limiting distribution of the queue length multiplied by \( \epsilon \) is an exponential distribution. Moreover, the mean of the exponential depends only on the variance of the inter-arrival and service distributions, but not on the whole distribution. Recent work [11, 15, 25] has also characterized the rate of convergence to the exponential, thus enabling us to approximate the stationary queue length when \( \epsilon \) is not small.

Recent developments in online platforms and matching markets such as ride-hailing, food delivery services, etc have led to an interest in the study of two-sided queues. In a two-sided queue, both servers and customers arrive, wait until they are matched, and then immediately depart the system. The behaviour of two-sided queues is different from that of classical queues. In particular, a two-sided queue is never stable without external control. To see this, note that if the arrival rates on the two sides don’t match, the system is clearly unstable. But when the rates match, it is analogous to a symmetric random walk on a line, which is null-recurrent [38]. Therefore, two-sided queues have to be always studied under an external control that modulates the arrival rates in a state-dependent manner with levers such as prices in online platforms. In contrast to a large amount of literature on classical queues, there is comparatively very little work on two-sided queues.

Analogous to classical queues, except in special cases, it is hard to obtain the exact stationary distribution of queue length in a two-sided queue. The goal of this paper is to develop a heavy-traffic theory of two-sided queues, that will enable us to completely characterize the queueing behaviour in an appropriately defined asymptotic regime. However, unlike in classical queues, there is no natural notion of ‘heavy-traffic’ here, and we overcome this challenge as follows. Suppose that the uncontrolled arrivals have an equal rate on both sides. Now, we study the system in the regime when the state-dependent control goes to zero. As mentioned before, in the regime when the control is zero, the system is null-recurrent, and the regime is reminiscent of the heavy-traffic regime of a single-server queue.

To further motivate the aforementioned asymptotic regime, we consider the revenue management viewpoint. A popular class of pricing policies considered in the literature (see e.g. [3, 4, 26, 30, 37]) are either static or its perturbed version. These pricing policies are of interest as they are shown to be near-optimal. Note that, a perturbed pricing policy corresponds to a small perturbation of the state-independent control. Thus, our analysis is of relevance to this line of work and can be possibly extended to other models considered in the literature.

In two-sided queues, there are two ways in which the state-dependent control can be sent to zero. The first is clearly to scale the magnitude of the control by $\varepsilon$ which is sent to zero. The second is to apply the control only at larger and larger values of queues, which we control using a parameter $\gamma$ that is sent to $\infty$. These parameters are more precisely defined in (3). It turns out that the relative speed at which these two parameters go to their asymptote plays an important role in the limiting behaviour of the two-sided queue. In particular, the primary contribution of this paper is to demonstrate that there is a phase transition in the limiting behaviour of the two-sided queue depending upon the limiting value of $\varepsilon \gamma$. We christen the regime when $\varepsilon \gamma \to 0$ the quality-driven regime and the regime when $\varepsilon \gamma \to \infty$ the profit-driven regime for reasons outlined in Section 3. The phase transition happens in the intermediary regime when $\varepsilon \gamma$ goes to a nonzero real number, which we call the critical regime.

1.1 Main Contributions

The main contributions of this paper are the following.

- To illustrate the phase-transition behaviour, we first, consider the simplest two-sided queue with the simplest possible control, viz., the one with Bernoulli arrivals that is controlled with a two-price policy. Analogous to an $M/M/1$ (more precisely, a $Geo/Geo/1$) queue, one can obtain an exact stationary distribution here. By explicitly taking the asymptotic limit of this distribution, we show that the appropriately scaled queue length converges to a Laplace distribution in quality-driven regime, a Uniform distribution in the profit-driven regime and a hybrid of the above two in the critical regime. This is presented in Section 3.
The motivation to study the asymptotic behaviour is, of course, its utility when we can’t find the exact stationary distribution. Thus, in Section 4, we study a general two-sided queue with general arrival distributions and pricing curves. We show that the behaviour in quality-driven regime continues to be Laplace distribution, but the behaviour in the critical regime generalizes to a Gibbs distribution. The behaviour in the profit-driven regime is conjectured to be a Uniform distribution and is left as future work. The results are summarized in Table 1.

The third contribution of the paper is methodological. We present two different proof techniques to study the two regimes. To establish the result in the quality-driven regime, we generalize the characteristic function method, which was first developed in [25]. To study the critical regime, we develop the inverse Fourier transform method.

The above results show that the heavy-traffic behaviour in two-sided queues is much richer than that of a classical single-server queue. This is due to the state-dependent control in a two-sided queue, while classical heavy-traffic theory focuses on the case when the arrival rates in a single server queue are fixed. In Section 5 we show that even the classical single server queue exhibits a phase-transition behaviour if the arrival rates of customers are modulated in a state-dependent manner.

### 1.2 Literature Review

Single server queue in heavy traffic has been extensively studied in the literature. A popular approach is to use diffusion limits and study the resultant Brownian control problem. This was first done in literature by Kingman [27]. Even though they analyze the waiting time in a $G/G/1$ queue in continuous time, it is analogous to the queue lengths in a single server queue in discrete-time. Later, this method was generalized to analyze more general settings like heterogeneous customers [19], Parallel servers [20, 31], generalized switch [36], generalized Jackson networks [12], etc. More recently, direct methods which work with the original system, as opposed to the diffusion limit have been developed. One of these methods is the Drift method introduced in [11] which analyzes the single server queue. This method was further generalized to analyze switch [29], flexible load balancing [41], generalized switch [23], etc. Other methods which can be used to analyze such

Table 1. A Summary of Heavy-Traffic Phase Transitions in Two-Sided queues.
systems include transform method [25], basic adjoint relationship (BAR) method [7], and Stein’s method [16]. In addition, a single-server queue with state-dependent control was studied in [26]. Among these methodologically, the closest to the current work is the transform method presented in [25].

There has been interest in two-sided queues in recent years with applications in ride-hailing and online markets [4, 5, 30, 37], kidney exchange [32], matching markets [21], online marketplaces, etc. In addition, dynamic matching models studied in [1, 2, 8, 9] are closely related to two-sided queueing systems. The two-sided queueing model that we consider in this paper was studied in [30] in the context of ride-hailing, and it was recently extended to incorporate strategic behaviour of agents in [37]. Both these papers study the problem of designing a state-dependent control policy that optimizes an objective consisting of profit and mean delay.

Phase transition is of course a widespread phenomenon in many systems in general and a large class of queueing systems. The simplest is the trivial phase transition in a single server queue, which is stable when under-loaded and unstable when over-loaded. A single server queue with abandonment, on the other hand, is stable even when it is over-loaded. Such a system is known to exhibit a phase transition in the limiting distribution of queue length, as it moves from under-loaded to over-loaded [39]. Another example is the behaviour of many server queues in heavy traffic, where the famous Halfin-Whitt phase transition was presented in [18]. Load balancing systems also are known to exhibit phase transitions in the many servers heavy traffic regime [24, 28], even though the behaviour is not yet completely characterized.

1.3 Notation
We denote the imaginary unit \(\sqrt{-1}\) by \(j\). For a real number \(x \in \mathbb{R}\), we denote its positive part by \([x]^+ \overset{\Delta}{=} \max\{x, 0\}\) and negative part by \([x]^− \overset{\Delta}{=} \max\{-x, 0\}\). In addition, we denote the smallest integer greater than or equal to \(x\) by \([x]\) and the largest integer smaller than or equal to \(x\) by \(\lfloor x \rfloor\). For a set \(A \subseteq \mathbb{R}\), we denote its indicator function \(1_{x\in A}\) by \(1\{A\}\). In addition, we define the sign function by \(\text{sgn}(x)\) which is equal to 1 for all \(x \geq 0\) and -1 otherwise. Fourier transform of a function \(f\) is either denoted by \(\mathcal{F}(f)\) or \(\hat{f}\) and inverse Fourier transform is denoted by either \(\mathcal{F}^{-1}(f)\) or \(\hat{f}\). Any function \(f, g\) of \(\varepsilon\) such that \(\lim_{\varepsilon \to 0} \frac{|f(\varepsilon)|}{|g(\varepsilon)|} = 0\) is denoted by \(f(\varepsilon) = o(g(\varepsilon))\). We denote the space of infinitely differentiable functions by \(C^\infty_{\text{pol}}\). A sequence of random variable \(\{X_n\}\) converging in distribution to \(X\) is denoted by \(X_n \xrightarrow{D} X\).

2 MODEL
We consider a two-sided queue operating in discrete-time with customers and servers both arriving in the system. At a given time epoch \(k\), let \(q^c(k)\) and \(q^s(k)\) be the number of customers and servers waiting in the queue respectively. A waiting customer is matched to a server (and vice versa) as soon as possible, and the pair instantaneously departs from the system. Therefore, both servers and customers cannot be waiting at the same time, and so the main quantity of interest is the imbalance in the queue defined by \(z(k) \overset{\Delta}{=} q^c(k) − q^s(k)\) Thus, for any \(k \in \mathbb{Z}_+\), we have \(q^c(k)q^s(k) = 0\) with probability 1. Thus, it suffices to consider the imbalance \(z(k)\) as the state descriptor for the queue as \(q^c(k) = [z(k)]^−\) and \(q^s(k) = [z(k)]^+\).

Consider a two-sided queue with customers and servers both arriving in the system with exogenous arrival rates \(\lambda^*\) and \(\mu^*\) respectively. We take \(\lambda^* = \mu^*\) to balance the arrival rates, otherwise one of the queue lengths will go to infinity. Unfortunately, \(\lambda^* = \mu^*\) is not a sufficient condition for stability as the system will be null recurrent in this case (refer to [38, Section III B] for more detailed explanation). Thus, we need additional external control to stabilize the system. In general,
we consider state-dependent arrival rates. It is often the case with two-sided platforms that the system operator can use pricing to influence the arrival rate of customers and servers. For example, the system operator can increase the customer price to reduce its arrival rate as fewer customers would be willing to accept the higher price and similarly, increase the server price to increase its arrival rate as more servers would be willing to serve for a higher price offered.

Given the imbalance $z$, let $\phi^c(z)$ and $\phi^s(z)$ be the state-dependent control applied to the arrival rate of the customers and servers respectively. In particular, the effective arrival rate of the customers and servers are $\lambda^* + \phi^c(z)$ and $\mu^* + \phi^s(z)$ respectively. We will refer to this additional control as a pricing policy and we are interested in analyzing the imbalance given a pricing policy. After defining the arrival rates, we will now define the arrival process. Given a time epoch $(WLOG)$, we assume that the greatest common divisor (GCD) of the support (except 0) of the functions $\phi^c(z)$ and $\phi^s(z)$ for all $z \in \mathbb{Z}$ and $k \in \mathbb{Z}_+$. Moreover, the variances are a function of the mean and is denoted by $\text{Var}[\phi^c(z,k)] \overset{\Delta}{=} \sigma^c(\lambda^* + \phi^c(z))$ and $\text{Var}[\phi^s(z,k)] \overset{\Delta}{=} \sigma^s(\mu^* + \phi^s(z))$ for some continuous functions $\sigma^c(\cdot)$ and $\sigma^s(\cdot)$. Assume that there exists an $A_{\text{max}}$ such that $|\phi^c(z,k)| \leq A_{\text{max}}$ and $|\phi^s(z,k)| \leq A_{\text{max}}$ with probability 1 for all $z, k$. In addition, we also assume that the arrivals are independent across time and given the imbalance, the customer and server arrivals are independent of each other.

Now, we are ready to define imbalance as a discrete-time Markov chain (DTMC) denoted as $\{z(k) : k \in \mathbb{Z}_+\}$. The imbalance evolves as follows: at the start of the time epoch, the system operator observes the imbalance $z(k)$ and set the customer and server price which leads to customer and server arrivals given by $a^c(z(k),k)$ and $a^s(z(k),k)$ respectively. Mathematically, the evolution equation is given by

$$z(k+1) = z(k) + a^c(z(k),k) - a^s(z(k),k)$$ (1)

We make the following mild assumption on the arrival distributions which ensures that the DTMC $\{z(k) : k \in \mathbb{Z}_+\}$ is irreducible.

**Assumption 2.1.** There exists $p_{\text{min}} > 0$ such that for all $z \in \mathbb{Z}$ and $k \in \mathbb{Z}_+$, we have

$$\mathbb{P}(a^c(z,k) > a^s(z,k)) \geq p_{\text{min}}, \mathbb{P}(a^c(z,k) < a^s(z,k)) \geq p_{\text{min}}$$

Intuitively, given a time epoch $k$ and imbalance $z$, there is a non-zero probability that the DTMC will transition to a higher or a lower value of imbalance. In addition, without loss of generality (WLOG), we assume that the greatest common divisor (GCD) of the support (except 0) of the random variable $|a^c(z,k) - a^s(z,k)|$ is 1. It is WLOG as we can scale all the random variables appropriately to ensure the same. This implies that the DTMC governing imbalance is aperiodic. To summarize, the DTMC governing the imbalance is irreducible (over $\mathbb{Z}$) and aperiodic.

Therefore, given the pricing policy, if the DTMC is positive recurrent, there exists a unique stationary distribution and we say that the DTMC is stable. We denote the imbalance in steady state with a bar on top, i.e. $\bar{z}$.

Ideally, one would like to analytically obtain the exact distribution of the imbalance in the steady state. However, this is not possible in general, and so we study the two-sided queue in an asymptotic regime. In particular, we will consider a sequence of pricing policies parametrized by $\eta$. Thus, we have a sequence of functions $(\phi^c_\eta(\cdot), \phi^s_\eta(\cdot))$ and the sequence of policies are such that $\phi^c_\eta \to 0, \phi^s_\eta \to 0$ uniformly as $\eta \to \infty$.

$$\phi^c_\eta \to 0, \phi^s_\eta \to 0 \text{ uniformly as } \eta \to \infty.$$ (2)

In words, we are interested in the performance of pricing policies such that the external control vanishes, analogous to the heavy traffic regime in a single server queue as explained in the introduction. In particular, we focus on the following family of policies that are characterized by two...
parameters, \( \epsilon_\eta > 0 \) and \( \tau_\eta > 0 \).

\[
\lambda_\eta(z) = \lambda^* + \epsilon_\eta \phi^c \left( \frac{z}{\tau_\eta} \right), \quad \mu_\eta(z) = \mu^* + \epsilon_\eta \phi^d \left( \frac{z}{\tau_\eta} \right) \quad \forall z \in \mathbb{Z}, \forall \eta > 0.
\]

Here, \( \phi^c(\cdot) \) and \( \phi^d(\cdot) \) are fixed bounded functions. In particular, there exists a \( \phi^c_{\text{max}} > 0 \) such that \( \phi^c(x) \leq \phi^c_{\text{max}} \) and \( \phi^d(x) \leq \phi^d_{\text{max}} \) for all \( x \in \mathbb{R} \). Note that, we differentiate \((\phi^c(\cdot), \phi^d(\cdot))\) from \((\hat{\phi}^c(\cdot), \hat{\phi}^d(\cdot))\) with a tilde as the former defines a sequence of pricing policies involving the scaling parameter \( \eta \) and the later defines a single pricing policy that is free of any scaling. For a fixed \( \eta \), we can interpret it as \( \hat{\phi}^c(z) = \epsilon_\eta \phi^c \left( \frac{z}{\tau_\eta} \right) \) and \( \hat{\phi}^d(z) = \epsilon_\eta \phi^d \left( \frac{z}{\tau_\eta} \right) \) for all \( z \in \mathbb{Z} \).

This class of state-dependent controls are not only general, but are shown in the literature to have good performance in terms of delay and profit. Such a class of controls was first introduced in [26] in the context of a classical single server queue. They presented a near-optimal static, two-sided queue when \( \lim_{\eta \to \infty} \epsilon_\eta = 0 \), we let the control vanish. The influence of the parameter \( \tau_\eta \) is more subtle. It lets us tune the scale of the imbalance \( z \) at which we apply the control. In other words, by doubling \( \tau_\eta \), we apply the same control only when the imbalance is doubled. Thus, if we let \( \lim_{\eta \to \infty} \tau_\eta = \infty \), we end up applying no state-dependent control, and so this is equivalent to removing the control. Thus, we will study the two-sided queue when \( \lim_{\eta \to \infty} \epsilon_\eta = 0 \) and \( \lim_{\eta \to \infty} \tau_\eta = \infty \). The parameter \( \epsilon_\eta \) is similar to the heavy-traffic parameter in a classical single server queue. The parameter \( \tau_\eta \) is new in this context and it appears because we use state-dependent control.

Whenever the DTMC \( \{z_\eta(k) : k \in \mathbb{Z}_+\} \) is positive recurrent, denote the random variable with distribution same as its stationary distribution by \( \tilde{z}_\eta \). In the asymptotic regime when the control goes to zero, the imbalance \( \tilde{z}_\eta \) also blows up because we know that the system is null recurrent when there is no external control. Therefore, we need to scale it by the rate at which it blows up in order to study its limiting behaviour. A striking feature of the two-sided queue is that this rate as well as the limiting behaviour crucially depend on the rate at which \( \epsilon_\eta \) and \( \tau_\eta \) converges to 0 and \( \infty \) respectively. In particular, we define \( l \overset{\Delta}{=} \lim_{\eta \to \infty} \epsilon_\eta \tau_\eta \) and consider three cases. When \( l = 0 \), we will see that \( \tilde{z}_\eta = \Theta(1/\epsilon_\eta) \) and so we will study the limiting behaviour of \( \epsilon_\eta \tilde{z}_\eta \) as \( \eta \to \infty \). We call this the quality-driven regime as explained in the next section. When \( l = \infty \), we will see that \( \tilde{z}_\eta = \Theta(\tau_\eta) \) and so we study the limiting behaviour of \( \eta \tilde{z}_\eta/\tau_\eta \) as \( \eta \to \infty \). We call this the profit-driven regime. Lastly, in the other case when \( l \in (0, \infty) \), we will see that \( \tilde{z}_\eta = \Theta(1/\epsilon_\eta) = \Theta(\tau_\eta) \), and we study the limiting behaviour of \( \epsilon_\eta \tilde{z}_\eta \) as \( \eta \to \infty \), which is same as that of \( \tilde{z}_\eta/\tau_\eta \) up to the multiplicative factor \( l \). We call this the critical regime. The objective of this paper is to characterize the limiting distribution of appropriately scaled imbalance \( \epsilon_\eta \tilde{z}_\eta \) or \( \tilde{z}_\eta/\tau_\eta \) in the steady state as \( \eta \to \infty \) for any given \( \epsilon_\eta \), \( \tau_\eta \), \( \phi^c \), and \( \phi^d \). We will demonstrate a phase transition in the limiting distribution across the three regimes described above. In the next section, we present a simple example to illustrate this behaviour.

In the further sections, all the quantities concerned with the \( \eta^{th} \) system is sub-scripted by \( \eta \). In addition, for the simplicity of notations, we omit the \( \eta \) dependence on \( \epsilon \) and \( \tau \) everywhere and also omit \( \eta \) dependence whenever it is clear from the context.

3 AN ILLUSTRATIVE EXAMPLE: BERNOULLI TWO-SIDED QUEUE

The goal of this section is to illustrate the phase transition phenomenon exhibited by the limiting distribution of the scaled imbalance by considering a simple system to analyze. We will consider
a two-sided queue operating under the two-price policy and when the arrivals are Bernoulli. First, we define the two-price policy formally.

**Definition 3.1.** The two price policy is a special case of (3) with \( \phi^c(x) = -1\{x > 1\} \) and \( \phi^s(x) = -1\{x < -1\} \). Specifically,

\[
\lambda_\eta(z) = \lambda^* - \epsilon \mathbb{1}\{z > \tau\}, \quad \mu_\eta(z) = \mu^* - \epsilon \mathbb{1}\{z < -\tau\} \quad \forall z \in \mathbb{Z}, \forall \eta > 0.
\]

In words, when there are too many customers in the system \( (z > \tau) \), we increase the price for the customers which leads to the reduction in the arrival rate by \( \epsilon \). Similarly, when there are too many servers \( (z < -\tau) \), we decrease the price offered to the servers which leads to an \( \epsilon \) reduction in the arrival rate. Thus, two-price policy is a simple intuitive pricing policy, where \( \epsilon \) is the perturbation of the arrival rates when the imbalance is outside a threshold \( \tau \). This example also illustrates the need for two different parameters \( \epsilon \) and \( \tau \), and how they can be separately tuned to make the control vanish. It has been shown in [30] and [37] that two-price policy is near-optimal in terms of the profit earned by the system operator and delay experienced by the customers and servers.

Consider a two-sided queue operating under the two-price policy given by Definition 3.1 such that \( \lambda^* + \epsilon < 1 \) and \( \lambda^* - \epsilon > 0 \). The arrivals are Bernoulli arrivals i.e. \( a^c_\eta(z, k) = 1 \) with probability \( \lambda_\eta(z) \) and 0 otherwise. Similarly, \( a^s_\eta(z, k) = 1 \) with probability \( \mu_\eta(z) \) and 0 otherwise. We will use this example to illustrate that the imbalance exhibits phase transition for \( l = 0 \) and \( l = \infty \). In particular, we show that appropriately scaled imbalance converges to Laplace distribution for \( l = 0 \), Uniform distribution for \( l = \infty \) and a hybrid of Laplace and Uniform distribution for \( l \in (0, \infty) \). Mathematically, we define Hybrid \((b, c)\) as follows:

\[
F_{\text{Hybrid}}(x) = \begin{cases} 
\frac{b}{2(b+c)} e^{\frac{-x}{2(b+c)}} & \text{if } x < -c \\
\frac{1}{2(b+c)} (x + c) + \frac{b}{2(b+c)} e^{\frac{-x}{2(b+c)}} & \text{if } x \in (-c, c) \\
1 - \frac{b}{2(b+c)} e^{\frac{-x}{2(b+c)}} & \text{if } x \geq c.
\end{cases}
\]

In essence this distribution is obtained by stitching together the pdfs of a continuous Uniform distribution between \(-c\) and \( c\) and a Laplace \((0, b)\) distribution. A Laplace distribution with parameters \( 0 \) and \( b \) is a double exponential distribution with mean \( b \) centered at 0. The hybrid distribution essentially flattens the parts between \(-c\) and \( c\) as shown in Figure 1. Note that, when \( c = 0 \), the hybrid distribution is same as a Laplace \((0, b)\) and when \( b \to 0 \), the hybrid distribution is approximately same as a Uniform \([-c, c]\). Now, we present the phase transition formally.

**Proposition 3.2.** Let \( \{\epsilon_\eta\}_{\eta>0} \) and \( \{\tau_\eta\}_{\eta>0} \) be such that \( \lim_{\eta \to \infty} \epsilon_\eta \tau_\eta = l \). Consider a two-sided queue operating under the two-price policy given by Definition 3.1. In addition, also assume that \( a^c_\eta(z, k) \sim \text{Bernoulli}(\lambda_\eta(z)) \) and \( a^s_\eta(z, k) \sim \text{Bernoulli}(\mu_\eta(z(k))) \) for all \( z \in \mathbb{Z}, k \in \mathbb{Z}_+, \eta > 0 \). Then,

1. When \( l = 0 \), we have

\[
\epsilon_\eta \tilde{z}_\eta \overset{D}{\to} \text{Laplace} \left( 0, \frac{\lambda^*(1-\lambda^*) + \mu^*(1-\mu^*)}{2} \right)
\]

2. When \( l \in (0, \infty) \), we have

\[
\epsilon_\eta \tilde{z}_\eta \overset{D}{\to} \text{Hybrid} \left( \frac{\lambda^*(1-\lambda^*) + \mu^*(1-\mu^*)}{2}, l \right) \quad \text{(5a)}
\]

\[
\tilde{z}_\eta \overset{D}{\to} \text{Hybrid} \left( \frac{\lambda^*(1-\lambda^*) + \mu^*(1-\mu^*)}{2l}, 1 \right) \quad \text{(5b)}
\]

, Vol. 1, No. 1, Article . Publication date: October .
(3) When \( l = \infty \), we have
\[
\frac{\tilde{z}_\eta}{\eta} \xrightarrow{D} \mathcal{U}(-1, 1)
\]

The proof of the proposition is presented in Appendix A. The key idea is that the resulting DTMC governing the imbalance is a simple discrete-time birth and death process. This enables us to explicitly evaluate the stationary distribution for every \( \eta \). Taking appropriate limits we get the three cases presented in the proposition.

The above proposition presents a phase transition from a Laplace distribution to a Uniform distribution. An illustration of the limiting distribution for various values of \( l \) is presented in Fig. 1. For this, we consider \( \mu_0 = \mu_1 = 0.5 \) and plot the limiting distribution of \( \varepsilon \mathbf{z}_\eta \) and \( \frac{\mathbf{z}_\eta}{\tau} \) for different values of \( l \in [0, \infty) \). When \( l = 0 \), the PDF flattens out for \( \frac{\mathbf{z}_\eta}{\tau} \) which means that the probability mass escapes to infinity. Thus, to get a meaningful limit when \( l = 0 \), we need to scale \( \mathbf{z}_\eta \) by \( \varepsilon \) as \( \varepsilon \) decays to zero faster than \( 1/\tau \). It can be seen in the Fig. 1a that the limiting PDF of \( \varepsilon \mathbf{z}_\eta \) is a Laplace distribution when \( l = 0 \). Similarly, as \( l \) becomes very large, the PDF of \( \varepsilon \mathbf{z}_\eta \) flattens out to zero which means that the probability mass escapes to infinity. Thus, to get a meaningful limit when \( l = \infty \), we need to scale \( \mathbf{z}_\eta \) by \( \tau \) as \( \frac{1}{\tau} \) decays to zero faster than \( \varepsilon \). It can be seen in the Fig. 1b that the limiting PDF of \( \frac{\mathbf{z}_\eta}{\tau} \) is nearly a uniform distribution for \( l = 10 \).

Another way to interpret this phase transition is as follows: Consider the Critical Regime that results in the Hybrid distribution. In particular, the limiting distribution of \( \varepsilon \mathbf{z}_\eta \) is \( \text{Hybrid}(\lambda^* (1 - \lambda^*), l) \). Now, if we let \( l \to 0 \), then the Hybrid distribution converges to Laplace distribution which is the limiting distribution of \( \varepsilon \mathbf{z}_\eta \) in the quality-driven regime. In addition, in the critical regime, the limiting distribution of \( \mathbf{z}_\eta/\tau \) is \( \text{Hybrid}(\lambda^* (1 - \lambda^*)/l, 1) \). Now, if we let \( l \to \infty \), then the Hybrid distribution converges to Uniform distribution which is the limiting distribution of \( \mathbf{z}_\eta/\tau \) in the profit-driven regime. We will later see that such a phase transition holds in more generality.

In the case when \( l = 0 \), the limiting pdf of imbalance has an exponentially decaying tail, and so the delay incurred by the customers and servers will decay fast. Therefore, we christen it the quality-driven regime. To intuitively understand this regime, consider the case when \( \tau \) is a constant. Then, \( \varepsilon \tau \to 0 \) as \( \varepsilon \to 0 \). In this case, \( \varepsilon \) acts similar to the heavy traffic parameter in a single server queue. The result we obtain is also analogous. In particular, the limiting distribution of scaled
queue length in a single server queue is exponential and we obtain a Laplace distribution for two-sided queues which is a two-sided exponential distribution. This is because imbalance is a signed random variable. The proposition says that the limiting distribution is invariant to the growth rate of \( r \) as long as \( l = 0 \).

In systems such as ride-hailing, since control is based on pricing incentives, it costs the platform. Consider the case when \( l = \infty \). Here, the pricing control is being applied for larger and larger values of the imbalance, and thus, is applied less often. So, the total cost of control in this regime is smaller than in the quality-driven regime leading to higher profit for the system operator. So we christen this the profit-driven regime. Next, to intuitively understand the profit-driven regime, consider \( \epsilon \) to be a constant. Then, \( \epsilon r \to \infty \) as \( r \to \infty \). Outside the threshold, we have a drift towards zero which is always bounded away from zero. Due to this, the mass of the limiting distribution of imbalance is concentrated between the two thresholds. Inside the threshold, all the states are identical to each other which leads to a uniform distribution between the thresholds. The proposition proves that even when \( \epsilon \downarrow 0 \), we will observe such a distribution as long as \( l = \infty \).

Lastly, we observe a mixed behaviour when \( l \in (0, \infty) \). In particular, when \( l \downarrow 0 \), the parameter \( c \) in the hybrid distribution converges to 0 which makes it the Laplace distribution and when \( l \to \infty \), it converges to \( \infty \) which results in an ill-defined distribution, because it appears to be an infinitely spread uniform distribution. This is because \( \bar{z}_p = \Theta(r) \) and so, if the imbalance is scaled by \( r \) instead of \( \epsilon \), we obtain a uniform distribution between \( (-1, 1) \).

The primary reason for considering the limiting regime is to understand the stationary behaviour even when we are unable to explicitly find it. Therefore, in the next section, we consider the two-sided queue under general arrivals and a general pricing policy.

### 4 PHASE TRANSITION: GENERAL ARRIVALS AND PRICING POLICY

In this section, we will extend the result from previous section to general case i.e. given any \( \phi^c \) and \( \phi^s \) and the arrival process governed by an arbitrary distribution. First, we will show that under suitable conditions on the pricing policy, the DTMC is positive recurrent. Then, we first introduce the inverse Fourier transform method to analyze the imbalance given \( \epsilon r \to l \in (0, \infty) \) in the critical regime. Next, we observe that as \( l \to 0 \), we obtain the result for the quality-driven regime and then use the characteristic function method to rigorously prove it. Lastly, we observe that as \( l \to \infty \), we obtain the result for profit-driven regime and present it as a conjecture.

#### 4.1 Positive Recurrence

To ensure positive recurrence, we need a drift that pushes the imbalance towards zero. In particular, if imbalance is a very large positive value, then there are a lot of customers in the queue and a sensible pricing policy will either reduce the customer arrival rate or increase the server arrival rate. Similarly, if the imbalance is a very large negative value, increasing the customer arrival rate or decreasing the server arrival rate would be sensible. We present the following condition on the pricing curves which ensures the same.

**Condition 4.1 (Negative Drift).** There exists \( \delta > 0 \) and \( K > 0 \) such that for all \( x > K \), \( \phi^c(x) - \phi^s(x) < -\delta \) and for all \( x < -K \), \( \phi^c(x) - \phi^s(x) > \delta \).

Now, under the given condition, we will show that the underlying DTMC is positive recurrent.

**Proposition 4.2.** Under Condition 4.1, for all \( \eta > 0 \), the DTMC \( \{z_\eta(k) : k \in \mathbb{Z}_+\} \) is positive recurrent. Also

\[
\mathbb{E} \left[ |\bar{z}_\eta| \right] \leq \frac{2A_{\text{max}}^2 + \epsilon_\eta \tau_\eta K(2\phi_{\text{max}} + \delta)}{\epsilon_\eta \delta}.
\]
The proof is based on using the Foster-Lyapunov theorem. We analyze the drift of the quadratic test function, \( z^2 \), and show that it is negative outside a finite set, which immediately implies positive recurrence. The bound on mean absolute imbalance follows from a well-known corollary of Foster-Lyapunov theorem [17, Proposition 6.13].

### 4.2 Main Theorem: Phase Transition

We will first consider the case when \( l \in (0, \infty) \). In this regime, it turns out that the limiting distribution explicitly depends on the pricing curves \( \phi^c(\cdot) \) and \( \phi^s(\cdot) \). To characterize this distribution, first define

\[
g_{b,c}(x) = \frac{2b}{\sigma^c(\lambda^*) + \sigma^s(\mu^*)} \left( \phi^s\left( \frac{X}{c} \right) - \phi^c\left( \frac{X}{c} \right) \right). \tag{7}
\]

Intuitively, \( g_{b,c}(z) \) characterizes the drift towards zero for imbalance equal to \( z \). Then, define the Gibbs distribution \( \text{Gibbs}(g) \) that corresponds to a function \( g(\cdot) \) by the PDF,

\[
e^{-\int_{-\infty}^{\infty} g(y) dy} \int_{-\infty}^{\infty} e^{-\int_{y}^{\infty} g(y) dy} dx. \tag{8}
\]

We need the following condition to state the limiting behaviour in this regime.

**Condition 4.3.** \( \phi^c(\cdot) \) and \( \phi^s(\cdot) \) belong to \( C^\infty_{\text{pol}} \), i.e. they are infinitely differentiable.

Now, we present the main theorem in this regime.

**Theorem 4.4 (Hybrid Regime).** Let \( \{\epsilon_\eta\}_{\eta > 0} \) and \( \{\tau_\eta\}_{\eta > 0} \) be such that \( \lim_{\eta \to \infty} \epsilon_\eta \tau_\eta = 1 \). Consider the positive recurrent DTMC \( \{z_\eta(k) : k \in \mathbb{Z}_{+}\} \) for any \( \eta > 0 \) and for any \( \phi^c(\cdot) \) and \( \phi^s(\cdot) \) satisfying Condition 4.1 and let \( \tilde{z}_\eta \) denote its steady state random variable. If in addition, Condition 4.3 is satisfied, we have,

\[
\epsilon_\eta \tilde{z}_\eta \xrightarrow{D} \text{Gibbs}(g_{1,1}), \quad \frac{\tilde{z}_\eta}{\tau_\eta} \xrightarrow{D} \text{Gibbs}(g_{1,1}). \tag{9}
\]

In order to understand the Gibbs distribution, consider the special case of two-price policy from Definition 3.1. Here, we get \( g_{1,1}(z) = -\mathbb{1}\{z > l\} + \mathbb{1}\{z < -l\} \) and so,

\[
\int_{0}^{\infty} g_{1,1}(y) dy = \mathbb{1}\{x > l\}(l - x) - \mathbb{1}\{x < -l\}(l + x).
\]

This gives that the pdf defined in (8) is the hybrid distribution given by (5). While this is consistent with the result in Proposition 3.2, note that we cannot apply Theorem 4.4 in this case because the pricing curves under two price policy have jumps, and so do not satisfy the Condition 4.3. This suggests that the Condition 4.3 may not be necessary in Theorem 4.4, and is possibly an artefact of our proof. While relaxing Condition 4.3 is future work, note that it is not too restrictive because all polynomials satisfy it. Any continuous pricing curve can be then approximated by a polynomial arbitrarily well due to the Stone-Weierstrass theorem.

Now, we will consider the limiting distribution of \( \text{Gibbs}(g_{1,1}) \) defined above in the Theorem 4.4 as \( l \to 0 \). Note that, we have

\[
e^{-\frac{X^2}{2(\sigma^c(\lambda^*) + \sigma^s(\mu^*))}} \int_0^X \left( \phi^s\left( \frac{t}{c} \right) - \phi^c\left( \frac{t}{c} \right) \right) dt = \begin{cases} e^{-\frac{-X^2}{2(\sigma^c(\lambda^*) + \sigma^s(\mu^*))}} \phi^s(-\infty) - \phi^c(-\infty) & \text{if } x > 0 \\ e^{-\frac{-X^2}{2(\sigma^c(\lambda^*) + \sigma^s(\mu^*))}} \phi^c(-\infty) - \phi^s(-\infty) & \text{if } x < 0, \end{cases}
\]

Under the condition \( \phi^c(-\infty) - \phi^s(-\infty) = \phi^s(\infty) - \phi^c(\infty) \), the right hand side is the PDF of a Laplace distribution. This illustrates that we should expect the limiting distribution of \( \epsilon_\eta \tilde{z}_\eta \) to be Laplace distribution in the quality-driven regime. Although, note that this is not a formal proof due to
unjustified limit interchanges. We will now first state the result formally and then rigorously prove
the result using a different approach. First, assume that the pricing curves satisfy the following
condition:

CONDITION 4.5 (Symmetry). \( \lim_{x \to \infty} \phi^i(x) \) and \( \lim_{x \to -\infty} \phi^i(x) \) exists and are denoted by \( \phi^i(\infty) \) and \( \phi^i(-\infty) \) respectively for \( i \in \{c, s\} \). In addition, \( \phi^c(\infty) - \phi^s(\infty) = \phi^c(-\infty) - \phi^s(\infty) = 1 \).

Another way to interpret the above condition is as follows: As we are considering the regime
where \( \epsilon \tau \to 0 \), value of \( \phi^c(\cdot) \) and \( \phi^s(\cdot) \) at \( \pm \infty \) will be crucial as (loosely speaking) \( z/\tau \) will escape to
infinity. Condition 4.5 imposes a symmetry condition on the values of \( \phi^c(\cdot) \) and \( \phi^s(\cdot) \) at \( \pm \infty \) so that we can expect \( \epsilon \tilde{z}_\eta \) to converge to a Laplace distribution which is symmetric around 0. Without loss
of generality, we can assume \( \phi^s(\infty) - \phi^c(\infty) = 1 \) and re-define \( \epsilon \) by scaling it with \( \phi^s(\infty) - \phi^c(\infty) \).

Now, we present the result below which extends the Case 1 of Proposition 3.2.

THEOREM 4.6 (Quality-Driven Regime). Let \( \{\epsilon_\eta\}_{\eta > 0} \) and \( \{\tau_\eta\}_{\eta > 0} \) be such that \( \lim_{\eta \to \infty} \epsilon_\eta \tau_\eta = 0 \). Consider the positive recurrent DTMC \( \{z_\eta(k) : k \in \mathbb{Z}_+\} \) for any \( \eta > 0 \) and for any \( \phi^c(\cdot) \) and \( \phi^s(\cdot) \) satisfying Condition 4.1 and let \( \tilde{z}_\eta \) denote its steady state random variable. If in addition, Condition 4.5 is satisfied, we have,

\[
\epsilon_\eta \tilde{z}_\eta \sim \text{Laplace}\left(0, \frac{\sigma^c(\lambda^*) + \sigma^s(\mu^*)}{2}\right).
\]

Next, we consider the profit-driven regime. Note that the limiting distribution of \( \tilde{z}_\eta/\tau \) is Gibbs\((g_{l,1})\) in the hybrid regime with the temperature of the distribution proportional to \( l \). Now, if we let \( l \to \infty \), then the PDF of Gibbs\((g_{l,1})\) will vanish everywhere except where \( \int_0^x (\phi^s(t) - \phi^c(t))dt \) attains its minimum. This is same as soft-min converging to exact minimum in the limit. Thus, we expect the limiting distribution of \( \tilde{z}_\eta/\tau \) to be Uniform over the set of arguments that minimizes \( \int_0^x (\phi^s(t) - \phi^c(t))dt \). Denote by \( \Phi^* \) the set of minimizers of \( \int_0^x (\phi^s(t) - \phi^c(t))dt \) and assume \( \Phi^* \neq \emptyset \).

Now, we will state the result as a conjecture and discuss the difficulties in proving such a result in
a later section.

CONJECTURE 4.7 (Profit-Driven Regime). Let \( \{\epsilon_\eta\}_{\eta > 0} \) and \( \{\tau_\eta\}_{\eta > 0} \) be such that \( \lim_{\eta \to \infty} \epsilon_\eta \tau_\eta = \infty \). Consider the positive recurrent DTMC \( \{z_\eta(k) : k \in \mathbb{Z}_+\} \) for any \( \eta > 0 \) and for any \( \phi^c(\cdot) \) and \( \phi^s(\cdot) \) satisfying Condition 4.1 and let \( \tilde{z}_\eta \) denote its steady state random variable. Then

\[
\frac{\tilde{z}_\eta}{\tau_\eta} \sim \mathcal{U}(\Phi^*)
\]

This conjecture is consistent with Proposition 3.2 when \( \phi^c \) and \( \phi^s \) are pricing curves corresponding to the two price policy. In particular, \( \Phi^* = (-1, 1) \).

4.3 Sketch of Proofs

4.3.1 Hybrid Regime: Theorem 4.4. The proof is based on the novel inverse Fourier transform
method, which we outline here. The complete proof is presented in Section 6.

SKETCH OF PROOF OF THEOREM 4.4. The proof is presented in three steps.

Step 1: The first step is to establish the tightness of the family of random variables \( \Pi \Delta \{\epsilon \tilde{z}_\eta : \eta > 0\} \), so that every sequence of random variables in this family has a sub-sequence that converges
in distribution. Let \( \tilde{z}_{\omega_0} \) denote a random variable with distribution of this limit. Tightness can be easily established using the bound on the imbalance in (6) of Proposition 4.2.

Step 2: The key idea in the proof is to use \( e^{\epsilon \omega z} \) as the test function for \( \omega \in \mathbb{R} \) and set its drift to zero in steady state. While this step is similar to the transform method in [25], the key challenge
varma and maguluri

is that when we let \( \eta \uparrow \infty \), we do not get an explicit expression for the characteristic function of \( \tilde{z}_\infty \). We instead get that the limit of every convergent subsequence satisfies the following implicit equation:

\[
E \left[ e^{j\omega \tilde{z}_\infty} g_{1,1}(\tilde{z}_\infty) \right] = j\omega E \left[ e^{j\omega \tilde{z}_\infty} \right].
\]

Existence of a limit (of the sub-sequence) from Step 1 plays a crucial role in obtaining this equation. Suppose we show that there is a unique distribution that solves this equation, then using standard arguments on convergence, it follows that the family \( \tilde{z}_\infty \) also converges to the same distribution. This completes the proof.

**Step 3:** To complete the proof, the focus of this step is to show that (10) has a solution, which is the Gibbs(\( g_{1,1} \)) distribution, and more importantly, to show uniqueness. While existence of the solution can be easily verified by plugging the Gibbs(\( g_{1,1} \)) distribution into (10), we use the following argument, which helps us prove uniqueness. Suppose that \( \tilde{z}_\infty \) has a continuously differentiable PDF \( \rho_{\tilde{z}_\infty} \), whose Fourier transform exists. Then, (10) can be interpreted as

\[
\mathcal{F} \left( \rho_{\tilde{z}_\infty} g_{1,1} + \rho'_{\tilde{z}_\infty} \right) = 0,
\]

since the differentiation theorem of Fourier transform gives \( j\omega \mathcal{F}(\rho_{\tilde{z}_\infty}) = -\mathcal{F}(\rho'_{\tilde{z}_\infty}) \). Applying inverse Fourier transform, we get the differential equation,

\[
\rho_{\tilde{z}_\infty} g_{1,1} + \rho'_{\tilde{z}_\infty} = 0,
\]

solving which we get the Gibbs distribution. Results from the theory of Fourier transform then gives us the uniqueness. We formalize this argument in Section 4.2 using the theory of Schwartz functions and Tempered distributions.

Transform method was first introduced in [25], and was used to study queues under static arrival rates. Consequently, [25] directly gets a closed form expression for the characteristic function of the limiting distribution which immediately establishes convergence in distribution to an exponential distribution. In contrast, due to the dynamic arrivals, we obtain an implicit equation (10). A major methodological contribution in this section is the introduction of the use of inverse Fourier transform to solve the implicit equation to obtain the limiting distribution. Moreover, due to the implicit equation, we have to separately establish the guarantee that our family converges in distribution. We believe that our proposed method will enable one to use transform techniques in a large class of stochastic network beyond the ones studied in [25].

4.3.2 Quality-Driven Regime: Theorem 4.6.

**Sketch of proof of Theorem 4.6.** Positive recurrence under Condition 4.1 is already shown in Proposition 4.2. The key idea in proving the convergence result is the following. It is known from the Levy’s continuity theorem (e.g. see: [40, Chapter 18]) that convergence in distribution is equivalent to convergence of characteristic functions. So, we will focus on finding the characteristic function of the limiting imbalance. The proof consists of two key steps.

**Step 1:** First, we show that \(|\varepsilon\tilde{z}_\eta|\) converges to an exponential distribution. We do this by setting the drift of the test function, \( e^{j\epsilon|\tilde{z}_\eta|} \) to zero in steady state and obtaining a bound on \( E \left[ e^{j\epsilon|\tilde{z}_\eta|} \right] \). Then, taking the limit as \( \eta \to \infty \), we show that \( \lim_{\eta \to \infty} E \left[ e^{j\epsilon|\tilde{z}_\eta|} \right] \) converges to the characteristic function of an exponential distribution. This proof technique was first introduced in [25] in the case of a single server queue. However, we overcome several technical challenges that arise due to the state-dependent control in a two-sided queue.

**Step 2:** In Step 2, we show that \( \tilde{z}_\eta \) is indeed symmetric around origin, thus completing the proof of the theorem. We first set the drift of the test function, \( \operatorname{sgn}(\tilde{z}_\eta)e^{j\epsilon|\tilde{z}_\eta|} \) to zero and show that
the expectation, \( \mathbb{E} \left[ \text{sgn}(z_\eta) e^{i\theta|z_\eta|} \right] \) converges to zero as \( \eta \uparrow \infty \). This establishes symmetry of the limiting \( z_\eta \).

**Step 3:** Putting together the results from Step 1 and Step 2, we get that the limiting distribution of \( e|z_\eta| \) is two-sided exponential, viz., the Laplace distribution. We do this by considering the following functional identity:

\[
e^{i\theta|z|} + e^{-i\theta|z|} = e^{i\theta z} + e^{-i\theta z} = 2e^{i\theta z} + \text{sgn}(x)e^{-i\theta \text{sgn}(x)} - \text{sgn}(x)e^{i\theta \text{sgn}(x)}.
\]

Now taking expectation of these under the distribution \( z_\eta \) and taking the limit as \( \eta \to \infty \), we get,

\[
\lim_{\eta \to \infty} \mathbb{E} \left[ e^{i\theta|z_\eta|} + e^{-i\theta|z_\eta|} \right] = \lim_{\eta \to \infty} \mathbb{E} \left[ 2e^{i\theta \text{sgn}(z_\eta)} + \text{sgn}(z_\eta)e^{-i\theta \text{sgn}(z_\eta)} - \text{sgn}(z_\eta)e^{i\theta \text{sgn}(z_\eta)} \right].
\]

Both the terms on LHS are characterized from Step 1. We know that the last two terms on the RHS are zero from Step 2. Thus, we have an explicit form for \( \lim_{\eta \to \infty} 2\mathbb{E} \left[ e^{i\theta \text{sgn}(z_\eta)} \right] \), which we show is the characteristic function of Laplace \( 0, \frac{\sigma^*(\lambda^* + \sigma^*(\mu^*))}{2} \). This completes the proof.

The inverse Fourier transform method is not directly applicable here because we’d obtain an implicit equation of the form (10) with \( g(x) = \text{sgn}(x) \) which does not satisfy Condition 4.3. Thus, we resort to modification of transform method. We work with the absolute value of imbalance, \( |z| \) which is similar to the queue length in a single server queue. The reason we obtain a closed form expression of the characteristic function of \( |z| \) is that the value of pricing curves only at \( \pm \infty \) is preserved which makes it analogous to the static arrival rate setting. However, we have to deal with the pricing curves and overcome technical challenges to make this argument rigorous. After this, we translate the result on \( |z| \) to a result in \( z \) by exploiting the underlying symmetry.

## 5 CLASSICAL SINGLE SERVER QUEUE

The heavy-traffic limiting behaviour of a two-sided queue studied in the previous section exhibits a much richer phase transition behaviour than that of a classical single server queue studied in the literature. This is primarily because most of the literature focuses on a constant arrival rate for a single server queue, whereas we studied two-sided queue under state-dependent control. Single server queue with state-dependent control also exhibits phase transition as studied in the previous sections.

Consider a sequence of single server queue \( \{q_\eta(k) : k \in \mathbb{Z}_+ \} \) for \( \eta > 0 \) with state-dependent arrival \( a_\eta(q_\eta) \) with expectation given by \( \mathbb{E} \left[ a_\eta(q_\eta) \right] = \lambda_\eta(q_\eta) = \lambda^* + \phi^* \left( \frac{q_\eta}{\rho} \right) \epsilon \), and variance given by \( \text{Var} \left[ a_\eta(q_\eta) \right] = \sigma^2(\lambda_\eta(q_\eta)) \). Similarly, the state-dependent potential service \( s_\eta(q_\eta) \) has expectation \( \mathbb{E} \left[ s_\eta(q_\eta) \right] = \mu_\eta(q_\eta) = \mu^* + \phi^* \left( \frac{q_\eta}{\rho} \right) \epsilon \), and variance \( \text{Var} \left[ s_\eta(q_\eta) \right] = \sigma^2(\mu_\eta(q_\eta)) \). Without loss of generality, we assume that \( \lambda^* = \mu^* \) and \( \phi^*(\infty) = \phi^*(\infty) = 1 \). Next, we assume that there exists an \( A_{\text{max}} > 0 \) such that \( |a_\eta(q_\eta)| \leq A_{\text{max}} \) and \( |s_\eta(q_\eta)| \leq A_{\text{max}} \) with probability 1. Now, we can write the queue evolution equation as follows:

\[
q_\eta(k + 1) = q_\eta(k) + a_\eta(q_\eta(k)) - s_\eta(q_\eta(k)) + u_\eta(q_\eta(k)),
\]

where \( u_\eta(q_\eta(k)) \) is the unused service if there are not enough customers waiting in the queue to be served and a fraction of the potential service \( s_\eta(q_\eta(k)) \) is not utilized. This implies that

\[
q_\eta(k + 1)u_\eta(q_\eta(k)) = 0.
\]

First, to illustrate the phase transition, we consider a single server queue operating in discrete-time under Bernoulli arrivals, Bernoulli service, and a two-price policy. In particular, assume that \( \lambda^* - \epsilon > 0, \lambda^* < 1 \), and the pricing curves are given by \( \lambda_\eta(q) = \lambda^* - \epsilon(q > \tau) \), and \( \mu_\eta(q) = \mu^* \) for all \( q \in \mathbb{Z}_+ \). Lastly, the arrival and service distribution are given by \( a_\eta(q_\eta) \sim \text{Bernoulli}(\lambda_\eta(q_\eta)) \),
and $s_\eta(q_\eta) \sim \text{Bernoulli}(\mu_\eta(q_\eta))$. As the arrival and service distribution is Bernoulli, the single server queue is a birth-death process as shown in Fig. 2. Now, we present the phase transition result below:

**Proposition 5.1.** Let $\{\epsilon_\eta\}_{\eta > 0}$ and $\{\tau_\eta\}_{\eta > 0}$ be such that $\lim_{\eta \to \infty} \epsilon_\eta \tau_\eta = 1$. Consider a single server queue operating under the two-price policy for customer arrival. Then, we have the following results.

1. When $l = 0$, we have
   
   $$\epsilon_\eta \bar{q}_\eta \xrightarrow{D} \text{Exp}\left(\frac{\lambda^*(1 - \lambda^*) + \mu^*(1 - \mu^*)}{2}\right)$$

2. When $l \in (0, \infty)$, we have $\epsilon_\eta \bar{q}_\eta \xrightarrow{D} \bar{q}_\infty$ such that
   
   $$\mathbb{P}(\bar{q}_\infty \leq q) = \begin{cases} 1 - \frac{m}{(l + m)} e^{-\frac{q}{m}} & \text{if } q \geq l \\ \frac{q}{(l + m)} & \text{if } q \in [0, l). \end{cases}$$

   The distribution mentioned above is a one sided hybrid distribution.

3. When $l = \infty$, we have
   
   $$\frac{\bar{q}_\eta}{\tau_\eta} \xrightarrow{D} \mathcal{U}(0, 1).$$

Thus, a single server queue also exhibits the phase transition behaviour under state-dependent control. For general arrivals, service and pricing policies, one can obtain results similar to the ones in Section 4, by essentially following the same methods. We present the result below. First, we introduce a negative drift condition analogous to Condition 4.1 to ensure positive recurrence for a general pricing policy.

**Condition 5.2 (Negative Drift).** There exists $\delta > 0$ and $K > 0$ such that for all $x > K$, we have $\phi^c(x) - \phi^b(x) < -\delta$.

Next, we show that $\epsilon_\eta \bar{q}_\eta$ converges in distribution to an exponential random variable in the quality-driven regime and to Gibbs distribution on the non negative axis denoted by $\text{Gibbs}_s(\cdot)$ in the critical regime. In particular, the PDF of $\text{Gibbs}_s(g)$ is given by

$$\frac{1}{\int_0^\infty \int_0^\infty e^{-\int_0^s g(t) dt} dx} e^{-\int_0^s g(t) dt} 1\{x \geq 0\}.$$ 

Now, we present the result below.

**Theorem 5.3.** Consider the positive recurrent DTMC $\{q_\eta(k) : k \in \mathbb{Z}_+\}$ for any $\eta > 0$ and for any $\phi^c(\cdot)$ and $\phi^b(\cdot)$ satisfying Condition 5.2 and let $\bar{q}_\eta$ denote its steady state random variable.

1. If $\epsilon_\eta \tau_\eta \to 0$, then we have,

   $$\epsilon_\eta \bar{q}_\eta \xrightarrow{D} \text{Exp}\left(\frac{\sigma^c(\lambda^*) + \sigma^b(\mu^*)}{2}\right).$$

![Fig. 2. Single server queue with Bernoulli arrivals and two-price policy with $m \Delta = \lambda^*(1 - \mu^*)$](image-url)
(2) If $\epsilon_{\eta} \tau_{\eta} \to l$ for $l \in (0, \infty)$ and Condition 4.3 is satisfied, then we have
\[
eq_{\eta} D \xrightarrow{\text{Gibbs}}(g_{1, l})
\]
where $g_{1, l}$ is given by (7).

Transform method introduced in [25] provided the stationary distribution of a single server queue with static arrival and service rate. In particular, they obtain a closed form expression for the characteristic function of the limiting distribution which immediately establishes convergence in distribution. In contrast, to prove part (2) of the theorem, we obtain an implicit equation ((36) in Appendix), to solve which, we use the inverse Fourier transform method. Therefore, the method presented in [25] is inadequate to obtain the limiting distribution for a single server queue with dynamic arrival rates.

In the further sections, we outline the proof of Theorem 4.4 and Theorem 4.6. The proof of Theorem 5.3 is analogous to these theorems and thus, we defer all the proof details to the Appendix F.

6 PROOF OF THEOREM 4.4: INVERSE FOURIER TRANSFORM METHOD

In this section, we will first use Proposition 4.2 and show tightness to complete Step 1. Next, we will carry out the drift analysis to obtain an implicit equation involving characteristic function of imbalance which will complete step 2 and then present a key lemma to prove uniqueness of the implicit equation which will complete Step 3 and finally, we will present the proof of Theorem 4.4.

6.1 Step 1: Tightness

**Lemma 6.1.** Under Condition 4.1, for the choice of $\epsilon$ and $\tau$ such that $\epsilon \tau \to l$ as $\eta \to \infty$, for every sequence in the family of random variables $\Pi = \{\epsilon \tilde{z}_{\eta} : \eta > 0\}$ such that $\eta \to \infty$, there exists a sub-sequence that converges in distribution.

The proof of the Lemma is presented in Appendix C.1. Now, we will consider an arbitrary sequence in the family of random variables $\Pi$. By the above lemma, there exists a sub sequence that converges in distribution. Denote by $\tilde{z}_{\infty}$ the limit of this convergent sub sequence. We will work with this sub sequence in the further sections.

6.2 Step 2: Drift Analysis

In this section, we will consider the characteristic function of the imbalance as the test function and set its drift to zero in steady state. Firstly, we present the update equation for the imbalance in steady state. Denote by $a^{c}(\tilde{z})$ and $a^{s}(\tilde{z})$ as the effective arrival in steady state when the imbalance is $\tilde{z}$. The imbalance after one transition $\tilde{z}_{\eta}^{+}$ follows the following evolution equation:
\[
\tilde{z}_{\eta}^{+} = \tilde{z}_{\eta} + a^{c}(\tilde{z}_{\eta}) - a^{s}(\tilde{z}_{\eta}).
\]  
We formally define the drift of a function $V(z)$. This is similar to the definition given in [25, Definition 1] and we present it below for completeness.

**Definition 6.2 (Drift of a function).** Let $V : \mathbb{R} \to \mathbb{C}$ be a function. We define the drift of $V$ at $z$ as
\[
\Delta V(z) = (V(z(k + 1)) - V(z(k))) \mathbb{I}\{z(k) = z\}.
\]
If $\mathbb{E}[|V(\tilde{z})|] < \infty$, then we say that we set the drift of $V$ to zero when we use the property
\[
\mathbb{E}[\Delta V(z)] = \mathbb{E}[V(\tilde{z}^{+}) - V(\tilde{z})] = 0.
\]
Now, we present the result in the following lemma:
Lemma 6.3.

\[ \mathbb{E} \left[ e^{j\omega z} g_{1,t} (z_\infty) \right] = j\omega \mathbb{E} \left[ e^{j\omega z} \right]. \]

Proof of Lemma 6.3. For \( \omega \in \mathbb{R} \), we define the test function

\[ W(z) = e^{j\omega z}. \]

We now set its drift to zero in steady state as \( |e^{j\omega z}| = 1 \).

\[
\mathbb{E} \left[ \Delta W(z) \right] = \mathbb{E} \left[ e^{j\omega z} \right] - e^{j\omega z} = e^{j\omega (z_\infty + \alpha^c (z_\infty) - \alpha^s (z_\infty))} - e^{j\omega z} = e^{j\omega \alpha^c (z_\infty) - \alpha^s (z_\infty)} - 1. \]

\[
= \mathbb{E} \left[ e^{j\omega z_\infty} \left( j \frac{c}{\tau} (\tilde{z}_\eta - \tilde{z}_\eta) \right) - \frac{1}{2} \sigma^c \left( \tilde{z}_\eta - \tilde{z}_\eta \right)^2 + o(\epsilon^2) \right] + o(\epsilon^2).
\]

where (a) follows by Taylor’s Theorem. The reader can refer to Lemma E.1 for precise analysis. Next, (b) follows by the tower property of expectation and (3) and (c) follows by the tower property of expectation and using the definition of arrivals. For precise calculations, refer to (25). Now, by setting \( \mathbb{E} \left[ \Delta W(z) \right] = 0 \) and rearranging terms, we get

\[
\mathbb{E} \left[ e^{j\omega z} \phi^c \left( \frac{z_\eta}{\tau} \right) - \phi^s \left( \frac{z_\eta}{\tau} \right) \right] = \frac{j\omega}{2} \left( \sigma^c (\lambda^*) + \sigma^s (\mu^*) \right) \mathbb{E} \left[ e^{j\omega z} \right] + o(1) + \frac{j\omega}{2} \mathbb{E} \left[ e^{j\omega z} \left( \sigma^c (\lambda (z_\eta)) + \sigma^s (\mu (z_\eta)) - \sigma^c (\lambda^*) - \sigma^s (\mu^*) \right) \right] .
\]

Now, taking the limit as \( \eta \to \infty \) and noting that \( \epsilon \tau = l \), the last term in RHS disappears, \( \frac{z_\eta}{\tau} \) converges to \( z_\infty / l \), and thus, we get a functional equation as stated in the following claim.

Claim 6.4. By taking the limit as \( \eta \to \infty \) in (12), we get

\[ \mathbb{E} \left[ e^{j\omega z} g_{1,t} (z_\infty) \right] = j\omega \mathbb{E} \left[ e^{j\omega z} \right]. \]

The proof of the claim is presented in Appendix C.2. This completes the proof of the Lemma. \( \square \)

6.3 Step 3: Uniqueness

In this section, we will show that \( \text{Gibbs}(g_{1,t}) \) distribution is a unique solution of the functional equation obtained in Lemma 6.3.

Lemma 6.5. Let \( g \in C^\infty_{\text{pol}}(\mathbb{R}) \) and \( \omega \in \mathbb{R} \) and \( X \) be a random variable satisfying the following equation:

\[ \mathbb{E} \left[ e^{j\omega X} g(X) \right] = j\omega \mathbb{E} \left[ e^{j\omega X} \right]. \]

Then \( X \) has \( \text{Gibbs}(g) \) distribution.
We will present some results which are required to complete the proof of Theorem 4.6. All the proofs in this sub-section have been deferred to the Appendix D.1.

7.1 Preliminary Lemmas

We will present some results which are required to complete the proof of Theorem 4.6. All the proofs in this sub-section have been deferred to the Appendix D.1.

**Lemma 7.1.** For any function \( g \) such that \( \lim_{x \to \infty} g(x) = \lim_{x \to -\infty} g(x) = c_\infty \), and there exists a \( g_{\max} > 0 \) such that \( g(x) \leq g_{\max} \) for all \( x \in \mathbb{R} \), we have

\[
\lim_{\eta \to \infty} \mathbb{E} \left[ g \left( \frac{\tilde{z}_\eta}{\tau} \right) \right] = c_\infty.
\]

**Lemma 7.2.** For some \( c > 0 \), let \( g_n \) be a sequence of functions such that

\[
\lim_{n \to \infty} g_n(x) = c \quad \text{uniformly} \quad \forall x \in \mathbb{R}.
\]

Then for any sequence of random variables \( \{Y_n\} \), we have

\[
\lim_{n \to \infty} \mathbb{E} \left[ g_n(Y_n) \right] = c.
\]

The lemmas presented above will be used to show convergence of some terms which will give us a closed form expression of the limiting value of the characteristic function. Next, we present an identity which will be used later to simplify some expressions.
We will analyze each term separately. To simplify, we will consider the test function \( e^{j \omega |z_\eta|} \), which will allow us to characterize the limiting distribution of \( e|z_\eta| \). Consider the family of random variables \( \Pi = \{ \epsilon \bar{z}_\eta : \eta > 0 \} \). Now, we present the result which characterizes the limiting distribution of \( e|z_\eta| \).

**Lemma 7.4.** Under Condition 4.5, any sequence in the family of random variables \( \Pi \), converges in distribution to \( \bar{z}_\infty \) such that

\[
\mathbb{E}[e^{j \omega |z_\infty|}] = \frac{1}{1 - j \omega \sigma^2(\lambda^*) + \sigma^2(\mu^*)}.
\]

**Proof.** For \( \omega \in \mathbb{R} \), we define the test function

\[
V(z) \overset{\Delta}{=} e^{j \omega |z|} = e^{j \omega \epsilon \operatorname{sgn}(z)}.
\]

As \( |V(z)| = 1 \), its expectation in steady state is finite. Thus, we will set the drift of the above defined test function to zero in steady state.

\[
\mathbb{E}[\Delta \bar{V}(z_\infty)] = \mathbb{E}[V(z_\infty) - V(z_\eta)] = \mathbb{E} \left[ e^{j \omega \epsilon \operatorname{sgn}(z_\eta)} \left( \phi^c \left( \frac{\bar{z}_\eta}{\tau} \right) - \phi^s \left( \frac{\bar{z}_\eta}{\tau} \right) \right) \right]
\]

\[
- \frac{1}{2} e^2 \omega^2 \left( \sigma^c(\lambda^*) - \sigma^s(\mu^*) \right) \mathbb{E} \left[ e^{j \omega \epsilon \operatorname{sgn}(z_\eta)} \right] + o(\epsilon^2).
\]

We will analyze each term separately. To simplify \( T_2 \), we will first use the update equation of imbalance given by (11). Then, we will use Taylor’s Theorem to expand and consider up to the second order term. After using some basic properties about expectations, we get the following:

**Claim 7.5.**

\[
T_2 = j \epsilon^2 \omega \mathbb{E} \left[ e^{j \omega \epsilon \operatorname{sgn}(z_\eta)} \phi^c \left( \frac{\bar{z}_\eta}{\tau} \right) - \phi^s \left( \frac{\bar{z}_\eta}{\tau} \right) \right] \operatorname{sgn}(\bar{z}_\eta)
\]

\[
- \frac{1}{2} e^2 \omega^2 \left( \sigma^c(\lambda^*) - \sigma^s(\mu^*) \right) \mathbb{E} \left[ e^{j \omega \epsilon \operatorname{sgn}(z_\eta)} \right] + o(\epsilon^2).
\]

The proof of the claim has been deferred to Appendix D.3 and here we continue with the proof of Lemma 7.4. To simplify \( T_1 \), directly use Taylor’s Theorem and consider the expansion up to the second order term.

\[
T_1 = \mathbb{E} \left[ e^{j \omega \epsilon \operatorname{sgn}(z_\eta)} - e^{j \omega \epsilon \operatorname{sgn}(z_\eta)} \right]
\]

\[
\overset{(a)}{=} \mathbb{E} \left[ \left( e^{j \omega \epsilon \operatorname{sgn}(z_\eta)} - e^{j \omega \epsilon \operatorname{sgn}(z_\eta)} \right) 1 \{|\bar{z}_\eta| \leq A_{\max} \} \right]
\]

\[
= \mathbb{E} \left[ e^{j \omega \epsilon \operatorname{sgn}(z_\eta)} 1 \{|\bar{z}_\eta| \leq A_{\max} \} - e^{j \omega \epsilon \operatorname{sgn}(z_\eta)} 1 \{|\bar{z}_\eta| \leq A_{\max} \} \right]
\]

\[
\overset{(b)}{=} \mathbb{E} \left[ j \epsilon \omega \bar{z}_\eta^+ \left( \operatorname{sgn}(z_\eta^+ - \operatorname{sgn}(z_\eta) \right) 1 \{|\bar{z}_\eta| \leq A_{\max} \} \right] + o(\epsilon^2)
\]

\[
= \mathbb{E} \left[ j \epsilon \omega \bar{z}_\eta^+ \left( \operatorname{sgn}(z_\eta^+ - \operatorname{sgn}(z_\eta) \right) \right] + o(\epsilon^2),
\]

Vol. 1, No. 1, Article . Publication date: October .
where (a) follows as \( \text{sgn}(z^*) = \text{sgn}(z) \) if \( |z^*| > A_{\text{max}} \) as the arrivals are bounded by \( A_{\text{max}} \) with probability 1. Next, (b) follows by Taylor’s theorem. For a more precise argument, the reader should refer to Lemma E.1. Now, the above can be simplified by Lemma 7.3 to get

\[
T_1 = -j\epsilon^2 \omega \mathbb{E} \left[ \left( \phi^c \left( \frac{\bar{z}_n}{\tau} \right) - \phi^s \left( \frac{\bar{z}_n}{\tau} \right) \right) \text{sgn}(\bar{z}_n) \right] + o(\epsilon^2)
\]

Lastly, setting the drift of \( V \) to zero, we get

\[
0 = \mathbb{E} [\Delta V(\bar{z}_n)] = T_1 + T_2 = \mathbb{E} \left[ e^{j\epsilon\omega \bar{z}_n} \left( \phi^c \left( \frac{\bar{z}_n}{\tau} \right) - \phi^s \left( \frac{\bar{z}_n}{\tau} \right) \right) \text{sgn}(\bar{z}_n) \right] \\
+ \frac{j\omega}{2} \mathbb{E} \left[ e^{j\epsilon\omega \bar{z}_n} (\sigma^c(\lambda(\bar{z}_n)) + \sigma^s(\mu(\bar{z}_n))) \right] - \mathbb{E} \left[ \left( \phi^c \left( \frac{\bar{z}_n}{\tau} \right) - \phi^s \left( \frac{\bar{z}_n}{\tau} \right) \right) \text{sgn}(\bar{z}_n) \right] + o(1)
\]

Rearranging the above terms, we get

\[
\left( -1 + \frac{j\omega}{2} (\sigma^c + \sigma^s) \right) \mathbb{E} \left[ e^{j\epsilon\omega \bar{z}_n} \right] \\
= \mathbb{E} \left[ \left( \phi^c \left( \frac{\bar{z}_n}{\tau} \right) - \phi^s \left( \frac{\bar{z}_n}{\tau} \right) \right) \text{sgn}(\bar{z}_n) \right] - \mathbb{E} \left[ e^{j\epsilon\omega \bar{z}_n} \left( 1 + \phi^c \left( \frac{\bar{z}_n}{\tau} \right) - \phi^s \left( \frac{\bar{z}_n}{\tau} \right) \right) \text{sgn}(\bar{z}_n) \right] \\
+ \frac{j\omega}{2} \mathbb{E} \left[ e^{j\epsilon\omega \bar{z}_n} \left( \sigma^c(\lambda(\bar{z}_n)) + \sigma^s(\mu(\bar{z}_n)) \right) \right] - \mathbb{E} \left[ e^{j\epsilon\omega \bar{z}_n} (\sigma^c(\lambda(\bar{z}_n)) - \sigma^c(\lambda(\bar{z}_n)) - \sigma^s(\mu(\bar{z}_n))) \right].
\]

Now, we will show that \( T_2 \rightarrow -1, T_4 \rightarrow 0 \) and \( T_5 \rightarrow 0 \) which will give us the result. We will use Lemma 7.1 to show these limits. First, we can upper bound \( T_5 \), to get

\[
|T_5| \leq \mathbb{E} \left[ \left| 1 + \left( \phi^c \left( \frac{\bar{z}_n}{\tau} \right) - \phi^s \left( \frac{\bar{z}_n}{\tau} \right) \right) \text{sgn}(\bar{z}_n) \right| \right]
\]

Similarly, we can upper bound \( T_4 \), to get

\[
|T_4| \leq \frac{\omega}{2} \mathbb{E} \left[ \left| \sigma^c(\lambda(\bar{z}_n)) + \sigma^s(\mu(\bar{z}_n)) \right) \text{sgn}(\bar{z}_n) \right| \right]
\]

Now, by Lemma 7.1, and Condition 4.5, we have

\[
\lim_{\eta \to \infty} T_3 = \lim_{\eta \to \infty} \mathbb{E} \left[ \left( \phi^c \left( \frac{\bar{z}_n}{\tau} \right) - \phi^s \left( \frac{\bar{z}_n}{\tau} \right) \right) \text{sgn}(\bar{z}_n) \right] = 1
\]

\[
\lim_{\eta \to \infty} \mathbb{E} \left[ \left| 1 + \left( \phi^c \left( \frac{\bar{z}_n}{\tau} \right) - \phi^s \left( \frac{\bar{z}_n}{\tau} \right) \right) \text{sgn}(\bar{z}_n) \right| \right] = 0.
\]

In addition, as \( \sigma^+ \) and \( \sigma^c \) are continuous function

\[
\left| \sigma^c(\lambda(x)) + \sigma^s(\mu(x)) - \sigma^c(\lambda(\bar{z}_n)) - \sigma^s(\mu(\bar{z}_n)) \right| \to 0 \quad \text{uniformly as } \eta \to \infty.
\]

Thus, by Lemma 7.2, we get

\[
\lim_{\eta \to \infty} \frac{\omega}{2} \mathbb{E} \left[ \left| \sigma^c(\lambda(\bar{z}_n)) + \sigma^s(\mu(\bar{z}_n)) - \sigma^c(\lambda(\bar{z}_n)) - \sigma^s(\mu(\bar{z}_n)) \right| \right] = 0.
\]

This completes the proof. \( \square \)
7.3 Step 2: Imbalance has Symmetrical Distribution

The previous lemma shows that the limiting distribution of $\epsilon|\tilde{z}_\eta|$ is exponential. Now, we will show that the limiting distribution of $\epsilon\tilde{z}_\eta$ is symmetrical, which will complete the Step 3 of proof of the Theorem 4.6.

**Lemma 7.6.** Under Condition 4.5, for any sequence in the family of random variables $\Pi$, we have

$$\lim_{\eta \to \infty} \mathbb{E} \left[ \text{sgn}(\tilde{z}_\eta) e^{i\epsilon|\tilde{z}_\eta|} \right] = 0.$$ 

The proof of this lemma is similar to the proof of Lemma 7.4 and thus, we defer the details of the proof to the Appendix D.2.

7.4 Proof of Theorem 4.6

**Step 3: Proof of Theorem 4.6.** Note that Step 1 is completed by Lemma 7.4 and Step 2 is completed by 7.6. Now, we will combine these parts together to complete the proof of the Theorem 4.6. For all $x \in \mathbb{R}$, we have

$$2e^{i\epsilon x} + \text{sgn}(x)e^{-i\epsilon x\text{sgn}(x)} - \text{sgn}(x)e^{i\epsilon x\text{sgn}(x)} = e^{i\epsilon x} + e^{-i\epsilon x} = e^{i\epsilon|x|} + e^{-i\epsilon|x|}$$

By substituting $x = \epsilon\tilde{z}_\eta$ and taking expectation on both sides, we get

$$2\mathbb{E} \left[ e^{i\epsilon\tilde{z}_\eta} \right] + \mathbb{E} \left[ \text{sgn}(\tilde{z}_\eta)e^{-i\epsilon\tilde{z}_\eta\text{sgn}(\tilde{z}_\eta)} \right] - \mathbb{E} \left[ \text{sgn}(\tilde{z}_\eta)e^{i\epsilon\tilde{z}_\eta\text{sgn}(\tilde{z}_\eta)} \right] = \mathbb{E} \left[ e^{i\epsilon\tilde{z}_\eta} \right] + \mathbb{E} \left[ e^{-i\epsilon\tilde{z}_\eta} \right].$$

Now, by taking the limit as $\eta \to \infty$ on both sides and using Lemma 7.4 for the RHS and Lemma 7.6 for the LHS, we get

$$2 \lim_{\eta \to \infty} \left( \mathbb{E} \left[ e^{i\epsilon\tilde{z}_\eta} \right] \right) = \frac{1}{1 - \frac{\epsilon^2}{2\lambda}\sigma^2(\lambda^*) + \sigma^2(\mu^*)} + \frac{1}{1 + \frac{\epsilon^2}{2\lambda}\sigma^2(\lambda^*) + \sigma^2(\mu^*)}$$

$$= \frac{2}{1 + \frac{\epsilon^2}{2\lambda} (\sigma^2(\lambda^*) + \sigma^2(\mu^*))^2}.$$

This completes the proof. \qed

8 CONCLUSION AND FUTURE WORK

In this paper, we developed the heavy traffic theory of two-sided queues. First in the simple case of Bernoulli arrivals and two-prize policy we illustrated a phase transition behaviour. We named the three regions, the quality-driven regime, critical regime and profit-driven regime. Under general arrivals, service and control policies, we show that the appropriately scaled limiting imbalance has the Laplace distribution in the quality-driven regime and Gibbs distribution in the critical regime. We obtained these results using the characteristic function method and developing a novel inverse Fourier transform method. We illustrated that the single server queue under state-dependent control exhibits a similar phase transition behaviour in heavy-traffic.

There are a number of possible future directions. An immediate future work is to characterize the limiting behaviour in the profit-driven regime and possibly prove Conjecture 4.7.

The model of single link two-sided queue presented in this paper is a fundamental building block of matching platforms. Richer version of this model has been considered in [30] [37] [38] which accounts for heterogeneous customers and servers, selfish servers and a network of two-sided queues respectively. Along with pricing, there is an additional matching/routing component for these more elaborate models. Another line of future work is to develop heavy-traffic theory for such models.
REFERENCES

We fix a birth and death process, it is a reversible DTMC. Thus, by solving the detailed balance equations, we get

\[ P_{i,j} = \begin{cases} 
  m & \text{if } j = i \pm 1, |i| \leq \tau \\
  m + \epsilon \mu^* & \text{if } j = i - \text{sgn}(i), |i| > \tau \\
  m - \epsilon (1 - \mu^*) & \text{if } j = i + \text{sgn}(i), |i| > \tau \\
  1 - 2m & \text{if } j = i, |i| \leq \tau \\
  1 - 2m + \epsilon (1 - 2\mu^*) & \text{if } j = i, |i| > \tau \\
  0 & \text{otherwise.}
\end{cases} \]

As this is a birth and death process, it is a reversible DTMC. Thus, by solving the detailed balance equations, we get

\[ \pi_i = \begin{cases} 
  \frac{1}{2|\tau|+1+2m/\epsilon} & \text{if } |i| \leq |\tau| \\
  \frac{m}{2|\tau|+1+2m/\epsilon} (1 - \frac{\epsilon}{m+\epsilon \mu^*})^{-|i|-[\tau]-1} & \text{otherwise.}
\end{cases} \]

Now, we will calculate the moment generating function of \( \epsilon \bar{z}_\eta \) for Case 1 and 2 and \( \bar{z}/\tau \) for Case 3. We fix a \( t \) such that \( t < 1/m \). There exists \( \epsilon_0 \) such that for all \( \epsilon < \epsilon_0 \), we have \( (1-\epsilon/(m+\epsilon \mu^*))e^{\epsilon t} < 1. \)
For the further calculations, we consider $\eta > \eta_0$ such that $\epsilon < \epsilon_0$. We have

$$\mathbb{E} \left[ e^{\epsilon \tau_2} \right] = \sum_{i=-\infty}^{\infty} \pi_i e^{\epsilon r_i}$$

$$= \sum_{i=-\infty}^{-[\tau]-1} \pi_i e^{\epsilon r_i} + \sum_{i=[\tau]}^{[\tau]} \pi_i e^{\epsilon r_i} + \sum_{i=[\tau]+1}^{\infty} \pi_i e^{\epsilon r_i}$$

$$= \frac{1}{2[\tau] + 1 + 2m/\epsilon} \left( \frac{m}{m + \epsilon \mu^*} \sum_{i=-\infty}^{-[\tau]-1} \left( 1 - \frac{\epsilon}{m + \epsilon \mu^*} \right)^{-[\tau]-1} e^{\epsilon \tau_i} + \sum_{i=[\tau]}^{[\tau]} e^{\epsilon \tau_i} + \sum_{i=[\tau]+1}^{\infty} e^{\epsilon \tau_i} \right)$$

$$+ \frac{m}{m + \epsilon \mu^*} \sum_{i=[\tau]+1}^{\infty} \left( 1 - \frac{\epsilon}{m + \epsilon \mu^*} \right)^{-[\tau]-1} e^{\epsilon \tau_i}$$

$$= \frac{e^{-\epsilon [\tau]}}{2[\tau] + e + 2m} \left( \frac{m}{m + \epsilon \mu^*} \sum_{i=-\infty}^{-[\tau]-1} \left( 1 - \frac{\epsilon}{m + \epsilon \mu^*} \right)^{-[\tau]-1} e^{-\epsilon [\tau]} + \sum_{i=[\tau]}^{[\tau]} e^{-\epsilon [\tau]} + \sum_{i=[\tau]+1}^{\infty} e^{-\epsilon [\tau]} \right)$$

$$+ \frac{m}{m + \epsilon \mu^*} \left( 1 - e^{-\epsilon [\tau]} + \frac{e^{-\epsilon [\tau]}}{m + \epsilon \mu^*} \right)$$

Now, we will take the limit as $\eta \to \infty$ for the above equation for Case 1 and 2 separately.

**Case 1:** Note that, in this case, we have $\epsilon [\tau] \to 0$, $\epsilon \to 0$ and $\tau \to \infty$. In addition, note that $|\epsilon [\tau] - \eta \epsilon| \leq \epsilon$, which gives us $\epsilon [\tau] \to 0$. Now, we will take the limit for each of three terms in (16) separately. In particular, we resort to Taylor series expansion of the exponential terms and then take the limit as $\eta \to \infty$.

$$\frac{e^{-\epsilon [\tau]} - e^{-\epsilon [\tau]+1}}{1 - e^{-\epsilon [\tau]}} = \epsilon^{-\epsilon [\tau]} - \epsilon^{\epsilon [\tau]} + o(\epsilon) = \frac{-e^{-\epsilon [\tau]} - e^{-\epsilon [\tau]+1} + o(\epsilon)}{-\epsilon + o(\epsilon)} \to 0$$

$$\frac{e^{-\epsilon [\tau]+1}}{1 - e^{-\epsilon [\tau]}} = \epsilon^{-\epsilon [\tau]+1} - \epsilon^{-\epsilon [\tau]} + o(\epsilon) = \frac{-e^{-\epsilon [\tau]+1} + o(\epsilon)}{-\epsilon + o(\epsilon)} \to \frac{1}{1/m - t}$$

$$\frac{e^{-\epsilon [\tau]+1}}{1 - e^{-\epsilon [\tau]}} = \epsilon^{-\epsilon [\tau]+1} - \epsilon^{-\epsilon [\tau]} + o(\epsilon) = \frac{-e^{-\epsilon [\tau]+1} + o(\epsilon)}{-\epsilon + o(\epsilon)} \to \frac{1}{1/m + t}.$$}

Now, by using (17) to simplify (16) we get

$$\mathbb{E} \left[ e^{\epsilon \tau_2} \right] \to \frac{1}{2m} \left( \frac{1}{1/m + t} + 0 + \frac{1}{1/m - t} \right) = \frac{1}{1 - m^2 t^2} \text{ as } \eta \to \infty.$$}

This completes Case 1 as the above is the MGF of a Laplace distribution with parameters $(0, m)$.

**Case 2:** Note that, in this case, we have $\epsilon \tau \to l \in (0, \infty)$, $\epsilon \to 0$ and $\tau \to \infty$. In addition, note that $|\epsilon [\tau] - \eta \epsilon| \leq \epsilon$ which gives us $\epsilon [\tau] \to l$. Now, we will evaluate the limit of (16) by using

![Fig. 3. Single link two-sided queue with Bernoulli arrivals](image-url)
Taylor series expansion.

\[
\frac{e^{-et[\tau]} - e^{et([\tau]+1)}}{1 - e^{et}} = e^{-et[\tau]} - e^{et([\tau]+1)} = \frac{e^{-et[\tau]} - e^{et([\tau]+1)}}{-t + o(1)} \rightarrow t \frac{e^{lt} - e^{-lt}}{t} \quad (18a)
\]

\[
\frac{e^{-et[\tau]} + \frac{e^{et}}{m+\mu_s}}{1 - e^{et}} = e^{-et[\tau]} + \frac{1}{m+\mu_s} + o(e) = \frac{e^{-et[\tau]} + \frac{1}{m+\mu_s} + o(e)}{t + \frac{1}{m+\mu_s} + o(e)} \rightarrow t \frac{e^{lt} - e^{-lt}}{1/m - t} \quad (18b)
\]

\[
\frac{e^{-et[\tau]} + \frac{e^{et}}{m+\mu_s} + o(e)}{1 - e^{et}} = e^{-et[\tau]} + \frac{1}{m+\mu_s} + o(e) = \frac{e^{-et[\tau]} + \frac{1}{m+\mu_s} + o(e)}{t + \frac{1}{m+\mu_s} + o(e)} \rightarrow t \frac{e^{lt} - e^{-lt}}{1/m + t} \quad (18c)
\]

Now, by using (18) to simplify (16) we get

\[
\mathbb{E} \left[ e^{et[\eta]} \right] \rightarrow \frac{1}{2l + 2m} \left( \frac{e^{lt} - e^{-lt}}{1/m + t} + \frac{e^{lt} - e^{-lt}}{1/m - t} \right) \quad (19)
\]

The above is the MGF of the hybrid distribution with parameters \((m, l)\). We can verify it as follows for \(X \sim \text{Hybrid}(b, c)\) as follows:

\[
\mathbb{E} \left[ e^{tx} \right] = \int_0^\infty \rho_{\text{Hybrid}}(x) e^{tx} dx = \frac{1}{2(b + c)} \left( \int_{-c}^c e^{-c e^{c/2}} e^{tx} dx + \int_t^\infty e^{tx} dx + \int_0^t e^{-c e^{c/2}} e^{tx} dx \right)
\]

\[
= \frac{1}{2(b + c)} \left( e^{c/2} e^{c/2} + e^{tx} \right)_{-c}^t + e^{c/2} e^{c/2} \int_{-c}^t e^{-c e^{c/2}} e^{tx} dx \right)
\]

\[
= \frac{1}{2(b + c)} \left( e^{-ct} + e^{ct} \right) \left( 1/b + t \right) \frac{1}{1/b + t} + e^{ct} \frac{1}{1/b + t} \left( \frac{1}{1/b + t} \right)
\]

Note that, the limiting value of \(\mathbb{E} \left[ e^{et[\eta]} \right]\) can be similarly calculated. We omit the details here as they are repetitive. Intuitively, by substituting \(t \rightarrow t/l\) in (19), we get

\[
\mathbb{E} \left[ e^{et[\eta]} \right] \rightarrow \frac{1}{2 + 2m/l} \left( \frac{e^{lt} - e^{-lt}}{l/m + t} + \frac{e^{lt} - e^{-lt}}{l/m - t} \right)
\]

The above is the MGF of the Hybrid distribution with parameters \((m/l, 1)\). This completes the proof for Case 2.

Case 3: In this case, we will consider the MGF of \(\tilde{\eta}/\eta\) and carry out similar calculations as in (16). In particular, let \(\eta > \eta_0\) such that \(\tau > 1/\epsilon_0\) which implies that \((1 - \epsilon/(m + \mu_s^*)) e^{t/\tau} < 1\). We skip some steps as they are repetitive and directly write the MGF below.

\[
\mathbb{E} \left[ e^{et[\tilde{\eta}]/\tau} \right] = \frac{e^{et[\tau]} + \frac{e^{et}}{m + \mu_s} + o(e)}{1 - e^{et[\tau]}} \frac{e^{et[\tau] + \frac{e^{et}}{m+\mu_s} + o(e)}}{1 - e^{et[\tau] + \frac{e^{et}}{m+\mu_s} + o(e)}} \left( \frac{m + \mu_s^*/1 - e^{-t/\tau} + e^{t/\tau}}{m + \mu_s^*/1 - e^{-t/\tau} + e^{t/\tau}} \right) \quad (20)
\]

Note that, in this case, we have \(\epsilon \tau \rightarrow \infty, \epsilon \rightarrow 0\) and \(\tau \rightarrow \infty\). In addition, note that \(|e[\tau] - \tau| \leq \epsilon\) which gives us \(\epsilon[\tau] \rightarrow \infty\). In addition, as \(|[\tau]/\tau - 1| \leq 1/\tau\), we have \([\tau]/\tau \rightarrow 1\). Now, we will
evaluate the limit of (16) by using Taylor series expansion.

\[
\begin{align*}
\frac{e^{\frac{\epsilon}{\tau}}(\lfloor \epsilon \rfloor + 1)}{2[\tau]e + \epsilon + 2m} - \frac{e^{-\epsilon}}{1 - e^{-\tau}} + \frac{\epsilon e^{\epsilon / \tau}}{m + \epsilon \mu} & = \frac{e^{\frac{\epsilon}{\tau}}(\lfloor \epsilon \rfloor + 1)}{2[\tau]e + \epsilon + 2m - \frac{\epsilon}{\mu} / \tau + o(1/\tau)} \\
\frac{e^{-\frac{\epsilon}{\tau}}(\lfloor \epsilon \rfloor + 1)}{2[\tau]e + \epsilon + 2m} - \frac{e^{\frac{\epsilon}{\tau}}(\lfloor \epsilon \rfloor + 1)}{2[\tau]e + \epsilon + 2m} - \frac{\epsilon e^{-\epsilon / \tau}}{m + \epsilon \mu} & = \frac{e^{\frac{\epsilon}{\tau}}(\lfloor \epsilon \rfloor + 1)}{2[\tau]e + \epsilon + 2m - \frac{\epsilon}{\mu} / \tau + o(1/\tau)} \\
\frac{e^{-\frac{\epsilon}{\tau}}(\lfloor \epsilon \rfloor / \tau) - e^{\frac{\epsilon}{\tau}}(\lfloor \epsilon \rfloor / \tau)}{2[\tau]e + \epsilon + 2m} & = \frac{e^{-\frac{\epsilon}{\tau}}(\lfloor \epsilon \rfloor / \tau) - e^{\frac{\epsilon}{\tau}}(\lfloor \epsilon \rfloor / \tau)}{2[\tau]e + \epsilon + 2m - \frac{\epsilon}{\mu} / \tau + o(1/\tau)} \\
\frac{e^{-\frac{\epsilon}{\tau}}(\lfloor \epsilon \rfloor / \tau) - e^{\frac{\epsilon}{\tau}}(\lfloor \epsilon \rfloor / \tau)}{-2[\tau]e + \epsilon + o(1)} & = \frac{e^{-\frac{\epsilon}{\tau}}(\lfloor \epsilon \rfloor / \tau) - e^{\frac{\epsilon}{\tau}}(\lfloor \epsilon \rfloor / \tau)}{2t}
\end{align*}
\]

(21a) (21b) (21c) (21d)

Now, by using (21) in (20), we get

\[
\mathbb{E} \left[ e^{\frac{\epsilon z}{T}} \right] \to \frac{e^t - e^{-t}}{2t} \Rightarrow \frac{\hat{Z}_\eta}{\tau} \to U[-1, 1].
\]

\[\square\]

### B  POSITIVE RECURRENCE

**PROOF OF PROPOSITION 4.2.** We will analyze the drift of the test function \(z^2\) and show that it is negative outside a finite set.

\[
\mathbb{E} \left[ z^2 \right] - z^2(0) = z
\]

\[
\mathbb{E} \left[ (a^z(0), k) - a^z(k) \right] = z
\]

\[
\mathbb{E} \left[ (a^z(k, z) - a^z(k, z)) \right] + 2z\mathbb{E} \left[ a^z(k, z) - a^z(k, z) \right]
\]

\[
\leq 4A^2_{max} + 2z\mathbb{E} \left[ a^z(k, z) - a^z(k, z) \right]
\]

\[
\leq 4A^2_{max} + 2z\mathbb{E} \left[ \frac{\phi^c(z)}{\tau} - \frac{\phi^s(z)}{\tau} \right]
\]

\[
= 4A^2_{max} + 2z\mathbb{E} \left[ \frac{\phi^c(z)}{\tau} - \frac{\phi^s(z)}{\tau} \right] \mathbb{I} \{|z| \leq \tau\} + 2z\mathbb{E} \left[ \frac{\phi^c(z)}{\tau} - \frac{\phi^s(z)}{\tau} \right] \mathbb{I} \{|z| > \tau\}
\]

\[
\leq 4A^2_{max} + 4z\mathbb{E} \mathbb{K}_{\phi_{max}} - 2z\mathbb{E} \mathbb{I} \{|z| > \tau\}
\]

\[
\leq -4A^2_{max} - 4z\mathbb{E} \mathbb{K}_{\phi_{max}} \forall |z| \geq \max \left[ 2K\tau, \frac{4A^2_{max} + 4z\mathbb{E} \mathbb{K}_{\phi_{max}}}{\epsilon} \right],
\]

where (a) follows by the update equation of imbalance given by (1). Next, (b) follows as \(|a^z(k, z)| \leq A_{max} \) and \(|a^z(k, z)| \leq \lambda^* \) with probability 1 for all \(z \in \mathbb{Z} \) and \(k \in \mathbb{Z}_+ \). Now, (c) follows by the definition of \(\lambda^* \) and \(\mu^* \) given by (3) and noting that \(\lambda^* = \mu^* \) by definition. Finally, (d) follows as \(\phi^c(z) \) and \(\phi^s(z) \) are bounded and satisfy the negative drift condition given by Condition 4.1.
So, for any given $\varepsilon > 0$ and $\tau > 0$, we have negative drift outside a finite set. Thus, for any $\eta > 0$, by the Foster-Lyapunov theorem, \( \{z_\eta(k) : k \in \mathbb{Z}_+\} \) is positive recurrent. By Moment bound theorem [17, Proposition 6.14], we get
\[
2\varepsilon \mathbb{E} \left[ |\tilde{z}_\eta| \mathbb{1}(|\tilde{z}_\eta| > K\tau) \right] \leq 4A_{\max}^2 + 4\varepsilon K\phi_{\max}
\]
\[
\Rightarrow \mathbb{E} \left[ |\tilde{z}_\eta| \right] \leq \frac{2A_{\max}^2 + \varepsilon K(2\phi_{\max} + \delta)}{\varepsilon \delta}.
\]
\[\square\]

C TECHNICAL DETAILS FOR THE PROOF OF THEOREM 4.4

C.1 Tightness

Proof of Lemma 6.1. First, we will show tightness of the sequence of random variables $\varepsilon \tilde{z}_\eta$. As $\varepsilon \tau \downarrow l$, there exists $\tau_{\max} > 0$ such that $\varepsilon \tau \leq \tau_{\max}$ for all $\eta > 0$. Now, by Proposition 4.2, we have
\[
\mathbb{E} \left[ |\varepsilon \tilde{z}_\eta| \right] \leq \frac{2A_{\max}^2 + \varepsilon K(2\phi_{\max} + \delta)}{\varepsilon \delta} \leq \frac{2A_{\max}^2 + \tau_{\max} K(2\phi_{\max} + \delta)}{\delta}
\]
Now, for any $\omega > 0$, we can pick $N = \frac{2A_{\max}^2 + \tau_{\max} K(2\phi_{\max} + \delta)}{\delta \omega}$ independent of $\eta$ to get
\[
\mathbb{P} \left( |\varepsilon \tilde{z}_\eta| > N \right) \leq \frac{1}{N} \mathbb{E} \left[ |\varepsilon \tilde{z}| \right] = \omega \quad \forall \eta > 0.
\]
Thus, the family of random variables $\Pi = \{\varepsilon \tilde{z}_\eta\}$ is tight. By [6, Theorem 5.1], $\Pi$ is relatively compact. Thus, for any sequence in the family $\Pi$, there exists a sub-sequence that converges in distribution. \[\square\]

C.2 Drift Analysis

Before proving Claim 6.4, we need the following technical lemma which we present with proof below.

Lemma C.1. For some $c \in \mathbb{R}$, let $g_n$ be a sequence of functions such that
\[
\lim_{n \to \infty} g_n(x) = c \quad \text{uniformly on compact sets } \forall x \in \mathbb{R}.
\]
Then for any tight sequence of random variables $\{Y_n\}$, we have
\[
\lim_{n \to \infty} \mathbb{E} \left[ g_n(Y_n) \right] = c.
\]
Proof. For any $\delta, K > 0$, there exists $n_0$ such that for all $n > n_0$
\[
|g_n(x) - c| \leq \delta \quad \forall x \in \mathcal{B}[0, K],
\]
where $\mathcal{B}[0, K]$ is a closed ball with center 0 and radius $K$. Thus for all $n \geq n_0$
\[
\mathbb{P} \left( |g_n(Y_n) - c| > \delta \right) = \mathbb{P} \left( |g_n(Y_n) - c| > \delta | Y_n \in \mathcal{B}[0, K] \right) \mathbb{P} \left( Y_n \in \mathcal{B}[0, K] \right) + \mathbb{P} \left( |g_n(Y_n) - c| > \delta | Y_n \notin \mathcal{B}[0, K] \right) \mathbb{P} \left( Y_n \notin \mathcal{B}[0, K] \right)
= \mathbb{P} \left( |g_n(Y_n) - c| > \delta | Y_n \notin \mathcal{B}[0, K] \right) \mathbb{P} \left( Y_n \notin \mathcal{B}[0, K] \right).
\]
As the sequence of random variables $\{Y_n\}$ is tight, for any $\delta' > 0$, there exists $K > 0$ such that
\[
\mathbb{P} \left( Y_n \notin \mathcal{B}[0, K] \right) \leq \delta' \quad \forall n \geq n_0.
\]
Thus for all \( n \geq n_0 \)
\[
(c - \delta)(1 - \delta') - g_{\text{max}}\delta' \leq \mathbb{E}[g_n(Y_n)] \leq (c + \delta)(1 - \delta') + g_{\text{max}}\delta'
\]

Now, by taking \( n \to \infty \), we get
\[
\lim_{n \to \infty} \mathbb{E}[g_n(Y_n)] = c.
\]

As the above is true for all \( \delta, \delta' > 0 \), we get
\[
\lim_{n \to \infty} \mathbb{E}[g_n(Y_n)] = c.
\]

□

Now, we will use the above lemma to prove Claim 6.4.

**Proof of Claim 6.4.** We rewrite the pre-limit equation for the convenience of the reader.

\[
\mathbb{E}\left[ e^{i\phi_{\tau,\eta}} \left( \frac{Z_{\tau \eta}}{\tau} - \frac{Z_{\tau \eta}}{\tau} \right) \right] = \frac{j\omega}{2} \left( \sigma^c(\lambda^*) + \sigma^s(\mu^*) \right) \mathbb{E}\left[ e^{i\phi_{\tau,\eta}} \right] + o(1)
\]

\[
+ \frac{j\omega}{2} \mathbb{E}\left[ e^{i\phi_{\tau,\eta}} \left( \sigma^c(\lambda(\tilde{Z}_{\tau \eta})) + \sigma^s(\mu(\tilde{Z}_{\tau \eta})) - \sigma^c(\lambda^*) - \sigma^s(\mu^*) \right) \right].
\]

Now, the first term in the RHS converges by Levy’s continuity theorem (e.g.
see: [40, Chapter 18]). In particular, if a sequence of random variables converges in distribution, the corresponding characteristic functions also converge.

\[
\lim_{\eta \to \infty} \mathbb{E}\left[ e^{i\phi_{\tau,\eta}} \right] = \mathbb{E}\left[ e^{i\phi_{\tau,\eta}} \right] \quad (\text{as } \epsilon \tilde{Z}_{\tau \eta} \overset{D}{\to} \tilde{Z}_\infty).
\]

Next, the second term in RHS can be bounded as follows:

\[
\left| \frac{j\omega}{2} \mathbb{E}\left[ e^{i\phi_{\tau,\eta}} \left( \sigma^c(\lambda(\tilde{Z}_{\tau \eta})) + \sigma^s(\mu(\tilde{Z}_{\tau \eta})) - \sigma^c(\lambda^*) - \sigma^s(\mu^*) \right) \right] \right|
\]

\[
\leq \left| \frac{|\omega|}{2} \mathbb{E}\left[ \left| \sigma^c(\lambda(\tilde{Z}_{\tau \eta})) + \sigma^s(\mu(\tilde{Z}_{\tau \eta})) - \sigma^c(\lambda^*) - \sigma^s(\mu^*) \right| \right] \right|
\]

Now, by Lemma 7.2 the upper bound converges to zero as by the continuity of \( \sigma^c(\cdot) \) and \( \sigma^s(\cdot) \), we have

\[
\lim_{\eta \to \infty} \left( \sigma^c(\lambda^* + \epsilon \phi^c(x)) + \sigma^s(\mu^* + \epsilon \phi^s(x)) - \sigma^c(\lambda^*) - \sigma^s(\mu^*) \right) = 0 \quad \text{uniformly } \forall x \in \mathbb{R}.
\]

Finally, the LHS can be simplified as follows:

\[
\frac{2}{\sigma^c(\lambda^*) + \sigma^s(\mu^*)} \mathbb{E}\left[ e^{i\phi_{\tau,\eta}} \left( \frac{Z_{\tau \eta}}{\tau} - \frac{Z_{\tau \eta}}{\tau} \right) \right] = \mathbb{E}\left[ e^{i\phi_{\tau,\eta}} g_{1,1} \left( \frac{1}{\epsilon} \tilde{Z}_{\tau \eta} \right) \right].
\]

By Heine-Cantor Theorem [35, Theorem 4.19], as \( g_{1,1} \) is continuous, it is uniformly continuous over any compact set. Now, as \( \epsilon \tau \to l \) as \( \eta \to \infty \) and \( g_{1,1} \) is a uniformly continuous on compact sets and bounded, for all \( \delta' > 0 \) and compact set \( B \), there exists \( \eta_0 \) such that for all \( \eta > \eta_0 \)

\[
\left| g_{1,1} \left( \frac{1}{\epsilon} x \right) - g_{1,1}(x) \right| \leq \delta' \quad \forall x \in B.
\]

Now, as \( |\cos(x)| \leq 1 \), we have

\[
\left| \cos(\omega x) g_{1,1} \left( \frac{1}{\epsilon} x \right) - \cos(\omega x) g_{1,1}(x) \right| \leq \delta' \quad \forall x \in B.
\]
The above implies that
\[\cos(\omega x)g_{1,l}\left(\frac{l}{\epsilon T}\right) - \cos(\omega x)g_{1,l}(x) \to 0 \text{ as } \eta \to \infty \text{ uniformly on compact sets } \forall x \in \mathbb{R}.\]

Similarly, we will also have
\[\sin(\omega x)g_{1,l}\left(\frac{l}{\epsilon T}\right) - \sin(\omega x)g_{1,l}(x) \to 0 \text{ as } \eta \to \infty \text{ uniformly on compact sets } \forall x \in \mathbb{R}.\]

Thus, as \(\epsilon \bar{z}_\eta\) is tight by Lemma 6.1, by Lemma C.1, we get
\[
\lim_{\eta \to \infty} \mathbb{E} \left[ e^{i \epsilon \omega \bar{z}_\eta} g_{1,l}\left(\frac{l}{\epsilon T}\epsilon \bar{z}_\eta\right) \right] = \lim_{\eta \to \infty} \mathbb{E} \left[ e^{i \epsilon \omega \bar{z}_\eta} g_{1,l}(\epsilon \bar{z}_\eta) \right].
\]

Now, as we are working with a convergent sequence such that \(\epsilon \bar{z}_\eta \to D \bar{z}_\infty\) and as \(\cos(\omega x)g_{1,l}(x)\) and \(\sin(\omega x)g_{1,l}(x)\) are continuous bounded functions, by the definition of weak convergence, we have
\[
\lim_{\eta \to \infty} \mathbb{E} \left[ e^{i \epsilon \omega \bar{z}_\eta} g_{1,l}\left(\frac{l}{\epsilon T}\epsilon \bar{z}_\eta\right) \right] = \mathbb{E} \left[ e^{i \omega \bar{z}_\infty} g_{1,l}(\bar{z}_\infty) \right].
\]

This completes the proof. \(\square\)

C.3 Uniqueness

C.3.1 Schwartz Space and Tempered Distribution. Before presenting the proof of Lemma 6.5, we brief on the theory of Schwartz functions and tempered distributions [34, Chapter 7] [22, Chapter 11].

Definition C.2 (Schwartz Space). It is a vector space given by
\[S(\mathbb{R}) = \{ f \in C^\infty(\mathbb{R}) : ||f||_{\alpha, \beta} < \infty \forall \alpha, \beta \in \mathbb{Z}_+ \}\]
where \(||f||_{\alpha, \beta} = \sup_{x \in \mathbb{R}} |x^\alpha f^{(\beta)}(x)|\).

Intuitively, Schwartz functions are infinitely differentiable and each derivative decays faster than any polynomial. Now, we define the dual space of Schwartz functions which are called tempered distributions.

Definition C.3 (Tempered Distribution). \(\mathcal{T} : S(\mathbb{R}) \to \mathbb{R}\) is a tempered distribution if it is both linear and continuous.

Note that, \(\mathcal{T}\) is a functional and the set of linear and continuous functional on a vector space is called the continuous dual of the space. A famous tempered distribution is the impulse function \(\delta[\cdot]\) which operates on Schwartz functions and gives it’s value at 0. In particular, \(\delta[\varphi] = \varphi(0)\). For any continuous and bounded function \(f\), we can define it’s ‘corresponding’ tempered distribution as follows:
\[\mathcal{T}_f[\varphi] \triangleq \int_{\mathbb{R}} f(x)\varphi(x)dx.\]

Now, we will discuss some operations on tempered distributions which will use in the proof of Theorem 4.4. We will present some definitions and theorems without proofs.

Definition C.4 (Distributional Derivative).
\[\mathcal{T}'[\varphi] \triangleq -\mathcal{T}[\varphi']\]
The above definition is motivated by considering $T_f$ for some $f$.

$$T_f'[\varphi] = \int_{\mathbb{R}} f'(x) \varphi(x) \, dx$$

$$= f(x)\varphi(x)|_{-\infty}^{\infty} - \int_{\mathbb{R}} f(x)\varphi(x) \, dx$$

$$= \int_{\mathbb{R}} f(x)\varphi(x) \, dx$$

$$= -T_f[\varphi']$$

It can be shown that $T'$ is a tempered distribution as well by checking linearity and continuity. Fourier transform of a Schwartz function is given by

$$\hat{\mathcal{F}}(\varphi)(x) = \hat{\varphi}(x) = \frac{1}{\sqrt{2\pi}} \int_{\mathbb{R}} \varphi(x)e^{-ixy} \, dx. \quad (22)$$

In addition, the inverse Fourier transform also exists for a Schwartz function and by Fourier inversion theorem, we have

$$\mathcal{F}^{-1}(\varphi)(x) = \hat{\varphi}(x) = \frac{1}{\sqrt{2\pi}} \int_{\mathbb{R}} \varphi(y)e^{ixy} \, dy.$$

Definition C.5. Fourier transform of tempered distribution is defined as

$$\mathcal{F}(T)[\varphi] = \hat{T}[\varphi] = T[\hat{\varphi}]$$

and the inverse is given by

$$\mathcal{F}^{-1}(T)[\varphi] = \hat{T}[\varphi] = T[\hat{\varphi}]$$.

We will need the following results about tempered distributions which we present without proof.

**Proposition C.6.** The following are true about tempered distributions:

1. The Fourier transform is an isomorphism on $\mathcal{S}'(\mathbb{R})$.
2. $\mathcal{T'} = j\omega \hat{T}$
3. Multiplication by a test function: For $\eta \in C^\infty_{\text{pol}}(\mathbb{R})$, we have $\eta T[\varphi] = T[\eta \varphi]$.

**C.3.2 Proof of Lemma 6.5.**

**Proof.** Define a tempered distribution

$$T_{\omega \varphi}[\varphi] = \int_{\mathbb{R}} \varphi(x) dF_{\omega \varphi}(x) = \mathbb{E}[\varphi].$$

It is straightforward to verify that it is a tempered distribution as it is linear and continuous [34, Example 7.12(b)]. Now, we will write (13) in the form of a differential equation involving tempered
distribution $\mathcal{T}_{z_\infty}$. For any $\varphi \in \mathcal{S}$, we have

$$\int_{\mathbb{R}} \frac{-j\omega}{\sqrt{2\pi}} \left[ e^{-j\omega z_\infty} \right] \varphi(\omega) d\omega = \int_{\mathbb{R}} \int_{\mathbb{R}} \frac{-j\omega}{\sqrt{2\pi}} e^{-j\omega z} \varphi(\omega) dF_{z_\infty}(z) d\omega$$

where (a) follows by Fubini’s Theorem as $|\varphi(\omega)|$ is integrable with respect to $dF_{z_\infty} d\omega$. Next, (b) follows by the definition of Fourier transform given by (22). Next, (c) follows by the definition of Tempered distribution $\mathcal{T}_{z_\infty}$. Finally, (d) follows by the derivative theorem of Fourier transform. In addition, we also have

$$\int_{\mathbb{R}} \frac{1}{\sqrt{2\pi}} \left[ g(z) \right] e^{-j\omega z_\infty} \varphi(\omega) d\omega = \int_{\mathbb{R}} \int_{\mathbb{R}} \frac{1}{\sqrt{2\pi}} g(z) \varphi(\omega) dF_{z_\infty} d\omega$$

where (a) follows by Fubini’s Theorem as $|\varphi(\omega) g(z)|$ is integrable with respect to $dF_{z_\infty} d\omega$. Next, (b) follows by the definition of Fourier transform given by (22) and (c) follows by the definition of the Tempered distribution $\mathcal{T}_{z_\infty}$. Multiplying (13) on both sides by $\varphi(\cdot)$ and integrating and using (23) and (24) will imply

$$\mathcal{T}_{z_\infty} [\varphi'] + g\hat{\varphi} = 0 \quad \forall \varphi \in \mathcal{S}(\mathbb{R}).$$

As Fourier transform is a bijection on $\mathcal{S}(\mathbb{R})$ [34, Theorem 7.7], the above is equivalent to

$$\mathcal{T}_{z_\infty} [\varphi'] + g\varphi = 0 \quad \forall \varphi \in \mathcal{S}(\mathbb{R}).$$

This can be written as the following differential equation in tempered distribution using the definition of derivative of a distribution given in [34, Section 6.12].

$$\mathcal{T}_{z_\infty} [\varphi'] = g\mathcal{T}_{z_\infty} [\varphi] \quad \forall \varphi \in \mathcal{S}(\mathbb{R}).$$

By [13, Theorem 4] [14, Theorem 3.9], we can directly write the entire solution of the above differential equation to be

$$\mathcal{T}_{z_\infty} [\varphi] = C \int_{-\infty}^{\infty} e^{-G(x)} \varphi(x) dx \quad \forall \varphi \in \mathcal{S}(\mathbb{R})$$

for any constant $C$ and $G(x) = \int_{0}^{x} g(t) dt$. The steps to solve this differential equation is given in [14, Section IV B]. By the definition of $\mathcal{T}_{z_\infty}$, we conclude that $z_\infty$ has density

$$\rho_{z_\infty}(x) = Ce^{-G(x)} \text{, where } C = \frac{1}{\int_{-\infty}^{\infty} e^{-G(x)} dx}.$$
Thus, the above solution can be the only possible solution of (14). Now, we verify that the above is actually a solution of the functional equation. For some $\omega \in \mathbb{R}$, we have

$$\omega \mathbb{E} [\cos(\omega X)] = \frac{1}{C} \int_{-\infty}^{\infty} \omega \cos(\omega x)e^{-\int_{0}^{x} g(y)dy} dx$$

$$= \frac{1}{C} \int_{-\infty}^{0} \omega \cos(\omega x)e^{-\int_{0}^{x} g(y)dy} dx + \frac{1}{C} \int_{0}^{\infty} \omega \cos(\omega x)e^{-\int_{0}^{x} g(y)dy} dx$$

$$\equiv (a) - \frac{1}{C} \int_{-\infty}^{0} \omega \cos(\omega x) \int_{-\infty}^{x} g(t)e^{-\int_{t}^{x} g(y)dy} dt dx$$

$$+ \frac{1}{C} \int_{0}^{\infty} \omega \cos(\omega x) \int_{x}^{\infty} g(t)e^{-\int_{t}^{x} g(y)dy} dt dx$$

$$\equiv (b) - \frac{1}{C} \int_{-\infty}^{0} g(t)e^{-\int_{t}^{x} g(y)dy} \int_{t}^{x} \omega \cos(\omega x) dx dt$$

$$+ \frac{1}{C} \int_{0}^{\infty} g(t)e^{-\int_{0}^{x} g(y)dy} \int_{0}^{x} \omega \cos(\omega x) dx dt$$

$$\equiv (c) \frac{1}{C} \int_{-\infty}^{\infty} g(t)e^{-\int_{0}^{t} g(y)dy} \sin(\omega t) dt$$

$$= \mathbb{E} [g(X) \sin(\omega X)].$$

Now, (a) can be justified as follows: As $g(\cdot)$ is a continuous function, by the first part of the fundamental theorem of calculus [33, Theorem 7.11], we have

$$\frac{d}{dx} e^{-\int_{0}^{x} g(y)dy} = -e^{-\int_{0}^{x} g(y)dy} \frac{d}{dx} \int_{0}^{x} g(y)dy = -g(x)e^{-\int_{0}^{x} g(y)dy}.$$ 

Now, as $|g(x)e^{-\int_{0}^{x} g(y)dy}| \leq g_{\max} e^{g_{\max}K} \mathbb{1} \{ |x| \leq K \} + g_{\max} e^{-\delta|x-K|}$ which is Lebesgue integrable, thus by the Fundamental Theorem of calculus [33, Theorem 7.21], we have

$$\int_{-\infty}^{x} g(x)e^{-\int_{0}^{x} g(y)dy} dx = -\int_{-\infty}^{x} de^{-\int_{0}^{x} g(y)dy} = - \int_{0}^{x} g(y)dy$$

$$\int_{x}^{\infty} g(x)e^{-\int_{0}^{x} g(y)dy} dx = \int_{x}^{\infty} de^{-\int_{0}^{x} g(y)dy} = - \int_{0}^{x} g(y)dy$$

where (a) follows as $\int_{0}^{0} g(y)dy = -\infty$ and $\int_{0}^{\infty} g(y)dy = \infty$. Next, (b) follows by Fubini’s Theorem and (c) follows by Fundamental Theorem of calculus [33, Theorem 7.21]. Similarly, we will have $-\mathbb{E} [\omega \sin(\omega X)] = \mathbb{E} [g(X) \cos(\omega X)].$ This completes the proof as the real part and imaginary part are respectively equal.  

**D TECHNICAL DETAILS FOR THE PROOF OF THEOREM 4.6**

**D.1 Proof of Preliminary Lemmas**

For the proof of Lemma 7.1, we will need the following additional lemma which is presented below along with its proof.

**LEMMA D.1.** For any $K > 0$

$$\mathbb{P} \{ |\zeta_{\tau}| \leq K\tau \} \leq \frac{4K\phi_{\max}}{p_{\min}} e^{(\tau + 1)}$$

**PROOF.** For any given $x \in \mathbb{Z}$, consider the test function

$$V_{\lambda}(z) = z \mathbb{1} \{ \text{sgn}(x)z > \text{sgn}(x)x \}.$$
We will set the drift of above defined test function to zero in steady state to get a bound on $P(\bar{z}_\eta = x)$. Alternatively, one can analyze the drift of $zI\{z > x\}$ for $x \geq 0$ and $zI\{z < x\}$ for $x < 0$. To present a compact analysis, we consider $V_x(z)$ which combines both the cases mentioned above. For a better understanding of the proof, the reader can consider the case when $x \geq 0$ and $x < 0$ separately.

Now, setting the drift to zero of $V_\epsilon(\cdot)$, we get

$$0 = E\left[\bar{z}^*_\eta I\{\text{sgn}(x)\bar{z}^*_\eta > \text{sgn}(x)x\} - \bar{z}_\eta I\{\text{sgn}(x)\bar{z}_\eta > \text{sgn}(x)x\}\right]$$

$\Rightarrow 2\epsilon \phi_{\max} \geq E\left[\bar{z}^*_\eta I\{\text{sgn}(x)\bar{z}^*_\eta > \text{sgn}(x)x\} - I\{\text{sgn}(x)\bar{z}_\eta > \text{sgn}(x)x\}\right]$.

In step (a), we add and subtract $\bar{z}^*_\eta I\{\text{sgn}(x)\bar{z}_\eta > \text{sgn}(x)x\}$. Next, (b) follows by the evolution equation given by (11) and the tower property of expectation. To get the bound in (c), we take absolute values on both sides and use the fact that $|\phi^c|$ and $|\phi^s|$ are bounded by $\phi_{\max}$. Next, in (d), we simply add and subtract $x E\left[I\{\text{sgn}(x)\bar{z}^*_\eta > \text{sgn}(x)x\} - I\{\text{sgn}(x)\bar{z}_\eta > \text{sgn}(x)x\}\right]$ and note that it is just the drift of $I\{\text{sgn}(x)\bar{z}^*_\eta > \text{sgn}(x)x\}$ in steady state which is equal to zero. This gives us (e).

Next, (f) follows by noting that the term whose expectation we are calculating is non-negative with probability 1 when $x \geq 0$ and non-positive with probability 1 when $x < 0$.

Now, using the above equation, for all $x \in \mathbb{Z}$, by Assumption 2.1, we have

$$P(\bar{z}_\eta = x) \leq \frac{2\epsilon \phi_{\max}}{\rho_{\min}}.$$

Lastly, by using the union bound, for any $K > 0$, we get the Lemma. \hfill \Box

Now, we will use the above Lemma to prove Lemma 7.1.
Thus, we have
\[ P \left( g \left( \frac{\bar{z}_\eta}{\tau} \right) - c_\infty > \delta \right) = P \left( g \left( \frac{\bar{z}_\eta}{\tau} \right) - c_\infty > \delta \left| \bar{z}_\eta \right| \leq K\tau \right) P \left( \left| \bar{z}_\eta \right| \leq K\tau \right) \]
\[ + P \left( g \left( \frac{\bar{z}_\eta}{\tau} \right) - c_\infty > \delta \left| \bar{z}_\eta \right| > K\tau \right) P \left( \left| \bar{z}_\eta \right| > K\tau \right) \]
\[ = P \left( g \left( \frac{\bar{z}_\eta}{\tau} \right) - c_\infty > \delta \left| \bar{z}_\eta \right| \leq K\tau \right) P \left( \left| \bar{z}_\eta \right| \leq K\tau \right) \]
\[ \leq P \left( \left| \bar{z}_\eta \right| \leq K\tau \right) \]
\[ \leq \frac{4K\phi_{\max}}{\rho_{\min}} \epsilon (\tau + 1). \]

Thus, we have
\[ (c_\infty - \delta) \left( 1 - \frac{4K\phi_{\max}}{\rho_{\min}} \epsilon (\tau + 1) \right) - g_{\max} \frac{4K\phi_{\max}}{\rho_{\min}} \epsilon (\tau + 1) \leq \mathbb{E} \left[ g \left( \frac{\bar{z}_\eta}{\tau} \right) \right] \]
\[ \leq (c_\infty + \delta) \left( 1 - \frac{4K\phi_{\max}}{\rho_{\min}} \epsilon (\tau + 1) \right) + g_{\max} \frac{4K\phi_{\max}}{\rho_{\min}} \epsilon (\tau + 1). \]

Now, by taking the limit as \( \eta \uparrow \infty \), and noting that \( \epsilon \tau \rightarrow 0 \) and \( \epsilon \rightarrow 0 \), we get
\[ \left| \mathbb{E} \left[ g \left( \frac{\bar{z}_\eta}{\tau} \right) \right] - c_\infty \right| \leq \delta. \]

As \( \delta > 0 \) is arbitrary and LHS is independent of \( \delta \), the proof is complete. \( \square \)

**Proof of Lemma 7.2.** For any \( \delta, K > 0 \), there exists \( n_0 \) such that for all \( n > n_0 \)
\[ |g_n(x) - c| \leq \delta \quad \forall x \in \mathbb{R}, \]

Thus for all \( n \geq n_0 \)
\[ P \left( |g_n(Y_n) - c| > \delta \right) = 0. \]

Thus for all \( n \geq n_0 \)
\[ c - \delta \leq \mathbb{E} \left[ g_n(Y_n) \right] \leq c + \delta \]

Now, by taking \( n \uparrow \infty \), we get
\[ \lim_{n \uparrow \infty} \mathbb{E} \left[ g_n(Y_n) \right] - c \leq \delta \]

As the above is true for all \( \delta > 0 \), we get
\[ \lim_{n \uparrow \infty} \mathbb{E} \left[ g_n(Y_n) \right] = c. \]

\( \square \)

**Proof of Lemma 7.3.** We will analyze the drift of \( z \text{ sgn}(z) \) as follows:
\[ \mathbb{E} \left[ z_\eta(k+1) \text{ sgn}(z_\eta(k+1)) - z_\eta(k) \text{ sgn}(z_\eta(k)) \right| z_\eta(k) = z \]
\[ = \mathbb{E} \left[ z_\eta(k+1) \left( \text{ sgn}(z_\eta(k+1)) - \text{ sgn}(z_\eta(k)) \right) \right| z_\eta(k) = z \] \[ + \mathbb{E} \left[ \left( z_\eta(k+1) - z_\eta(k) \right) \text{ sgn}(z_\eta(k)) \right| z_\eta(k) = z \]
\[ = \mathbb{E} \left[ z_\eta(k+1) \left( \text{ sgn}(z_\eta(k+1)) - \text{ sgn}(z_\eta(k)) \right) \right| z_\eta(k) = z \] \[ + \epsilon \left( \phi^c \left( \frac{z}{\tau} \right) - \phi^s \left( \frac{Z}{\tau} \right) \right) \text{ sgn}(z) \]
\[ \leq -\epsilon \delta \quad \forall |z| > \max\{A_{\text{max}}, K\tau\} \]
where the last inequality follows as \( \text{sgn}(z\eta(k+1)) = \text{sgn}(z\eta(k)) \) if \(|z\eta(k)| > A_{\text{max}}\) and Condition 4.1. Thus, by Moment bound theorem [17, Proposition 6.14], we have

\[
\mathbb{E}[\tilde{z}_\eta^+(\text{sgn}(\tilde{z}_\eta^+) - \text{sgn}(\tilde{z}_\eta))] = -\epsilon \mathbb{E} \left[ \left( \phi^c \left( \frac{\tilde{z}_\eta}{\tau} \right) - \phi^s \left( \frac{\tilde{z}_\eta}{\tau} \right) \right) \text{sgn}(\tilde{z}_\eta) \right].
\]

\[ \square \]

D.2 Proof of Lemma 7.6

PROOF OF LEMMA 7.6. For \( \omega \in \mathbb{R} \), we define the test function

\[
\Delta U(z) = \text{sgn}(z) e^{j\epsilon \omega} \text{sgn}(z)
\]

Now, we will set the drift of this test function to zero.

\[
\mathbb{E}[\Delta U(\tilde{z}_\eta)] = \mathbb{E} \left[ \text{sgn}(\tilde{z}_\eta^+) e^{j\epsilon \omega} \text{sgn}(\tilde{z}_\eta^+) - \text{sgn}(\tilde{z}_\eta) e^{j\epsilon \omega} \text{sgn}(\tilde{z}_\eta) \right] = \mathbb{E} \left[ \text{sgn}(\tilde{z}_\eta^+) e^{j\epsilon \omega} \text{sgn}(\tilde{z}_\eta^+) - \text{sgn}(\tilde{z}_\eta) e^{j\epsilon \omega} \text{sgn}(\tilde{z}_\eta) \right] \left( T_6 \right)
\]

\[
+ \mathbb{E} \left[ \text{sgn}(\tilde{z}_\eta) e^{j\epsilon \omega} \text{sgn}(\tilde{z}_\eta) - \text{sgn}(\tilde{z}_\eta) e^{j\epsilon \omega} \text{sgn}(\tilde{z}_\eta) \right] \left( T_7 \right)
\]

We will analyze each of the above terms separately. In particular, \( T_7 \) is simplified by using the update equation of imbalance given by (11) and Taylor’s Theorem.

CLAIM D.2.

\[
T_7 = j\epsilon^2 \omega^2 \mathbb{E} \left[ e^{j\epsilon \omega} \text{sgn}(\tilde{z}_\eta) \left( \phi^c \left( \frac{\tilde{z}_\eta}{\tau} \right) - \phi^s \left( \frac{\tilde{z}_\eta}{\tau} \right) \right) \right] - \frac{1}{2} \epsilon^2 \omega^2 \mathbb{E} \left[ \text{sgn}(\tilde{z}_\eta) e^{j\epsilon \omega} \text{sgn}(\tilde{z}_\eta) \left( \sigma^c(\lambda(\tilde{z}_\eta)) + \sigma^s(\mu(\tilde{z}_\eta)) \right) \right] + o(\epsilon^2)
\]

Next, we simplify \( T_6 \) by using Taylor’s Theorem to get

CLAIM D.3.

\[ T_6 = o(\epsilon^2). \]

The proof of the Claim D.2 and D.3 has been deferred to Appendix D.3 and here we continue with the proof of Lemma 7.6. Now, by setting the drift of \( U \) to zero, we get

\[
0 = \mathbb{E} [T_6] + \mathbb{E} [T_7]
\]

\[
= \mathbb{E} \left[ e^{j\epsilon \omega} \text{sgn}(\tilde{z}_\eta) \left( \phi^c \left( \frac{\tilde{z}_\eta}{\tau} \right) - \phi^s \left( \frac{\tilde{z}_\eta}{\tau} \right) \right) \right] + \frac{j\omega}{2} \mathbb{E} \left[ \text{sgn}(\tilde{z}_\eta) e^{j\epsilon \omega} \text{sgn}(\tilde{z}_\eta) \left( \sigma^c(\lambda(\tilde{z}_\eta)) + \sigma^s(\mu(\tilde{z}_\eta)) \right) \right]
\]

\[
+ \frac{T_6}{j\epsilon^2 \omega} + o(1).
\]

which gives us

\[
\left( -1 + \frac{j\omega}{2} (\sigma^c + \sigma^s) \right) \mathbb{E} \left[ \text{sgn}(\tilde{z}_\eta) e^{j\epsilon \omega} |\tilde{z}_\eta| \right] = -\mathbb{E} \left[ e^{j\epsilon \omega} |\tilde{z}_\eta| \left( 1 + \left( \phi^c \left( \frac{\tilde{z}_\eta}{\tau} \right) - \phi^s \left( \frac{\tilde{z}_\eta}{\tau} \right) \right) \right) \text{sgn}(\tilde{z}_\eta) \right] \text{sgn}(\tilde{z}_\eta)
\]

\[
- \frac{T_6}{j\epsilon^2 \omega} + \frac{j\omega}{2} \mathbb{E} \left[ \text{sgn}(\tilde{z}_\eta) e^{j\epsilon \omega} |\tilde{z}_\eta| \left( \sigma^c(\lambda^*) + \sigma^s(\mu^*) - \sigma^c(\lambda(\tilde{z}_\eta)) - \sigma^s(\mu(\tilde{z}_\eta)) \right) \right] + o(1)
\]

, Vol. 1, No. 1, Article . Publication date: October.
Now, by taking the absolute value on both sides and upper bounding the LHS by using triangle inequality and using Claim D.3, we get
\[
\left(1 + \omega^2 \frac{(\sigma^c + \sigma^s)^2}{4}\right) \mathbb{E} \left| \text{sgn}(\bar{z}_\eta) e^{j\eta \omega z_1} \right| \leq \frac{|\omega|}{2} \mathbb{E} \left| \sigma^c(\lambda^*) + \sigma^s(\mu^*) - \sigma^c(\lambda(\bar{z}_\eta)) - \sigma^s(\mu(\bar{z}_\eta)) \right| + o(1) \\
+ \mathbb{E} \left| 1 + \left( \phi^c \left( \frac{\bar{z}_\eta}{r} \right) - \phi^s \left( \frac{\bar{z}_\eta}{r} \right) \right) \text{sgn}(\bar{z}_\eta) \right| \text{sgn}(\bar{z}_\eta) 
\]
Next, as $\sigma^s$ and $\sigma^c$ are continuous function
\[
\left| \sigma^c(\lambda^*) + \sigma^s(\mu^*) - \sigma^c(\lambda(\bar{z}_\eta)) - \sigma^s(\mu(\bar{z}_\eta)) \right| \rightarrow 0 \quad \text{uniformly as } \eta \uparrow \infty.
\]
Thus, by Lemma 7.2, we get
\[
\lim_{\eta \to 1} \frac{|\omega|}{2} \mathbb{E} \left| \sigma^c(\lambda^*) + \sigma^s(\mu^*) - \sigma^c(\lambda(\bar{z}_\eta)) - \sigma^s(\mu(\bar{z}_\eta)) \right| = 0.
\]
Next, by the Lemma 7.1, and Condition 4.5, we have
\[
\lim_{\eta \to 1} \mathbb{E} \left| \left(1 + \left( \phi^c \left( \frac{\bar{z}_\eta}{r} \right) - \phi^s \left( \frac{\bar{z}_\eta}{r} \right) \right) \text{sgn}(\bar{z}_\eta) \right| \text{sgn}(\bar{z}_\eta) \right| = \lim_{\eta \to 1} \mathbb{E} \left| \left(1 + \left( \phi^c \left( \frac{\bar{z}_\eta}{r} \right) - \phi^s \left( \frac{\bar{z}_\eta}{r} \right) \right) \right| \text{sgn}(\bar{z}_\eta) \right| = 0.
\]
This completes the proof. \qed

D.3 Proof of Claims for Lemma 7.4 and 7.6

PROOF OF CLAIM 7.5. $\mathcal{T}_2$ can be simplified as follows:
\[
\mathbb{E} \left[ e^{j\omega z_2} \text{sgn}(z_\eta) - e^{j\omega z_2} \text{sgn}(z_\eta) \right] \\
= \mathbb{E} \left[ e^{j\omega z_2} - e^{j\omega z_2} \right] 1 \{z_\eta \geq 0\} + e^{-j\omega z_2} - e^{-j\omega z_2} 1 \{z_\eta < 0\} \\
= \mathbb{E} e^{j\omega z_2} \left( e^{j\omega (a_\eta(\bar{z}_\eta) - a_\eta(\bar{z}_\eta))} - 1\right) 1 \{z_\eta \geq 0\} + e^{-j\omega z_2} \left( e^{-j\omega (a_\eta(\bar{z}_\eta) - a_\eta(\bar{z}_\eta))} - 1\right) 1 \{z_\eta < 0\} \\
= \mathbb{E} e^{j\omega z_2} \left( j\omega (a_\eta(\bar{z}_\eta) - a_\eta(\bar{z}_\eta)) - \frac{1}{2} j\omega^2 (a_\eta(\bar{z}_\eta) - a_\eta(\bar{z}_\eta))^2 \right) 1 \{z_\eta \geq 0\} + e^{-j\omega z_2} \left( j\omega (a_\eta(\bar{z}_\eta) - a_\eta(\bar{z}_\eta)) - \frac{1}{2} j\omega^2 (a_\eta(\bar{z}_\eta) - a_\eta(\bar{z}_\eta))^2 \right) 1 \{z_\eta < 0\} + o(\omega^2) \\
= \mathbb{E} e^{-j\omega z_2} \left( j\omega (a_\eta(\bar{z}_\eta) - a_\eta(\bar{z}_\eta)) - \frac{1}{2} j\omega^2 (a_\eta(\bar{z}_\eta) - a_\eta(\bar{z}_\eta))^2 \right) 1 \{z_\eta < 0\} + o(\omega^2) \\
= \mathbb{E} e^{j\omega z_2} \text{sgn}(z_\eta) \phi^c \left( \frac{\bar{z}_\eta}{r} \right) - \phi^s \left( \frac{\bar{z}_\eta}{r} \right) \text{sgn}(\bar{z}_\eta) \\
- \frac{1}{2} j\omega^2 \mathbb{E} e^{j\omega z_2} \text{sgn}(z_\eta) \phi^c \left( \frac{\bar{z}_\eta}{r} \right) - \phi^s \left( \frac{\bar{z}_\eta}{r} \right) \text{sgn}(\bar{z}_\eta) \\
+ o(\omega^2)
\]
where (a) follows by Lemma E.1 where we use Taylor’s Theorem to expand the real and imaginary part of $\mathbb{E} [j\omega z]$ separately and bound the higher order terms appropriately. Next, (b) follows by using the tower property of expectation and (3). Finally, (c) follows by combining terms and using
the definition of $\text{sgn}(z)$. Now, we will simplify the second term above by calculating the second moment of the arrivals.

$$
\begin{align*}
\mathbb{E} \left[ (a^*_n(z_n) - a^*_n(\tilde{z}_n))^2 | \tilde{z}_n \right] &= \text{Var} \left[ a^*_n(\tilde{z}_n) | \tilde{z}_n \right] + \mathbb{E} \left[ a^*_n(\tilde{z}_n) - a^*_n(\tilde{z}_n) | \tilde{z}_n \right]^2 \\
&= \sigma^c(\lambda(\tilde{z}_n)) + \sigma^s(\mu(\tilde{z}_n)) + \epsilon^2 \left( \phi^c \left( \frac{\tilde{z}_n}{\tau} \right) - \phi^s \left( \frac{\tilde{z}_n}{\tau} \right) \right)^2 \\
&= \sigma^c(\lambda(\tilde{z}_n)) + \sigma^s(\mu(\tilde{z}_n)) + o(\epsilon).
\end{align*}
$$

(25)

PROOF OF CLAIM D.2. We can simplify $\mathcal{T}_7$ as follows:

$$
\begin{align*}
\mathbb{E} \left[ \text{sgn}(\tilde{z}_n)e^{j\epsilon\omega t_n^*\text{sgn}(z_n)} - \text{sgn}(\tilde{z}_n)e^{j\epsilon\omega \text{sgn}(z_n)} \right] &= \mathbb{E} \left[ (e^{j\epsilon\omega t_n^*} - e^{j\epsilon\omega t_n}) \mathbb{1} \{ \tilde{z}_n \geq 0 \} \left( e^{j\epsilon\omega t_n} - e^{j\epsilon\omega t_n^*} \right) \mathbb{1} \{ \tilde{z}_n < 0 \} \right] \\
&= \mathbb{E} \left[ e^{j\epsilon\omega t_n} \left( e^{j\epsilon\omega (a^*_n(z_n) - a^*_n(\tilde{z}_n))} - 1 \right) \mathbb{1} \{ \tilde{z}_n \geq 0 \} - e^{j\epsilon\omega t_n} \left( e^{j\epsilon\omega (a^*_n(z_n) - a^*_n(\tilde{z}_n))} - 1 \right) \mathbb{1} \{ \tilde{z}_n < 0 \} \right] \\
&= (a) \mathbb{E} \left[ e^{j\epsilon\omega t_n} \left( \mathbb{1} \{ \tilde{z}_n \geq 0 \} - e^{j\epsilon\omega (a^*_n(z_n) - a^*_n(\tilde{z}_n))^2} \right) \right] - \mathbb{E} \left[ e^{j\epsilon\omega t_n} \left( \mathbb{1} \{ \tilde{z}_n < 0 \} + e^{j\epsilon\omega (a^*_n(z_n) - a^*_n(\tilde{z}_n))^2} \right) \right] + o(\epsilon^2) \\
&= (b) \mathbb{E} \left[ e^{j\epsilon\omega t_n} \left( \mathbb{1} \{ \tilde{z}_n \geq 0 \} - \frac{1}{2} e^{j\epsilon\omega (a^*_n(z_n) - a^*_n(\tilde{z}_n))^2} \right) \right] + o(\epsilon^2) \\
&= (c) \mathbb{E} \left[ e^{j\epsilon\omega t_n} \left( \mathbb{1} \{ \tilde{z}_n < 0 \} + \frac{1}{2} e^{j\epsilon\omega (a^*_n(z_n) - a^*_n(\tilde{z}_n))^2} \right) \right] + o(\epsilon^2),
\end{align*}
$$

where (a) follows by Lemma E.1. Next, (b) follows by the tower property of expectation and (3) and (c) follows by (25). 

PROOF OF CLAIM D.3.

$$
\begin{align*}
\mathcal{T}_6 &= \mathbb{E} \left[ \text{sgn}(z^+_n)e^{j\epsilon\omega t_n^*\text{sgn}(z^+_n)} - \text{sgn}(z_n)e^{j\epsilon\omega t_n\text{sgn}(z_n)} \right] \\
&= \mathbb{E} \left[ \left( \text{sgn}(z^+_n)e^{j\epsilon\omega t_n^*\text{sgn}(z^+_n)} - \text{sgn}(z_n)e^{j\epsilon\omega t_n\text{sgn}(z_n)} \right) \mathbb{1} \{ |z^+_n| \leq A_{\text{max}} \} \right] \\
&= \mathbb{E} \left[ \text{sgn}(z^+_n)e^{j\epsilon\omega t_n^*\text{sgn}(z^+_n)} \mathbb{1} \{ |z^+_n| \leq A_{\text{max}} \} - \text{sgn}(z_n)e^{j\epsilon\omega t_n\text{sgn}(z_n)} \mathbb{1} \{ |z^+_n| \leq A_{\text{max}} \} \right] \\
&= (a) \mathbb{E} \left[ \left( \text{sgn}(z^+_n) - \text{sgn}(z_n) \right) - \mathbb{E} \left[ \frac{1}{2} e^{j\epsilon\omega (z_n^+_n)^2} \left( \text{sgn}(z^+_n) - \text{sgn}(z_n) \right) \mathbb{1} \{ |z^+_n| \leq A_{\text{max}} \} \right] + o(\epsilon^2) \right] \\
&= \mathbb{E} \left[ \left( \text{sgn}(z^+_n) - \text{sgn}(z_n) \right) - \mathbb{E} \left[ \frac{1}{2} e^{j\epsilon\omega (z_n^+_n)^2} \left( \text{sgn}(z^+_n) - \text{sgn}(z_n) \right) \right] + o(\epsilon^2) \right] \\
&= (b) - \mathbb{E} \left[ \left( z_n^+_n \right) ^2 \left( \text{sgn}(z_n^+_n) - \text{sgn}(z_n) \right) \right] + o(\epsilon^2) \\
&\Rightarrow |\mathcal{T}_6| \leq \frac{1}{2} e^{2\epsilon^2} A_{\text{max}} \mathbb{E} \left[ \left( z_n^+_n \right) ^2 \left( \text{sgn}(z_n^+_n) - \text{sgn}(z_n) \right) \right] + o(\epsilon^2)
\end{align*}
$$
\[
\begin{align*}
&= \frac{1}{2} e^2 \omega^2 A_{\max} \mathbb{E} \left[ \hat{z}_\eta^+ \left( \text{sgn}(\hat{z}_\eta^+) - \text{sgn}(\hat{z}_\eta) \right) \right] + o(\epsilon^2) \\
&= \frac{1}{2} e^2 \omega^2 A_{\max} \mathbb{E} \left[ \left( \phi^+ \left( \frac{\hat{z}_\eta}{\tau} \right) - \phi^e \left( \frac{\hat{z}_\eta}{\tau} \right) \right) \text{sgn}(\hat{z}_\eta) \right] + o(\epsilon^2) \\
&\leq e^2 \omega^2 A_{\max} \phi_{\max} + o(\epsilon^2) = o(\epsilon^2),
\end{align*}
\]

where (a) follows by Lemma E.1. Next, (b) follows as |\text{sgn}(x)| \leq 1 and thus, \( \mathbb{E} \left[ \Delta(\text{sgn}(\hat{z}_\eta)) \right] = 0. \) Now, by taking mod on both sides and noting that \( \text{sgn}(\hat{z}_\eta^+) = \text{sgn}(\hat{z}_\eta) \) when \( |\hat{z}_\eta^+| \geq A_{\max}, \) we get (c). Next, (d) follows as \( \hat{z}_\eta^+(\text{sgn}(\hat{z}_\eta^+) - \text{sgn}(\hat{z}_\eta)) \geq 0 \) as for \( \hat{z}_\eta^+ > 0, \) \( \text{sgn}(\hat{z}_\eta^+) - \text{sgn}(\hat{z}_\eta) \geq 0 \) and for \( \hat{z}_\eta^+ < 0, \) \( \text{sgn}(\hat{z}_\eta^+) - \text{sgn}(\hat{z}_\eta) \leq 0. \) Finally, (e) follows by Lemma 7.3. \( \square \)

### E  Precise Argument for Taylor’s Theorem

**Lemma E.1.** Consider the set of mutually independent random variables denoted by \( \{Y_\eta : \eta > 0\} \) and \( \{X_\eta(y) : \eta > 0, y \in \mathbb{Z}\}. \) Also, there exists \( x_{\max} \) such that \( X_\eta(y) \leq x_{\max} \) with probability 1 for all \( \eta, y. \) Now, define functions \( f, h : \mathbb{R} \to \mathbb{C} \) given by \( f = f_1 + jf_2 \) and \( h = h_1 + jh_2. \) Also, \( f_1, f_2, h_1, h_2 \) are three continuously differentiable and \( |h_1''(x)| \leq 1, |h_2''(x)| \leq 1, |f_1(x)| \leq 1, |f_2(x)| \leq 1 \) for all \( x \in \mathbb{R}. \) Then, for some \( \omega \in \mathbb{R}, \) we have

\[
\frac{1}{\epsilon^2} \mathbb{E} \left[ f(Y_\eta)h(\epsilon \omega X_\eta(Y_\eta)) \right] - \mathbb{E} \left[ f(Y_\eta)h(0) \right] - j\epsilon \omega \mathbb{E} \left[ f(Y_\eta)h'(0)X_\eta(Y_\eta) \right] = \frac{1}{3} \epsilon |\omega|^3 x_{\max}^3.
\]

With a slight abuse of notation, we write

\[
\mathbb{E} \left[ f(Y_\eta)h(\epsilon \omega X_\eta(Y_\eta)) \right] = \mathbb{E} \left[ f(Y_\eta)h(0) \right] + j\epsilon \omega \mathbb{E} \left[ f(Y_\eta)h'(0)X_\eta(Y_\eta) \right] + \frac{1}{2} \epsilon^2 \omega^2 \mathbb{E} \left[ f(Y_\eta)h''(0)X_\eta^2(Y_\eta) \right] + o(\epsilon^2).
\]

**Proof.** We will analyze the real and imaginary part separately. By Taylor’s Theorem, we have

\[
h_i(x) = h_i(0) + h_i'(0)x + \frac{1}{2} h_i''(0)x^2 + \frac{1}{6} h_i'''(\bar{x})x^3 \quad \text{for some } \bar{x} \in (0, x) \quad \forall i \in \{1, 2\}.
\]

Thus,

\[
\left| h_i(x) - h_i(0) - h_i'(0)x - \frac{1}{2} h_i''(0)x^2 \right| \leq \frac{1}{6} |x|^3 \quad \forall x \in \mathbb{R}, \forall i \in \{1, 2\}.
\]

Now, substitute \( x \) by \( \epsilon \omega X_\eta(Y_\eta) \) and note that \( |X_\eta(Y_\eta)| \leq x_{\max} \) with probability 1 to get

\[
\left| h_i(\epsilon \omega X_\eta(Y_\eta)) - h_i(0) - \epsilon \omega X_\eta(Y_\eta)h_i'(0) - \frac{1}{2} \epsilon^2 \omega^2 X_\eta(Y_\eta)^2 h_i''(0) \right| \leq \frac{1}{6} |\epsilon \omega x_{\max}|^3 \quad \text{w.p.1} \forall i \in \{1, 2\}
\]

Now, as \( |f_1(Y_\eta)| \leq 1 \) and \( |f_2(Y_\eta)| \leq 1 \) with probability 1, multiplying on both sides, we get

\[
\left| \tilde{f}_k(Y_\eta)h_i(\epsilon \omega X_\eta(Y_\eta)) - f_\eta(Y_\eta)h_i(0) - f_\eta(Y_\eta)\epsilon \omega X_\eta(Y_\eta)h_i'(0) - \frac{1}{2} f_\eta(Y_\eta)\epsilon^2 \omega^2 X_\eta(Y_\eta)^2 h_i''(0) \right| \leq \frac{1}{6} |\epsilon \omega x_{\max}|^3 \quad \text{w.p.1} \forall i \in \{1, 2\} \forall k \in \{1, 2\}.
\]

Now, by adding \((i, k) = (1, 1)\) and \((i, k) = (2, 2)\) and using triangle inequality will give bound on the real part of (26) and by adding \((i, k) = (1, 2)\) and \((i, k) = (2, 1)\) and using triangle inequality will give bound on the imaginary part of (26). Now, by using the fact that for any vector \( x, \|x\|_1 \geq \|x\|_2 \), we get the lemma. \( \square \)
F CLASSICAL SINGLE SERVER QUEUE

F.1 Proof of Proposition 5.1

Proof. The transition probabilities for the underlying DTMC governing the single server queue operating under the two-price policy is given by

\[
P_{ij} = \begin{cases} 
  m & \text{if } j = i + 1, 0 < i \leq \tau \text{ or } (i, j) = (0, 1) \\
  1 - 2m & \text{if } j = i, 0 < i \leq \tau \\
  1 - m & \text{if } j = i = 0 \\
  m + \epsilon \mu^* & \text{if } j = i - 1, i > \tau \\
  m - \epsilon (1 - \mu^*) & \text{if } j = i + 1, i > \tau \\
  1 - 2m + \epsilon (1 - 2\mu^*) & \text{if } j = i, i > \tau \\
  0 & \text{otherwise.}
\end{cases}
\]

As the DTMC is a birth and death process, it is reversible. Thus, we can solve the local balance equations to get:

\[
\pi_i = \begin{cases} 
  \frac{1}{[\tau] + 1 + i/m} & \text{if } i \leq \lfloor \tau \rfloor \\
  \frac{m}{[\tau] + 1 + m/e} \left( 1 - \frac{\epsilon}{m + \epsilon \mu^*} \right)^{i - \lfloor \tau \rfloor - 1} & \text{if } i > \lfloor \tau \rfloor.
\end{cases}
\]

Note that for large \( \eta \), the stationary distribution of \( \tilde{q}_\eta \) is almost the same as the stationary distribution of \( \tilde{z}_\eta \). Indeed, the proof follows exactly as the proof of Proposition 3.2. We present it below for completeness.

Now, we will calculate the moment generating function of \( \epsilon \tilde{q}_\eta \) for Case 1 and 2 and \( \tilde{q}/\tau \) for Case 3. We fix a \( t \) such that \( t < 1/m \). There exists \( \epsilon_0 \) such that for all \( \epsilon < \epsilon_0 \), we have \((1 - \epsilon/(m + \epsilon \mu^*))e^{\epsilon t} < 1\). For the further calculations, we consider \( \eta > \eta_0 \) such that \( \epsilon < \epsilon_0 \). We have

\[
\mathbb{E} \left[ e^{\epsilon t \tilde{q}_\eta} \right] = \sum_{i=0}^{\infty} \pi_i e^{\epsilon t i} \\
= \sum_{i=0}^{\lfloor \tau \rfloor} \pi_i e^{\epsilon t i} + \sum_{i=\lfloor \tau \rfloor + 1}^{\infty} \pi_i e^{\epsilon t i} \\
= \frac{1}{[\tau] + 1 + m/e} \left( \sum_{i=0}^{\lfloor \tau \rfloor} e^{\epsilon t i} + \frac{m}{m + \epsilon \mu^*} \sum_{i=\lfloor \tau \rfloor + 1}^{\infty} \left( 1 - \frac{\epsilon}{m + \epsilon \mu^*} \right)^{i - \lfloor \tau \rfloor - 1} e^{\epsilon t i} \right) \\
= \frac{1 - e^{\epsilon t ([\tau] + 1)}}{[\tau] \epsilon + \epsilon + m} + \frac{m}{m + \epsilon \mu^*} \frac{e^{\epsilon t ([\tau] + 1)}}{1 - e^{\epsilon t}}
\]

Now, we will take the limit as \( \eta \to \infty \) for the above equation for Case 1 and 2 separately.

**Case 1:** Similar to the proof of Proposition 3.2, we will have

\[
\frac{1 - e^{\epsilon t ([\tau] + 1)}}{1 - e^{\epsilon t}} = \epsilon \frac{-e^{\epsilon t ([\tau] + 1)} + o(\epsilon \tau)}{-e^{\epsilon t} + o(\epsilon)} = \frac{-e^{\epsilon t ([\tau] + 1)} + o(\epsilon \tau)}{-t + o(1)} \to 0
\]

\[
\frac{e^{\epsilon t ([\tau] + 1)}}{1 - e^{\epsilon t} + \frac{e^{\epsilon t}}{m + \epsilon \mu^*} + o(\epsilon)} = \frac{-e^{\epsilon t} + \frac{e^{\epsilon t}}{m + \epsilon \mu^*} + o(\epsilon)}{-t + \frac{1}{m + \epsilon \mu^*} + o(\epsilon)} \to 1
\]

Vol. 1, No. 1, Article . Publication date: October .
Now, by using (28) to simplify (16) we get

$$\mathbb{E} \left[ e^{\tau \eta} \right] \rightarrow \frac{1}{1 - tm} \quad \text{as } \eta \rightarrow \infty.$$  

This completes Case 1 as the above is the MGF of an exponential distribution with parameter \( (m) \).

**Case 2:** Similar to the proof of Proposition 3.2, we have

$$\begin{align*}
\frac{1 - e^{\tau (\eta + 1)}}{1 - e^{\tau}} &= \frac{1 - e^{\tau (\eta + 1)}}{-\tau + o(\epsilon)} = \frac{1 - e^{\tau (\eta + 1)}}{-\tau + o(1)} \rightarrow \frac{e^{\eta t} - 1}{t} \\
\frac{\epsilon}{1 - e^{\tau (\eta + 1) + \frac{e^{\eta t}}{m + \epsilon \mu^*}}} &= \frac{-\epsilon t + o(\epsilon)}{e^{\tau (\eta + 1)} + \frac{e^{\eta t}}{m + \epsilon \mu^*} + o(\epsilon)} = \frac{-\epsilon t + o(1)}{-t + \frac{1}{m + \epsilon \mu^*} + o(\epsilon)} \rightarrow \frac{e^{\eta t} - 1}{1/m - t} 
\end{align*}$$

Now, by using (29) to simplify (27) we get

$$\mathbb{E} \left[ e^{\eta t \eta} \right] \rightarrow \frac{1}{l + m} \left( \frac{e^{\eta t} - 1}{t} + \frac{e^{\eta t}}{1/m - t} \right)$$

The above is the MGF of the non-negative hybrid distribution with parameters \((m, l)\). This can be verified similar to the proof of Proposition 3.2. We skip the steps here as they are repetitive. This completes the proof for Case 2.

**Case 3:** For large enough \( \eta \) and \( t < 1/m \), the MGF of \( \bar{q}_1^\tau \) can be calculated similar to (27) to get

$$\mathbb{E} \left[ e^{\eta t \bar{q}_1^\tau} \right] = \frac{\epsilon}{\eta} \left( 1 + \frac{e^{\eta t (\eta + 1)}/r}{1 - e^{\eta t}/r} + \frac{m}{m + \epsilon \mu^*} \frac{e^{\eta t (\eta + 1)}/r}{1 - e^{\eta t}/r + \frac{e^{\eta t}}{m + \epsilon \mu^*}} \right)$$

Similar to the proof of Proposition 3.2, we have

$$\begin{align*}
\frac{\epsilon}{\eta} \left( 1 + \frac{e^{\eta t (\eta + 1)}/r}{1 - e^{\eta t}/r} + \frac{m}{m + \epsilon \mu^*} \frac{e^{\eta t (\eta + 1)}/r}{1 - e^{\eta t}/r + \frac{e^{\eta t}}{m + \epsilon \mu^*}} \right) \rightarrow 0 \\
\frac{\epsilon}{\eta} \left( 1 - e^{\eta t (\eta + 1)}/r \right) \left( 1 + \frac{m}{m + \epsilon \mu^*} \frac{e^{\eta t (\eta + 1)}/r}{1 - e^{\eta t}/r + \frac{e^{\eta t}}{m + \epsilon \mu^*}} \right) \rightarrow 0
\end{align*}$$

Now, by using (31) in (30), we get

$$\mathbb{E} \left[ e^{\eta t \bar{q}_1^\tau} \right] \rightarrow \frac{e^{\eta t} - 1}{t} \Rightarrow \frac{\bar{q}^\eta_1}{\tau} \xrightarrow{D} \mathcal{U}[0, 1].$$

\[ \square \]

### F.2 Preliminaries: Single Server Queue

Similar to Proposition 4.2, we can show that if the functions \( \phi^\epsilon(\cdot), \phi^\tau(\cdot) \) satisfy Condition 5.2, then the single server queue is positive recurrent. We omit the details of this proof as it is intuitive and the steps are analogous to the proof of Proposition 4.2. To prove the theorem, we will first introduce the following notation: \( \bar{q}^\eta_1 \) is the random variable that has the same distribution as the stationary distribution of \( \{ \bar{q}^\eta_1(k) : k \in \mathbb{Z}_+ \} \) and \( \bar{q}^\eta_1^+ \) is the queue length one time epoch after \( \bar{q}^\eta_1 \). In addition, given the steady state queue length \( \bar{q}^\eta_1 \), let the arrival, potential service and unused service be denoted by \( \bar{a}^\eta_1, \bar{s}^\eta_1, \bar{a}^\eta_1 \) respectively. We omit the dependence of \( \bar{q}^\eta_1 \) on \( \bar{a}^\eta_1, \bar{s}^\eta_1, \bar{a}^\eta_1 \) for simplicity of notation. Thus, we have

$$\bar{q}^\eta_1^+ = \bar{q}^\eta_1 + \bar{a}^\eta_1 - \bar{s}^\eta_1 + \bar{a}^\eta_1.$$
F.3 Proof of Theorem 5.3: Case I

Proof of Theorem 5.3: \( \epsilon \tau \rightarrow 0 \). We will use the characteristic function of \( \bar{q}_\eta \) as the test function to prove the theorem. Firstly, note that

\[
\left( e^{\jmath \omega \bar{q}_\eta} - 1 \right) \left( e^{-\jmath \omega \bar{u}_\eta} - 1 \right) = 0
\]

as \( \bar{q}_\eta > 0 \) implies that \( \bar{u}_\eta = 0 \) and vice versa. Expanding the above expression and using the queue evolution equation results in

\[
e^{\jmath \omega \bar{q}_\eta} - e^{\jmath \omega (\bar{q}_\eta + \bar{a}_\eta - \bar{s}_\eta)} = 1 - e^{-\jmath \omega \bar{u}_\eta}.
\]

Now, by taking the expectation with respect to the stationary distribution of \( \{q(k) : k \in \mathbb{Z}_+ \} \) and noting that \( \mathbb{E} [\bar{q}_\eta] = \mathbb{E} [\bar{q}_\eta^+] \) by stationarity, we get

\[
\mathbb{E} \left[ e^{\jmath \omega \bar{q}_\eta} - e^{\jmath \omega (\bar{q}_\eta + \bar{a}_\eta - \bar{s}_\eta)} \right] = 1 - \mathbb{E} \left[ e^{-\jmath \omega \bar{u}_\eta} \right]. \tag{32}
\]

The LHS of the above equation can be simplified to get

\[
\mathbb{E} \left[ e^{\jmath \omega \bar{q}_\eta} - e^{\jmath \omega (\bar{q}_\eta + \bar{a}_\eta - \bar{s}_\eta)} \right] = \mathbb{E} \left[ e^{\jmath \omega \bar{q}_\eta} \left( 1 - e^{\jmath \omega (\bar{a}_\eta - \bar{s}_\eta)} \right) \right]
\]

\[
= \mathbb{E} \left[ e^{\jmath \omega \bar{q}_\eta} \left( -j \omega e (\bar{a}_\eta - \bar{s}_\eta) + \frac{\omega^2 e^2}{2} (\bar{a}_\eta - \bar{s}_\eta)^2 \right) \right] + o(\epsilon^2)
\]

\[
\overset{(a)}{=} \mathbb{E} \left[ e^{\jmath \omega \bar{q}_\eta} \left( -j \omega e (\bar{a}_\eta - \bar{s}_\eta) + \frac{\omega^2 e^2}{2} (\bar{a}_\eta - \bar{s}_\eta)^2 \right) \bar{q}_\eta \right] + o(\epsilon^2)
\]

\[
\overset{(b)}{=} \mathbb{E} \left[ e^{\jmath \omega \bar{q}_\eta} \left( -j \omega e (\bar{a}_\eta - \bar{s}_\eta) + \frac{\omega^2 e^2}{2} (\bar{a}_\eta - \bar{s}_\eta)^2 \right) \right] + o(\epsilon^2)
\]

\[
\overset{(c)}{=} \mathbb{E} \left[ e^{\jmath \omega \bar{q}_\eta} \left( j \omega e^2 \phi^s \left( \frac{\bar{q}_\eta}{\tau} \right) - \phi^c \left( \frac{\bar{q}_\eta}{\tau} \right) \right) + \frac{\omega^2 e^2}{2} (\sigma^c(\lambda(\bar{q}_\eta)) + \sigma^s(\mu(\bar{q}_\eta))) \right] + o(\epsilon^2), \tag{33}
\]

where \( (a) \) follows from Taylor’s theorem and the reader can refer to Lemma E.1 for precise argument. Next, \( (b) \) follows by the tower property of expectation and lastly, \( (c) \) follows by the definition of queue length dependent expectation and variance of \( \bar{a}_\eta \) and \( \bar{s}_\eta \).

Now, to simplify the RHS of (32), first consider \( \bar{q}_\eta \) as a test function and using \( \mathbb{E} \left[ \bar{q}_\eta^+ \right] = \mathbb{E} \left[ \bar{q}_\eta \right] \) will give us

\[
\mathbb{E} [\bar{u}_\eta] = \mathbb{E} [\bar{s}_\eta - \bar{a}_\eta] = \mathbb{E} \left[ \mathbb{E} [\bar{s}_\eta - \bar{a}_\eta|\bar{q}_\eta] \right] = \epsilon \mathbb{E} \left[ \phi^s \left( \frac{\bar{q}_\eta}{\tau} \right) - \phi^c \left( \frac{\bar{q}_\eta}{\tau} \right) \right]
\]

Now, we can simplify the RHS using Taylor’s theorem (Lemma E.1) to get

\[
1 - \mathbb{E} \left[ e^{-\jmath \omega \bar{u}_\eta} \right] = j \omega e \mathbb{E} \left[ \bar{u}_\eta \right] + o(\epsilon^2) = j \omega e^2 \mathbb{E} \left[ \phi^s \left( \frac{\bar{q}_\eta}{\tau} \right) - \phi^c \left( \frac{\bar{q}_\eta}{\tau} \right) \right] + o(\epsilon^2). \tag{34}
\]

Now, using (33) and (34), we get

\[
\mathbb{E} \left[ e^{\jmath \omega \bar{q}_\eta} \left( j \omega e^2 \left( \phi^s \left( \frac{\bar{q}_\eta}{\tau} \right) - \phi^c \left( \frac{\bar{q}_\eta}{\tau} \right) \right) \right) + \frac{\omega^2 e^2}{2} (\sigma^c(\lambda(\bar{q}_\eta)) + \sigma^s(\mu(\bar{q}_\eta))) \right] + o(\epsilon^2).
\]

\[
= j \omega e^2 \mathbb{E} \left[ \phi^s \left( \frac{\bar{q}_\eta}{\tau} \right) - \phi^c \left( \frac{\bar{q}_\eta}{\tau} \right) \right] + o(\epsilon^2). \tag{35}
\]
Dividing on both sides by $j\omega e^2$ and rearranging the terms, we get

$$
\frac{1 - \frac{j\omega}{2} (\sigma^c(\lambda^*) + \sigma^s(\mu^*))}{\mathbb{E} \left[ e^{j\omega \bar{q}_\eta} \right]} = \frac{\mathbb{E} \left[ \phi^s \left( \frac{\bar{q}_\eta}{\tau} \right) - \phi^c \left( \frac{\bar{q}_\eta}{\tau} \right) \right] - \mathbb{E} \left[ j\omega \bar{q}_\eta \left( \phi^s \left( \frac{\bar{q}_\eta}{\tau} \right) - \phi^c \left( \frac{\bar{q}_\eta}{\tau} \right) - 1 \right) \right]}{\mathbb{E} \left[ j\omega \bar{q}_\eta \left( \phi^s \left( \frac{\bar{q}_\eta}{\tau} \right) - \phi^c \left( \frac{\bar{q}_\eta}{\tau} \right) - 1 \right) \right]}
$$

The terms $T_6, T_9, T_{10}$ are analogous to the terms $T_3, T_4, T_5$ in the proof of Theorem 4.6. It can be similarly shown using Lemma 7.1 and the fact that $\phi^d(\infty) - \phi^e(\infty) = 1$ and $\bar{q}_\eta \geq 0$, we get $T_6 \to 1$, $T_9 \to 0$. In addition, by using Lemma 7.2, we get $T_{10} \to 0$. Thus, by taking the limit as $\eta \to \infty$, we get

$$
\mathbb{E} \left[ e^{j\omega \bar{q}_\eta} \right] = \frac{1}{1 - \frac{j\omega}{2} (\sigma^c(\lambda^*) + \sigma^s(\mu^*))}.
$$

This implies that $\epsilon \bar{q}_\eta$ converges to a random variable in distribution having exponential distribution with mean $0.5(\sigma^c(\lambda^*) + \sigma^s(\mu^*))$. \qed

### F.4 Proof of Theorem 5.3: Case II

**Proof of Theorem 5.3: $\epsilon \tau \to l$.** The first step is to show tightness of the family of random variables $\{\epsilon \bar{q}_\eta\}$ which can be proved similar to the proof of Lemma 6.1. We omit the details here for brevity. Now, the next step is to analyze the drift of the characteristic function of $\bar{q}_\eta$ and then obtain a functional equation by taking the limit as $\eta \to \infty$. Recall that by (35), we have

$$
\mathbb{E} \left[ e^{j\omega \bar{q}_\eta} \left( \phi^s \left( \frac{\bar{q}_\eta}{\tau} \right) - \phi^c \left( \frac{\bar{q}_\eta}{\tau} \right) \right) - \frac{j\omega}{2} \left( \sigma^c(\lambda(\bar{q}_\eta)) + \sigma^s(\mu(\bar{q}_\eta)) \right) \right] = \mathbb{E} \left[ \phi^s \left( \frac{\bar{q}_\eta}{\tau} \right) - \phi^c \left( \frac{\bar{q}_\eta}{\tau} \right) \right] + o(1).
$$

By taking the limit as $\eta \to \infty$ and following the steps same as in the proof of Claim 6.4, we get

$$
\mathbb{E} \left[ e^{j\omega \bar{q}_\infty} g(\bar{q}_\infty) \right] - j\omega \mathbb{E} \left[ e^{j\omega \bar{q}_\infty} \right] = \mathbb{E} \left[ g(\bar{q}_\infty) \right] \stackrel{\Delta}{=} C_1.
$$

Note that, this is same as the functional equation (10) if the RHS is zero. In particular, we get a non-zero RHS because of the unused service $\bar{u}_\eta$ which is responsible to ensure that the queue length is non negative. Now, we will write (36) as a differential equation in the space of tempered distribution which is analogous to taking the inverse Fourier transform. Define the following tempered distribution

$$
T_{\bar{q}_\infty}[\varphi] = \int_{\mathbb{R}} \varphi(x) dF_{\bar{q}_\infty}(x) = \mathbb{E} [\varphi] \quad \forall \varphi \in S(\mathbb{R}).
$$

Now, by using (23) and (24), the LHS of (36) can be written as follows:

$$
\mathbb{E} \left[ e^{j\omega \bar{q}_\infty} g(\bar{q}_\infty) \right] - j\omega \mathbb{E} \left[ e^{j\omega \bar{q}_\infty} \right] = -\sqrt{2\pi} T_{\bar{q}_\infty}[\varphi' + g\varphi].
$$
The RHS can be written in terms of the impulse distribution \( \delta(\cdot) \). In particular, denote the constant tempered distribution by \( \mathcal{T}_c \), i.e. \( \mathcal{T}_c[\varphi] = \int_{-\infty}^{\infty} \varphi(x)dx \). Then, we have

\[
\int_{-\infty}^{\infty} \varphi(x)dx = \mathcal{T}_c[\varphi] \overset{(a)}{=} \hat{\mathcal{T}}_c[\hat{\varphi}] \overset{(b)}{=} \delta[\hat{\varphi}],
\]

where (a) follows by [34, Definition 7.14] and (b) follows by [34, Example 7.16]. In particular, the Fourier transform of the constant tempered distribution is the impulse distribution. Thus, we can write (36) in terms of distribution functions as follows:

\[
\mathcal{T}_{\bar{q}}[\hat{\varphi}' + g\hat{\varphi}] = -\frac{C_1}{\sqrt{2\pi}} \delta[\hat{\varphi}] \quad \forall \varphi \in \mathcal{S}(\mathbb{R}).
\]

As Fourier transform is a bijection on \( \mathcal{S}(\mathbb{R}) \) [34, Theorem 7.7], the above is equivalent to

\[
\mathcal{T}_{\bar{z}}[\varphi'] - g\mathcal{T}_{\bar{z}}[\varphi] = -\frac{C_1}{\sqrt{2\pi}} \delta[\varphi] \quad \forall \varphi \in \mathcal{S}(\mathbb{R}).
\]

This can be written as the following differential equation in tempered distribution using the definition of derivative of a distribution given in [34, Section 6.12].

\[
\mathcal{T}_{\bar{z}}[\varphi] - g\mathcal{T}_{\bar{z}}[\varphi] = \frac{C_1}{\sqrt{2\pi}} \delta[\varphi] \quad \forall \varphi \in \mathcal{S}(\mathbb{R}).
\]

By [13, Theorem 4] [14, Theorem 3.9], we can directly write the entire solution of the above differential equation to be

\[
\mathcal{T}_{\bar{q}}[\varphi] = C \int_{-\infty}^{\infty} e^{-G(x)} \varphi(x)dx - \frac{C_1}{\sqrt{2\pi}} \delta \left[ e^{G(x)} \int_{-\infty}^{x} e^{-G(t)}(\varphi(t) - a_0\varphi_0(t))dt \right] \quad \forall \varphi \in \mathcal{S}(\mathbb{R})
\]

for any constant \( C \) and we have \( G(x) = \int_{0}^{x} g(t)dt, \int_{-\infty}^{\infty} \varphi_0(x) e^{-G(x)}dx = 1 \), and we have \( a_0 = \int_{-\infty}^{\infty} \varphi(x) e^{-G(x)}dx \). The steps to solve this differential equation is given in [14, Section IV B].

Now, the second term in the above equation can be simplified as follows:

\[
\delta \left[ e^{G(x)} \int_{-\infty}^{x} e^{-G(t)}(\varphi(t) - a_0\varphi_0(t))dt \right] \overset{(a)}{=} e^{G(0)} \int_{-\infty}^{0} e^{-G(t)}(\varphi(t) - a_0\varphi_0(t))dt \\
\overset{(b)}{=} \int_{-\infty}^{0} e^{-G(t)}(\varphi(t) - a_0\varphi_0(t))dt \\
\overset{(c)}{=} \int_{-\infty}^{0} e^{-G(t)} \varphi(t) - C_2 \int_{-\infty}^{\infty} \varphi(t) e^{-G(t)}dt,
\]

where (a) follows by the definition of impulse tempered distribution, (b) follows as \( G(0) = 0 \) by definition, and (c) follows by defining \( C_2 \equiv \int_{-\infty}^{0} e^{-G(t)} \varphi_0(t)dt \). Thus, we get

\[
\mathcal{T}_{\bar{q}}[\varphi] = \int_{-\infty}^{\infty} e^{-G(x)} \left( C - \frac{C_1 C_2}{\sqrt{2\pi}} - \frac{C_1}{\sqrt{2\pi}} \mathbb{1}\{x < 0\} \right) \varphi(x)dx
\]

By the definition of \( \mathcal{T}_{\bar{q}} \), we conclude that \( \bar{q} \) has density

\[
\rho_{\bar{q}}(x) = e^{-G(x)} \left( C + \frac{C_1 C_2}{\sqrt{2\pi}} - \frac{C_1}{\sqrt{2\pi}} \mathbb{1}\{x < 0\} \right).
\]
By the definition of $q_{\infty}$, we will first impose the condition that $\rho q_{\infty}(x) = 0$ for all $x < 0$ which implies that $C_1 = \sqrt{2\pi}C/(1 - C_2)$. This gives us

$$\rho q_{\infty}(x) = \frac{C}{1 - C_2}e^{-G(x)} \mathbb{1}\{x \geq 0\}.$$  

Now, we impose the condition that $\int_{-\infty}^{\infty} \rho q_{\infty}(x) dx = 1$ which implies that $C/(1 - C_2) = \int_0^{\infty} e^{-G(x)} dx$. This gives us

$$\rho q_{\infty}(x) = \frac{1}{\int_0^{\infty} e^{-G(t)} dt} e^{-G(x)} \mathbb{1}\{x \geq 0\}.$$  

Now, we need to verify that the above is indeed a solution of (36) which is omitted as this part of the proof is similar to the proof of Theorem 4.4. This completes the proof. □
