Recent experiments on mucociliary clearance, an important defense against airborne pathogens, have raised questions about the topology of 2D flows. We introduce a framework for studying ensembles of 2D time-invariant flow fields and estimating the probability for a particle to leave a finite area (to clear out). We establish two upper bounds on this probability by leveraging different insights about the distribution of flow velocities on the closed and open streamlines. We also deduce an exact power-series expression for the trapped area based on the asymptotic dynamics of flow-field trajectories and complement our analytical results with numerical simulations.

Understanding the topology of two-dimensional flows is also essential for important biological applications. For instance, one key biophysical mechanism employed in the body’s defense to respiratory pathogens is mucociliary clearance [8]. In humans and many other animals, the airway is covered by a thin, quasi-2D layer of mucus, which acts as a barrier to airborne pathogens. This mucus layer is actively ‘cleared’ by a layer of ciliated cells. The beating of these cells generates a quasi-static two-dimensional flow field in the mucus. This flow is directed [9], but exhibits significant spatial structure due to the disordered arrangement of ciliated cells [10] and the properties of the beating itself [12, 13]. It has been shown that an increased disorder in this system is associated with pathological outcomes in humans [10]. Recent work by Ramirez-San Juan et al. [14] has investigated the characteristics of disordered flows in the airway system. These authors show that the proportion of closed streamlines in the flow negatively impacted the ability to clear viral particles, which became ‘trapped’ in their orbits rather than being advected out of the system. Providing a precise characterization of the statistics of trapping in 2D flow may bring clarity about the magnitude of this effect. This might provide insight into the pathologies caused by increasing trapping.

There is a strong connection between the study of random flows and the study of magnetic fields in disordered materials. The zero-divergence condition present in both incompressible flows (due mass conservation) and magnetic fields (due to the absence of magnetic monopoles) means that the formal techniques used for one problem often also work for the other. In this context, the problem of identifying the trapped area in a magnetic field is closely related to certain variations of the Hall effect [15–17]. Electrons moving in a disordered material tend to follow magnetic field lines. As magnetic bias is provided, more and more streamlines become open, leading to a non-zero net flow. Isichenko [15] studied the proportion of topologically open versus topologically closed streamlines in a biased magnetic field as a function of the order parameter $\gamma$, given by the ratio of the average field magnitude to the standard deviation. According to [15], the critical point is $\gamma = 0$, and near this point the fraction $a$ of the area inside closed streamlines (the ‘trapped area’) scales as $1 - a \propto \gamma^{4/7}$. The scaling exponent is related to the known exponents of percolation theory [3, 15, 18–20]. This analysis, however, leaves open the question of the scaling behavior of $a$ in other regimes, particularly including the biologically relevant near-ordered behavior where $\gamma \to \infty$.

In this paper we develop novel theoretical insights about the the statistical topology of random streamlines in 2D biased random fluid flow (or magnetic field) for the full range of the order parameter $\gamma$. We first consider properties that are independent of the specific ensemble of flow fields, and identify a general upper bound on the trapped area, based on considerations about the expected value and variance of the velocity on open and closed streamlines. These insights are then extended to a more specific result, leading to an exact expression for the trapped area fraction $a$ in terms of the variance in the asymptotic displacement of the flow field. We then derive a formal power series for this quantity in terms
Thus, mean velocity in any trapped area is zero. Since the global mean velocity is $\mu \hat{v}_0$, the mean velocity on the remaining $1 - a$ fraction of the area must be $\mu \hat{v}_0/(1-a)$.

Let $A$ be the set of points on closed streamlines. We can now decompose the velocity as follows:

$$
\hat{v}(x) = \frac{\mu \hat{v}_0}{1-a} I[x \notin A] + \nu(x) I[x \in A]
$$

(1)

(2)

where $I(B)$ is the indicator function of set $B$.

Each of these terms represents a random variable with respect to the sampling of $x$, with the first representing a Bernoulli random variable with the probability $a$ and magnitude $\mu \hat{v}_0/(1 - a)$, and the second two representing zero-mean random variables. Taking the variance of the velocity magnitude over space $\sigma^2 = \langle v \cdot v \rangle - \mu^2$, we get

$$
\sigma^2 = \frac{\mu^2 a}{1-a} + a\sigma^2 + (1-a)\sigma^2,\quad (3)
$$

where $\sigma^2_A$ and $\sigma^2_A$ represent the conditional variances of velocity in the trapped and the escaping areas respectively. The last two terms are strictly positive, yielding the inequality $\sigma^2 \geq \frac{\mu^2 a}{1-a}$. Rearranging yields the following bound:

$$
a \leq \frac{1}{1+\gamma^2},\quad (4)
$$

where $\gamma = \mu/\sigma$ is the dimensionless parameter that quantifies the ratio of ‘order’ to ‘disorder’ of the velocity field.

An exact expression for the trapped area Consider a zero-mean flow ensemble from which we draw a divergence-free 2D vector field $v_1$, and a constant vector $\mu \hat{v}_0$, which we add to our zero-mean field $v_1$ to produce a biased random flow field $v$. We will denote by $\varphi_t$ the flow map induced by this field, and by $\Phi = \Phi_1 + \mu \hat{v}_0 \cdot x$ the streamfunction associated with the flow. Here the operator $R_{\pi/2}$ means a rotation by $\pi/2$. The central question we will be interested in is the following: how does the percentage of trapped area $a$ (i.e., the area that does not lie on an open, ‘escaping’ trajectory) change as the magnitude of the mean velocity $\mu$ increases?

We can leverage a relatively simple insight to obtain an upper bound on the trapped area. Consider a closed orbit $\partial B$ of the velocity, which represents the boundary of a trapped region $B$. The mean velocity in this area is

$$
\int_B v \, d^2x = R_{\pi/2} \int_B \nabla \Phi \, d^2x,\quad (1)
$$

Since $\partial B$ is a closed orbit and thus a level set of $\Phi$, it follows that the mean value of the gradient $\nabla \Phi$ in $B$ is zero. Thus, mean velocity in any trapped area is zero.

By symmetry, the mean velocity in the escaping area is $\hat{v}_0$

where $\gamma = \mu/\sigma$ is the dimensionless parameter that quantifies the ratio of ‘order’ to ‘disorder’ of the velocity field.

An exact expression for the trapped area Consider a zero-mean flow ensemble from which we draw a divergence-free 2D vector field $v_1$, and a constant vector $\mu \hat{v}_0$, which we add to our zero-mean field $v_1$ to produce a biased random flow field $v$. We will denote by $\varphi_t$ the flow map induced by this field, and by $\Phi = \Phi_1 + \mu \hat{v}_0 \cdot x$ the streamfunction associated with the flow. Here the operator $R_{\pi/2}$ means a rotation by $\pi/2$. The central question we will be interested in is the following: how does the percentage of trapped area $a$ (i.e., the area that does not lie on an open, ‘escaping’ trajectory) change as the magnitude of the mean velocity $\mu$ increases?

We can leverage a relatively simple insight to obtain an upper bound on the trapped area. Consider a closed orbit $\partial B$ of the velocity, which represents the boundary of a trapped region $B$. The mean velocity in this area is

$$
\int_B v \, d^2x = R_{\pi/2} \int_B \nabla \Phi \, d^2x,\quad (1)
$$

Since $\partial B$ is a closed orbit and thus a level set of $\Phi$, it follows that the mean value of the gradient $\nabla \Phi$ in $B$ is zero. Thus, mean velocity in any trapped area is zero.

By symmetry, the mean velocity in the escaping area is $\hat{v}_0$.
where $\kappa = \lim_{t \to \infty} \langle \mathbf{d}_t \cdot \mathbf{d}_t \rangle / t^2 - \mu^2$. Thus, if we can compute $\kappa$, we can compute the trapped area.

To get a handle on this expression, we can take the Taylor expansion of the displacement:

$$
\mathbf{d}_t(x) = \sum_{n=1}^{\infty} \frac{t^n}{n!} \mathbf{d}_n(x) = \sum_{n=1}^{\infty} \frac{t^n}{n!} (\mathbf{v} \cdot \nabla)^{n-1} \mathbf{v}.
$$

(7)

Subsequently we have

$$
\langle \mathbf{d}_t \cdot \mathbf{d}_t \rangle = \sum_{n=1}^{\infty} \sum_{m=1}^{\infty} \frac{t^{n+m}}{n!m!} (\mathbf{K}_v^{n-1} \cdot \mathbf{K}_v^{m-1} \mathbf{v}),
$$

(8)

where $\mathbf{K}_v := \mathbf{v} \cdot \nabla$. The objects $(\mathbf{K}_v^{n-1} \cdot \mathbf{K}_v^{m-1} \mathbf{v})$ are of fundamental interest for determining the trapped area. Note that $\mathbf{K}_v^* = -\mathbf{K}_v$ (the flow operator is unitary as it preserves the Lebesgue measure; therefore, its generator $\mathbf{K}_v$ must be anti-Hermitian). We have, therefore,

$$
\langle \mathbf{K}_v^{n-1} \cdot \mathbf{K}_v^{m-1} \mathbf{v} \rangle = (-1)^{n-1} \langle \mathbf{v}, \mathbf{K}_v^{n+m-2} \mathbf{v} \rangle.
$$

(9)

Hence,

$$
\langle \mathbf{d}_t \cdot \mathbf{d}_t \rangle = \sum_{n=2}^{\infty} \frac{t^n}{n!} (\mathbf{v} \cdot \mathbf{K}_v^{n-2} \mathbf{v}) \sum_{m=1}^{n-1} (-1)^{m-1} \left( \frac{n}{m} \right)

= \sum_{n=0}^{\infty} \frac{2t^{2n+2}}{(2n+2)!} (\mathbf{v} \cdot \mathbf{K}_v^{2n} \mathbf{v}).
$$

(10)

Note that when we take the time-average of $\langle \mathbf{d}_t \cdot \mathbf{d}_t \rangle / t^2$, the flow of time becomes equivalent to a rescaling transformation, since $\mathbf{K}_v$ is a covariant operator, and the coefficient in front of the term involving $\mathbf{K}_v^{2n}$ is $t^{2n}$. This suggests the possibility of a renormalization-type analysis for the trapped area.

Evaluating the series above for a generic flow ensemble is difficult. One flavor of this difficulty is discussed in Appendix A where we present an initial sketch of the calculations required for a particular Gaussian ensemble. Evaluating each term often requires a combinatorial expansion that becomes intractably difficult as the order of the terms increases; and, even in cases where simplifications arise, we have no guarantee that the resultant expressions will lend themselves to the kind of asymptotic analysis required to derive the trapped area.

**An upper bound on the trapped area for the Gaussian ensemble** While we have an upper bound on the trapped area in the form $\alpha \leq 1/(1 + \gamma^2)$ from simple considerations about the variance of the velocity, we can obtain an improved bound by using a different approach. This new bound leverages the simple insight that $\langle \mathbf{v}(x) \rangle_{x \in A} = 0$.

Since $A$ is a set with zero expected velocity, its area fraction $\alpha$ must be no larger than the area fraction of the maximal set $S$ such that $\langle \mathbf{v}(x) \rangle_{x \in S} = 0$. We will define this area fraction as $s$, and write our bound as $s \geq \alpha$.

Consider the case of a flow field $\mathbf{v}$ generated by a Gaussian process. Note that, for a velocity component $v_x \sim p$ with a positive expected value, the largest subset we can achieve with zero expected velocity is given by selecting all values of $v_x \leq k$ for some $k$ such that $\int_0^k v_x p(v_x) \, dv_x = 0$. The fraction of the total area belonging to this subset is then given by the value of the CDF at $k$, i.e., $\int_0^k p(v_x) \, dv_x$. In our case, the component of the velocity aligned with $\mathbf{e}_0$ is distributed according to $v \sim \mathcal{N}(\mu, \sigma/\sqrt{2})$, so we have the conditions

$$
0 = \int_{-\infty}^k v \exp \left( -\frac{(v-\mu)^2}{\sigma^2} \right) \, dv

= \sqrt{\pi} \mu \left( \text{erf} \left( \frac{k - \mu}{\sigma} \right) + 1 \right) - \sigma e^{-k^2/\sigma^2},
$$

(11)

In terms of $k$ we can write $s$ as

$$
s = \int \frac{1}{2} \left[ 1 + \text{erf} \left( \frac{k - \mu}{\sigma} \right) \right].
$$

(12)

Solving these equations numerically for $s$ gives us an upper bound on $a$ for the Gaussian ensembles. In Appendix B we show that this bound goes as $O(\gamma^{-1} e^{-\gamma})$ when $\gamma \to \infty$. If we find ourselves in possession of a convenient expression for the CDF of another ensemble, we can apply similar reasoning derive an upper bound for the trapped area in that ensemble.

This analysis also reveals a procedure for generating progressively tighter bounds on $a$. $A$ is defined to be precisely the set where the expected displacement is zero for all values of $t$. This entails that each derivative $\partial^r_n \mathbf{d}_t(x) = [\mathbf{v} \cdot \nabla]^n \mathbf{v}$ is zero. If we can identify the marginal distribution for each derivative or, better, the joint distribution between all derivatives, we can follow a similar argument to identify the largest set that has zero expected value for each derivative considered.

**Numerical results** In order to investigate the trapped area numerically, we start by generating values of $\gamma$ uniformly spaced in a logarithmic scale in the range $10^{-2} \leq \gamma \leq 4$. Subsequently, for each $\gamma$, we initialize 1000 random zero-mean streamfunctions, compute the value of $\mu$ associated with their variance, and generate a velocity field by combining the streamfunction gradient and the mean velocity. For each streamfunction we then integrate the trajectory that the point $\mathbf{x}_0 = (0,0)$ takes under this velocity field over a time range of $t = 600$. We then determine whether each trajectory is open or closed by examining whether the closest distance it approaches to the origin at large times exceeds a critical threshold, in which case we classify it as an open trajectory, and otherwise consider it closed. The proportion of closed trajectories out of the 1000 samples becomes our estimate for the trapped area for each value of $\gamma$.

In order to generate our streamfunctions, we note that, in the infinite-size limit, a stationary Gaussian process can be characterized exactly by its power spectral density. That process can, therefore, be sampled by choosing a random phase for each wavevector. We employ unbiased streamfunction of the form

$$
\Phi_1(x) = \sum_{|k| \leq 150} \exp \left( \frac{k^2}{2\lambda^2} \right) \cos \left( \frac{2\pi}{L} k \cdot \mathbf{x} - \phi_k \right),
$$

(13)
where $\lambda$ is a correlation-length parameter and $L$ is a parameter that picks the maximum wavelength that enters into the streamfunction. This approach approximates sampling a streamfunction with an RBF covariance kernel in the large-size limit. Each phase offset $\phi_k$ is sampled uniformly from the interval $[0, 2\pi]$. In this work, we choose $L = 5$ and $\lambda = 10$. This approach to sampling a streamfunction, as opposed to directly sampling a Gaussian process on a lattice, is beneficial because a) it is computationally efficient relative to direct sampling, which for an $N \times N$ lattice requires computing the Cholesky decomposition of a covariance matrix of size $N^2 \times N^2$ [an $O(N^6)$ operation]; b) it avoids discretization issues that could occur when integrating a trajectory derived from a velocity field sampled on a lattice; and c) it can be naturally extended to an arbitrary distance from the origin, which allows us to ignore boundary issues at the lattice edge. This approach, however, suffers from the potential drawback that it does not fully capture the statistics of the Gaussian process outside of the bandwidth used for sampling, which means that it is inapplicable for very small $\gamma$ (when the average loop size becomes smaller than the minimum wavelength) and for very large $\gamma$ (when the average loop size exceeds the finite system size). In practice, see below, we find that a large range of $a$ can be accessed for $\gamma$ that avoid these limits.

We first examine the scaling of the trapped area in the critical ($\gamma \to 0$) regime in Fig. 2 which is expected to follow the law $1 - a \propto \gamma^c$, with $c = 4/7$ [15]. In the $\gamma \leq 0.3$ range, we find a best-fit exponent of $c = 0.553(13)$, compatible with the value $c = 4/7 \approx 0.571$. For larger $\gamma$, however, the trapped area strongly deviates from this behavior. Indeed, as discussed above and in Appendix B in the $\gamma \to \infty$ limit, the trapped area is bounded by $a \leq e^{-\gamma^2}/(2\gamma\sqrt{\pi})$. Between these two limiting behaviors, we find empirically that there is a very robust exponential dependence of the form $a \approx \exp(-d\gamma)$, with a best-fit value of $d = 2.84(4)$, which we illustrate in Figure 3.

While there are no evident analytical simplifications that would allow us to predict this behavior directly, we note that intuitively this scaling means that the rate of decrease of a given trapped region as $\gamma$ increases is roughly proportional to the area contained inside. In short, the trapped area is effectively described by an exponential dependence on $\gamma$ for a wide range.

In this paper we have discussed the problem of determining the fraction of the ‘trapped area’, i.e., the area of topologically closed trajectories, for random two-dimensional flow fields. We introduce several techniques that lead both to a general upper bound for a broad class of flow ensembles and to a specific upper bound for Gaussian flow fields. We also derive a power-series expression for the trapped area using asymptotic analysis of the displacement variance under the flow map. Finally, we compute the trapped area numerically for a Gaussian flow field and find that beyond the critical regime it is well approximated by an exponential.

In addition to providing theoretical insights for the features of interest in two-dimensional flows, this work has a number of broader implications. First, we expect that the techniques introduced in this paper could be extended to allow an estimation or even an exact computation of other topological features of fluid flows, potentially even...
in higher-dimensional regimes. Second, in some applications of fluid flows and their close cousins, magnetic fields, the topology of orbits plays a crucial role in the overall behavior of the system. The orbit topology in magnetic materials has been related to certain electrical properties and to the Hall effect [15] [16]. Orbit topology has implications for the behavior of ciliated flows in biological systems, ranging from mucosal transport in the airway to the feeding of starfish larvae [14] [22] [24].

Being able to compute the proportion of area trapped in closed streamlines will enable analytical investigations into the fundamental principles and tradeoffs underlying these systems. In particular, this analysis may have significant implications for understanding the progress of infections in the airway, where areas of trapped flow provide a foothold for viral infections [14, 25].

Appendix A: Analyzing the series

We can express the term \( \langle v, K_2^n v \rangle \) using Einstein notation:

\[
\langle v, K_2^n v \rangle = v_i \cdots v_i \delta_i [v^k \partial_h [\partial_j v^l]].
\]  

(A1)

To evaluate these terms we need to sum over all ways to distribute the derivatives across each term. We can illustrate this symbolically as follows:

\[
\begin{vmatrix}
\cdots & v^1 & v^k & v^i \\
\partial_j & \partial_k & \partial_l & \partial_m \\
\partial_l & \partial_l & \partial_l & \partial_l \\
\partial_m & \partial_m & \partial_m & \partial_m \\
\vdots & \vdots & \vdots & \vdots
\end{vmatrix}
\]

(A2)

We then sum over each allowed choice of placement for each derivative term. We also note that \( v = R_{s/2} \nabla \Phi \) (or equivalently \( v^i = (-1)^i \partial_1 \cdots \partial_i \Phi \)), so we can ultimately express the entire term using derivatives of the n-point correlation function for \( \Phi \) at the origin. E.g.:

\[
\langle v_i v^k \partial_k v^j \partial_j v^l \rangle = (-1)^{j+k} \frac{\partial}{\partial w_{1-i}} \frac{\partial}{\partial y_{z-1-k}} \frac{\partial}{\partial y_{1-j}} \frac{\partial}{\partial x_{x-1-i}} C^4(w, z, y, x) \bigg|_{x, y, z, w = 0},
\]

(A3)

where

\[
C^n(w, x, y, z, \cdots) = \langle \Phi(w) \Phi(x) \Phi(y) \Phi(z) \cdots \rangle.
\]

(A4)

In order to proceed further we will need to get a handle on the correlation function. When \( \mu = 0 \), we can employ Wick’s theorem to express the even-order correlation functions as a sum over products of second-order correlations:

\[
C_{2n} = \prod_{i=1}^{n} \langle \Phi(x_{2i-1}) \Phi(x_{2i}) \rangle + \text{other pairings}
\]

(A5)

When \( \mu \neq 0 \), we can write \( C^n = \langle \Phi_1(x) + \mu R_{\pi/2} \hat{v}_0 \cdot x \rangle \langle \Phi_2(y) + \mu R_{\pi/2} \hat{v}_0 \cdot y \rangle \cdots \rangle \). Distributing terms gives

\[
C_{2n} = \sum_{S \in V} C_{0}^{2n-|S|} (V - S) \prod_{x \in S} (\mu R_{\pi/2} \hat{v}_0 \cdot x)
\]

(A6)

where \( V = \{x_1, \cdots, x_{2n}\} \) and \( C_{0}^{n} \) refers to the n-point correlation function for the unbiased streamfunction. To proceed further, we will have to posit a form for the unbiased two-point correlation function. We will choose the form

\[
C(x, y) = \frac{\lambda^2 \sigma^2}{2} \exp \left( -\frac{||x - y||^2}{2\lambda^2} \right)
\]

(A7)

where \( \lambda \) is the characteristic length. This choice ensures that \( \langle v \cdot v \rangle = Tr[\nabla_x \nabla_y C(0,0)] = \sigma^2 \). What happens when we differentiate this at the origin? The 2kth derivative of the Gaussian \( \exp(-\lambda^2 x^2/2) \) at the origin is \( (2k)!(-1)^k / ((2\lambda^2)^k k!) \), while all odd derivatives are zero.

Now we consider evaluating a term with a specific arrangement of auxiliary derivatives. We can categorize each such term using a list of tuples \( (a_i, b_i) \) for \( i = 1, \cdots, 2n + 2 \), where the tuple \( (a_i, b_i) \) indicates that the operator

\[
\frac{\partial^{a_i}}{\partial x_0^{a_0}} \frac{\partial^{b_i}}{\partial x_1^{b_1}}
\]

is applied to the ith argument. We then pair each argument with another, apply the respective derivatives to the two-point correlation function associated with the paired arguments, take the product of all the results, and
We will define $Q$ are in the various exponentials. Rewriting the first equation

\[ (-1)^{a_i-a_j+(b_i-b_j)} \frac{\lambda^2 \sigma^2}{2} \frac{2(a_i + a_j)!}{(a_i + b_i)! (b_i + b_j)!} \frac{2(b_i + b_j)!}{(a_i + a_j + b_i + b_j)!} \frac{1}{2} = Q. \]

Eq. (A8) assumes that $a_i + a_j$ and $b_i + b_j$ are even; otherwise the result is 0. We see that the parity associated with the overall order of the derivatives and the parity associated with the pairing of arguments for each component cancel out. If the pairing is specifically $(0,1), (0,1)$, the result from the deterministic component is $\mu^2$ (we assume without loss of generality that $v_0 = \hat{x}$), and otherwise the deterministic component contributes nothing.

How do we carry out this sum over pairings and over derivative arrangements? The authors of this paper were unable to satisfactorily answer this question, so we leave this as an exercise to the reader.

**Appendix B: Asymptotic scaling of the expectation bound**

The equations that determine the expectation bound are

\[ 0 = \sqrt{\pi} \left[ \text{erf} \left( \frac{k - \mu}{\sigma} \right) + 1 \right] - \gamma^{-1} e^{-(k-\mu)^2/\sigma^2}, \quad (B1) \]

\[ s = \frac{1}{2} \left[ 1 + \text{erf} \left( \frac{k - \mu}{\sigma} \right) \right]. \quad (B2) \]

We will define $Q = \frac{k - \mu}{\sigma}$ to be the negative argument in the various exponentials. Rewriting the first equation

\[ e^{-Q^2} \]

gives

\[ \gamma = \frac{e^{-Q^2}}{\sqrt{\pi} (\text{erf}(-Q) + 1)}. \quad (B3) \]

For large $Q$, $\text{erf}(-Q) \sim \frac{e^{-Q^2}}{\sqrt{\pi} Q^2} - 1$, so this expression reduces to

\[ \gamma \sim \frac{e^{-Q^2}}{\sqrt{\pi} Q^2} = Q. \quad (B4) \]

Substituting this into our relation for $s$ gives the asymptotic behavior of the bound:

\[ s \sim \frac{e^{-\gamma^2}}{2\gamma\sqrt{\pi}}. \quad (B5) \]

We actually consider a sum of two exponentials, $a = A_1 e^{-\gamma d_1} + A_2 e^{d_2 \gamma}$. This effective function fits all of our data up to $\gamma \approx 2$.
