Abstract

We introduce vector optimization problems with stochastic bandit feedback, which extends the best arm identification problem to vector-valued rewards. We consider $K$ designs, with multi-dimensional mean reward vectors, which are partially ordered according to a polyhedral ordering cone $C$. This generalizes the concept of Pareto set in multi-objective optimization and allows different sets of preferences of decision-makers to be encoded by $C$. Different than prior work, we define approximations of the Pareto set based on direction-free covering and gap notions. We study the setting where an evaluation of each design yields a noisy observation of the mean reward vector. Under subgaussian noise assumption, we investigate the sample complexity of the naïve elimination algorithm in an $(\epsilon,\delta)$-PAC setting, where the goal is to identify an $(\epsilon,\delta)$-PAC Pareto set with the minimum number of design evaluations. In particular, we identify cone-dependent geometric conditions on the deviations of empirical reward vectors from their mean under which the Pareto front can be approximated accurately. We run experiments to verify our theoretical results and illustrate how $C$ and sampling budget affect the Pareto set, returned $(\epsilon,\delta)$-PAC Pareto set and the success of identification.

1 INTRODUCTION

Motivation Pure exploration problems have attracted significant interest from both machine learning theorists and practitioners [Even-Dar et al. 2006; Bubeck et al. 2009; Audibert et al. 2010; Karnin et al. 2013]. The simplest pure exploration problem takes the form of a $K$-armed bandit with arm means $\mu_1, \ldots, \mu_K \in \mathbb{R}$, in which the learner aims to identify an optimal arm (aka design) by sequential experimentation under noisy feedback. In this setup, a noisy scalar reward is revealed to the learner immediately after the selection of a design. As experimentation consumes resources, the learner seeks to minimize the number of evaluations by adapting its arm selection based on past reward observations. This problem has been formalized in many different ways, with notable examples including $(\epsilon,\delta)$-probably approximately correct (PAC) [Even-Dar et al. 2006], fixed confidence and fixed budget [Karnin et al. 2013] best arm identification. Almost all research in this field focuses on devising sample-efficient algorithms that “beat the noise” by adaptive sampling and elimination. Algorithmic contributions include a plethora of techniques including Median Elimination [Even-Dar et al. 2006], Sequential Halving [Karnin et al. 2013], Track-and-Stop [Garivier and Kaufmann 2016], ABA [Hassidim et al. 2020], and many others. The difficulty of the problem depends on the suboptimality gap of each arm $i$, straightforwardly found as $\max_j \mu_j - \mu_i$. Without the noise, everything turns into a simple argmax operation over the design set.

Unfortunately, not many real-world problems naturally exhibit scalar rewards. Optimization of multi-dimensional performance metrics is necessary for tasks such as hardware design [Zuluaga et al. 2016] and clinical trials for drug development and dose identification [Lizotte and Laber 2016]. Nevertheless, vector-valued objectives $\mu_i$ can be scalarized by weights $w$ that encode the importance of each objective, turning the learning problem into a scalar one. The choice of $w$ is often left to the practitioner, and the right choice might be difficult to come up with.

To tackle this issue, another strand of literature focuses on identifying the set $P^*$ of Pareto optimal designs, whose mean vectors $\mu_i$ are not dominated by others’ mean vectors. In particular, for 2-dimensional vectors, $\mu_i = (\mu_{i1}, \mu_{i2})^T$ is dominated by $\mu_j = (\mu_{j1}, \mu_{j2})^T$
(\mu_i \preceq \mu_j) if and only if
\forall w \in [0,1]: w\mu_i^1 + (1-w)\mu_i^2 \leq w\mu_j^1 + (1-w)\mu_j^2,

which is equivalent to the usual componentwise order on \mathbb{R}^2. This multi-objective optimization problem has been extensively studied in the pure exploration setting with stochastic bandit feedback. Auer et al. (2016) study the sample complexity of Pareto set identification in stochastic K-armed bandit problem. Hernández-Lobato et al. (2016); Shah and Ghahramani (2016); Zhuanga et al. (2016) study Pareto set identification in problems with large design sets. They use Gaussian processes to capture correlations between designs such that a bulk of designs can be explored by a single sample.

While the multi-objective optimization viewpoint saves the practitioner from choosing \textbf{w}, it ends up returning a large set of designs (see, e.g., \textit{P}_{\pi/2}^* in Figure 1), which might be even more frustrating. Moreover, the practitioners may want to narrow down the set of alternatives by using their domain knowledge about the relative importance of each objective. For instance, if the practitioner wants to give at least \((100 \times \alpha)\)% relative importance to each objective for \(\alpha \in (0,0.5)\), then this can be achieved by defining a new partial order \(\preceq_{C'}\) with \(\mu_i \preceq_{C'} \mu_j\) if and only if
\forall w \in [\alpha,1-\alpha]: w\mu_i^1 + (1-w)\mu_i^2 \leq w\mu_j^1 + (1-w)\mu_j^2.

This is equivalent to a partial order induced by the cone \(C' = \{x \in \mathbb{R}^2 \mid \alpha x_1 + (1-\alpha)x_2 \geq 0,(1-\alpha)x_1 + \alpha x_2 \geq 0\}\) (see Figure 2 for examples of ordering cones in \(\mathbb{R}^2\), and Definition 3 for the precise definition of this order). Such a choice usually narrows down the set of Pareto optimal designs (see, e.g., \(P_{\pi/4}^*\) in Figure 1). In addition, the specification of the relative importance of each objective leads to a wide spectrum of Pareto optimal solutions that cannot be captured by multi-objective optimization.

**Contributions** The subfield of mathematical optimization which generalizes scalar and multi-objective optimization via partial orders induced by cones is called vector optimization (Jahn 2011, Löhne 2011). To the best of our knowledge, our work is the first to consider vector optimization within the stochastic K-armed bandit framework. In particular, we investigate the learnability of the Pareto optimal set under noisy observations for partial orders in \(\mathbb{R}^D\) induced by polyhedral ordering cones.

Our main contribution is to characterize the learning difficulty of a vector optimization problem by identifying fundamental gaps associated with the geometric properties of the ordering cone \(C\). When mean vectors are known, these gaps can be calculated by solving convex optimization problems involving quadratic and affine functions. Unlike prior works such as Auer et al. (2016), which define gaps based on specific directions (e.g., in the diagonal direction), we propose a natural, direction-free gap notion. We rely on the interpretation of the ordering cone as the set of all directions of improvement, and define two gaps between designs \(i, j\): \(m(i,j)\) as the minimum step-length in an arbitrary direction of improvement for \(i\) that is sufficient to avoid \(i\) being dominated by \(j\), \(M(i,j)\) as the
minimum step-length in an arbitrary direction of improvement for \( j \) that is sufficient to make \( j \) dominate \( i \). For the special case of multi-objective problems, while \( m(i, j) \) coincides with its analogue in \cite{Auer2016}, the analogue of \( M(i, j) \) in \cite{Auer2016} gives (much) higher values since the improvement is restricted to the diagonal direction. Hence, our definition of \( M(i, j) \) provides a more flexible gap calculation even in the multi-objective case. Instead of trying to identify all Pareto optimal points, we introduce a direction-free, cone-dependent \( \epsilon \)-covering requirement for the Pareto set. Based on this, we define the \((\epsilon, \delta)\)-PAC Pareto set identification problem. In the algorithmic side, we take a first step towards Pareto set identification by proposing a naïve elimination algorithm. In particular, we perform sample complexity analysis under the general norm-subgaussian noise assumption. We show that our algorithm successfully identifies an \((\epsilon, \delta)\)-PAC Pareto set with a sample complexity of \( O((K/\epsilon^2) \log(DK^2/\delta)) \). In addition, we provide numerical results for parametrized polyhedral cones, and establish a connection between the success rate of Pareto set identification and the angular width of the cone.

### 2 PRELIMINARIES

In this section, we fix the notation for the rest of the paper and recall some important definitions related to vector optimization. Let \( D \) be a positive integer. We write \([D] := \{1, \ldots, D\} \) and denote by \( \mathbb{R}^D \) the \( D \)-dimensional Euclidean space. The elements of \( \mathbb{R}^D \) are denoted by boldface letters. For a vector \( v \in \mathbb{R}^D \), \( \|v\|_2 \) represents its \( \ell_2 \) norm. For subsets \( A, A' \subseteq \mathbb{R}^D \), \( A \cup A' \) and \( A - A' \) denote their Minkowski sum and difference, respectively; \( \text{cl}(A) \), \( \text{int}(A) \), \( \text{bd}(A) \), \( A^c \) denote the closure, interior, boundary, and complement of \( A \subseteq \mathbb{R}^D \), respectively. For vectors \( v = (v^1, \ldots, v^D)^T \in \mathbb{R}^D \), we write \( v^+ := ((v^1)^+, \ldots, (v^D)^+)^T \) and \( v^- := ((v^1)^-, \ldots, (v^D)^-)^T \), where \( r^+ := \max\{0, r\} \) and \( r^- := -\min\{0, r\} \) for \( r \in \mathbb{R} \). For \( v \in \mathbb{R}^D \) and \( r \geq 0 \), \( B(v, r) \) represents the ball in \( \mathbb{R}^D \) with center \( v \) and radius \( r \). The distance of a vector \( v \in \mathbb{R}^D \) to a set \( A \subseteq \mathbb{R}^D \) is defined as \( d(v, A) := \inf_{x \in A} \|v - x\|_2 \).

We consider a vector optimization problem with \( D \) objectives and a finite set \([K]\) of designs, where \( D, K \) are positive integers. The mean vector of design \( i \in [K]\) is denoted by \( \mu_i = (\mu^1_i, \ldots, \mu^K_i)^T \in \mathbb{R}^D \). To compare mean vectors, we will introduce a partial order on \( \mathbb{R}^D \) based on an ordering cone. The latter notion is recalled next.

**Definition 1.** A set \( C \subseteq \mathbb{R}^D \) is called a cone if \( \lambda v \in C \) for every \( v \in C \) and \( \lambda \geq 0 \). A cone \( C \) is called pointed if \( C \cap (-C) = \{0\} \). A closed convex cone that is pointed and solid is called an ordering cone (proper cone).

Let \( C \subseteq \mathbb{R}^D \) be an ordering cone. As a consequence of the convexity of \( C \), it is immediate that \( C + C = C \). In general, an ordering cone can be polyhedral (e.g., the positive orthant \( C = \mathbb{R}^D_+ \)) or non-polyhedral (e.g., the ice-cream cone \( C = \{x \in \mathbb{R}^D \mid \|(x^1, \ldots, x^{D-1})^T\|_2 \leq x^D \} \) for \( D \geq 2 \)). For the purposes of this paper, we focus on the polyhedral case as detailed in the next definition.

**Definition 2.** A cone \( C \) is called polyhedral if it can be written as \( C = \{x \in \mathbb{R}^D \mid Wx \geq 0\} \) for some \( D \times N \) real matrix \( W \) with rows \( w_1, \ldots, w_N \), and positive integer \( N \).

Figure 2 illustrates several examples of polyhedral ordering cones in \( \mathbb{R}^2 \). Throughout the paper, we assume that \( C \) is a polyhedral ordering cone as described in Definition 2. Without loss of generality, we assume that this description has no redundancies, that is, \( W \) has the minimal number of rows; as well as that \( \|w_n\|_2 = 1 \) for each \( n \in [N] \). It follows that the interior of \( C \) is given by

\[
\text{int}(C) = \{x \in \mathbb{R}^D \mid Wx > 0\}.
\]

When all entries of \( W \) are nonnegative, it is clear that \( C \supseteq \mathbb{R}^D_+ \). In financial mathematics, such cones have found applications in multi-asset markets with transaction costs as “solvency cones”, where \( W \) is calculated in terms of the bid and ask prices of the assets; see Kabanov [1999].

In addition to polyhedrality, we assume that \( C \) satisfies the following geometric conditions:

\[
\beta_1 := \sup_{x \in C} \frac{d(x, C \cap (x + C))}{d(x, C)} < +\infty, \tag{2}
\]

\[
\beta_2 := \sup_{x \in \text{int}(C)} \frac{d(x, (\text{int}(C))^\circ \cap (x - C))}{d(x, (\text{int}(C))^\circ)} < +\infty. \tag{3}
\]

Note that we have \( \beta_1 \geq 1 \) and \( \beta_2 \geq 1 \). Let us also define \( \beta := \max\{\beta_1, \beta_2\} \).

In the examples below, we calculate \( \beta_1, \beta_2 \) for some standard ordering cones.

**Example 1.** Suppose that \( C = \mathbb{R}^D_+ \). Let \( x \notin C \). In this case, it is well-known that \( d(x, C) = \|x^\ominus\|_2 \).

Moreover, we have \( C \cap (x + C) = x^\ominus + \mathbb{R}^D_+ \) and hence

\[
d(x, C \cap (x + C)) = d(x, x^\ominus + \mathbb{R}^D_+) = d(x - x^\ominus, \mathbb{R}^D_+) = \|(x - x^\ominus)^\ominus\|_2 = \|x - x^\ominus\|_2 = \|x^\ominus\|_2.
\]

Therefore, \( d(x, C) = d(x, C \cap (x + C)) \) for every \( x \notin C \) so that \( \beta_1 = 1 < +\infty \). Similarly, for \( x \in \text{int}(C) \), it is easy to check that \( d(x, (\text{int}(C))^\circ) = d(x, (\text{int}(C))^\circ \cap (x - C)) = \min\{x^1, \ldots, x^D\} \). Hence, \( \beta_2 = 1 < +\infty \) as well.
Example 2. We take $D = 2$ in this example. Given $x \in \mathbb{R}^2$, let $\alpha(x) \in [0, 2\pi)$ denote the angle in the polar coordinates of $x$. Let $\theta \in (0, \pi/2]$ and define the ordering cone $C_\theta := \{x \in \mathbb{R}^2 \mid \alpha(x) \in [\pi/4 - \theta/2, \pi/4 + \theta/2]\}$. Let $x \notin C_\theta$. Using elementary planar geometry, it can be checked that $C_\theta \cap (x + C_\theta) = C_\theta$ so that $d(x, C_\theta) = d(x, C_\theta \cap (x + C_\theta))^\mu$ if $\alpha(x) \in (3\pi/4 + \theta/2, 7\pi/4 - \theta/2)$. If $\alpha(x) \in (0, \pi/4 - \theta/2) \cup (\pi/4 + \theta/2, 3\pi/4 + \theta/2) \cup (7\pi/4 - \theta/2, 2\pi)$, then $d(x, C_\theta \cap (x + C_\theta)) = d(x, C_\theta)csc(\theta)$. Hence, $\beta_1 = csc(\theta) < +\infty$. Similarly, for every $x \in \text{int}(C)$, we have $d(x, (\text{int}(C))^\mu \cap (x - C_\theta)) = d(x, (\text{int}(C))^\mu \cap (x - C_\theta))csc(\theta)$. Hence, $\beta_2 = csc(\theta) < +\infty$.

Example 3. In the setting of Example 2 let us now assume that $\theta \in (\pi/2, \pi)$. In this case, by planar geometry, it can be checked that $d(x, C_\theta) = d(x, C_\theta \cap (x + C_\theta))$ for every $x \notin C_\theta$ and $d(x, (\text{int}(C))^\mu) = d(x, (\text{int}(C))^\mu \cap (x - C_\theta))$ for every $x \in \text{int}(C)$. Hence, $\beta_1 = \beta_2 = 1 < +\infty$ for these larger cones.

Based on the observations in Examples 1 and 2 we conjecture that $\beta_1 = \beta_2 = 1$ for higher dimensions whenever $\mathbb{R}^D_+ \subseteq C$. We also conjecture that the finiteness assumptions on $\beta_1, \beta_2$ are valid for all polyhedral ordering cones.

The polyhedral ordering cone $C$ induces two non-total order relations on $\mathbb{R}^D$ as defined next.

**Definition 3.** For every $\mu, \mu' \in \mathbb{R}^D$, we write $\mu \preceq_C \mu'$ if $\mu' \in \mu + C$, and we write $\mu \prec_C \mu'$ if $\mu' \in \mu + \text{int}(C)$.

It can be checked that both $\preceq_C$ and $\prec_C$ are partial order relations on $\mathbb{R}^D$. If $C = \mathbb{R}^D_+$, then $\preceq_C$ coincides with the usual componentwise order on $\mathbb{R}^D$, which is the partial order used in multi-objective optimization.

To explain the motivation for using an ordering cone that is different from the positive orthant, let us first observe that

$$\mu \preceq_C \mu' \iff \forall n \in [N]: w_n^T \mu \leq w_n^T \mu' \quad (4)$$

for every $\mu, \mu' \in \mathbb{R}^D$. We denote by $C^+$ the convex cone generated by the rows of $W$, that is,

$$C^+ := \left\{ \sum_{n=1}^N \lambda_n w_n \mid \lambda_1, \ldots, \lambda_N \geq 0 \right\}. \quad (5)$$

It can be shown that $C^+$ is also a polyhedral ordering cone and it coincides with the so-called dual cone of $C$, that is, $C^+ = \{w \in \mathbb{R}^D \mid \forall x \in C: w^T x \geq 0\}$. It is well-known that the positive orthant is self-dual, that is, $\mathbb{R}^D_+ = \mathbb{R}^D_+$. By (5), we may rewrite (4) as

$$\mu \preceq_C \mu' \iff \forall w \in C^+: w^T \mu \leq w^T \mu'. \quad (6)$$

Here, each $w \in C^+$ can be considered as a “weight vector” since the partial order is determined by comparing the weighted sums of the components of $\mu, \mu'$ for all $w \in C^+$. Moreover, if $C'$ is another ordering cone, then we have $C \supseteq C'$ if and only if $C^+ \subseteq (C')^+$. In particular, if $W$ has non-negative entries so that $C \supseteq \mathbb{R}^D_+$, then we have $C^+ \subseteq \mathbb{R}^D_+$. Consequently, $\preceq_C$ is weaker than the componentwise order in this case, thanks to (6). In other words, in vector optimization, the decision-maker may have a more relaxed requirement when comparing two vectors, which is encoded by having a smaller set $C^+$ of weight vectors.

The above orders on $\mathbb{R}^D$ induce further orders on the design space $[K]$.

**Definition 4.** Let $i, j \in [K]$. Design $i \in [K]$ is said to be weakly dominated by design $j \in [K]$, denoted by $i \preceq_C j$, if $\mu_i \preceq_C \mu_j$. Design $i$ is said to be dominated by design $j$, denoted by $i \prec_C j$, if $\mu_i \prec_C \mu_j$. Design $i$ is strongly dominated by design $j$, denoted by $i \ll_C j$, if $\mu_i \ll_C \mu_j$.

Finally, we define Pareto optimality in the vector optimization setting.

**Definition 5.** A design $i \in [K]$ is called Pareto optimal if it is not dominated by any other design with respect to the ordering induced by $C$. The Pareto set $P^* := \{i \in [K] \mid \exists j \in [K]: i \preceq_C \{0\} j\}$ consists of all Pareto optimal designs.

In vector optimization, a Pareto optimal design $i \in P^*$ is sometimes called an efficient solution or a maximizer of the design space $[K]$, and the corresponding objective vector $\mu_i$ is called a $C$-maximal element of the objective set $\{\mu_j \mid j \in [K]\}$; see [Jahn 2011, Definition 3.1], [Heyde and Lßhne 2011, Definition 2.1].

**Remark 1.** Let us write $P^*(C) := P^*$ to emphasize the dependence on the ordering cone. Then, switching to a larger ordering cone $C' \supseteq C$ makes the dominance relation weaker. Consequently, the Pareto set becomes smaller under the larger cone: $P^*(C') \subseteq P^*(C)$.

## 3 PARETO SET IDENTIFICATION

We consider a learning problem where the mean vectors $\mu_i, i \in [K]$ are not known beforehand. Our goal is to identify $P^*$ from noisy observations of the objective values of chosen designs in as few evaluations as possible. We assume that the total number of evaluations, $T \geq 1$, is finite. Evaluations are done in a sequential manner with $t \in [T]$ representing the round in which the $t$th evaluation is made, and we denote by $I_t$ the random variable representing the design evaluated in round $t$. We consider a noisy feedback setting in which the evaluation in round $t$ yields a random reward vector $X_t = \mu_i + \eta_t$, where $\eta_t$ is the random noise vector associated to this evaluation. We assume that $Y_1, \ldots, Y_T$ are independent and centered.
random vectors, all of which are independent of the family \((I_t)_{t \in [T]}\). We also assume that the noise vectors \(Y_1, \ldots, Y_T\) are norm-subgaussian with a common parameter \(\alpha \geq 0\) as stated in the next definition.

**Definition 6.** [Jin et al. 2019, Definition 3] A centered random vector \(Y\) is called norm-subgaussian with parameter \(\alpha \geq 0\) if

\[
P(\|Y\|_2 \geq \epsilon) \leq 2e^{-\frac{\epsilon^2}{2}}
\]

for every \(\epsilon \geq 0\).

Examples of norm-subgaussian random vectors include bounded random vectors and subgaussian random vectors (up to a scaling of the parameter); see [Jin et al. 2019, Lemma 1].

Due to sampling noise, the sample complexity of identifying \(P^*\) depends on the hardness of distinguishing the designs in \(P^*\) from the designs that are not in \(P^*\). We quantify the hardness by the following gaps.

Given two designs \(i, j \in [K]\), we define \(m(i, j)\) as the minimum increment in \(\mu_j\) in an arbitrary direction of increase that makes design \(i\) not strongly dominated by design \(j\). Formally, we have

\[
m(i, j) := \inf\{s \geq 0 \mid \exists u \in B(0, 1) \cap C: \mu_i + su \notin \mu_j - \text{int}(C)\}. \tag{7}
\]

The next proposition lists some important properties of this gap. To that end, for each \(n \in [N]\), let us introduce the constant \(\alpha_n := \sup_{u \in B(0, 1) \cap C} w_n^T u\); note that \(\alpha_n \in (0, 1]\) since we assume that \(\sup_{u \in B(0, 1) \cap C} w_n^T u = \|w_n\|_n = 1\).

**Proposition 1.** Let \(i, j \in [K]\). (i) It holds \(m(i, j) < +\infty\). (ii) It holds \(m(i, j) = d(\mu_j - \mu_i, \text{int}(C)^c \cap (\mu_j - \mu_i - C))\). (iii) We have \(m(i, j) > 0\) if and only if \(i \not\preceq C j\). (iv) It holds \(m(i, j) = \min_{n \in [N]}(w_n^T (\mu_j - \mu_i))^+ / \alpha_n\).

**Proof.** We verify (i) and (iii) in the supplementary material. For (ii), note that

\[
m(i, j) = \inf\{s \geq 0 \mid \exists u \in B(0, 1) \cap C: \\
\mu_i + su \in (\mu_j - \text{int}(C))^c \}
= \inf\{s \geq 0 \mid \exists u \in B(0, 1) \cap C: \\
\mu_i + su \in \mu_j - \text{int}(C)^c \}
= \inf_{c \in \text{int}(C)^c} \inf\{s \geq 0 \mid \exists u \in B(0, 1) \cap C: \\
\mu_j - \mu_i - c = su \}
= \inf_{c \in \text{int}(C)^c \cap (\mu_j - \mu_i)^c} \inf\{s \geq 0 \mid \\
s = \|\mu_j - \mu_i - c\|_2\}
= d(\mu_j - \mu_i, (\text{int } C)^c \cap (\mu_j - \mu_i - C)) .
\]

For (iv), we have

\[
m(i, j) = \sup\{s \geq 0 \mid \forall u \in B(0, 1) \cap C: \\
\mu_i + su \notin \mu_j - C\}
= \sup\{s \geq 0 \mid \forall u \in B(0, 1) \cap C, \forall n \in [N]: \\
w_n^T (\mu_j - \mu_i) \geq sw_n^T u\}
= \sup\{s \geq 0 \mid \forall u \in [N]: \\
w_n^T (\mu_j - \mu_i) \geq s \sup_{u \in B(0, 1) \cap C} w_n^T u\}
= \sup\{s \geq 0 \mid \forall n \in [N]: w_n^T (\mu_j - \mu_i) \geq s\}
= \max\left\{0, \min_{n \in [N]} \frac{1}{\alpha_n} w_n^T (\mu_j - \mu_i)\right\}
= \min_{n \in [N]} \left(\frac{(w_n^T (\mu_j - \mu_i))^+}{\alpha_n}\right).
\]

The first equality of this derivation is justified rigorously in the supplementary material.

Similarly, given designs \(i, j \in [K]\), we define \(M(i, j)\) as the minimum increment in \(\mu_j\) in an arbitrary direction of increase that makes design \(i\) weakly dominated by design \(j\), that is,

\[
M(i, j) := \inf\{s \geq 0 \mid \exists u \in B(0, 1) \cap C: \\
\mu_j + su \in \mu_i + C\} . \tag{8}
\]

We collect the fundamental properties of this gap in the next proposition.

**Proposition 2.** Let \(i, j \in [K]\). (i) It holds \(M(i, j) < +\infty\). (ii) It holds \(M(i, j) = d(\mu_j - \mu_i, C \cap (\mu_j - \mu_i + C))\). (iii) We have \(M(i, j) = 0\) if and only if \(i \preceq C j\).

**Proof.** We verify (i) and (iii) in the supplementary material. For (ii), by elementary calculations, we have

\[
M(i, j) = \inf\{s \geq 0 \mid \exists u \in B(0, 1) \cap C; \exists c \in C: \\
\mu_j + su = \mu_i + c\}
= \inf_{c \in C} \inf\{s \geq 0 \mid \exists u \in B(0, 1) \cap C: \\
\mu_j - \mu_i - c = -su\}
= \inf_{c \in C \cap (\mu_j - \mu_i + C)} \inf\{s \geq 0 \mid \\
s = \|\mu_j - \mu_i - c\|_2\}
= \inf_{c \in C \cap (\mu_j - \mu_i + C)} ||\mu_j - \mu_i - c||_2
= d(\mu_j - \mu_i, C \cap (\mu_j - \mu_i + C)) ,
\]

which completes the proof.

**Remark 2.** From (8), it is clear that using a larger cone would result in smaller values of the gap \(M(i, j)\).
As an immediate consequence of Propositions\(^1\)(ii, iii) and\(^2\)(ii, iii), we obtain the following corollary.

**Corollary 1.** Let \(i, j \in [K]\). Then, exactly one of the following cases holds.

(i) We have both \(i \prec_C j\) and \(i \preceq_C j\) if and only if \(\mu_j - \mu_i \in \text{int}(C)\) and only if \(\text{if and only if } m(i,j) > 0\) and \(M(i,j) = 0\).

(ii) We have both \(i \not\prec_C j\) and \(i \not\preceq_C j\) if and only if \(\mu_j - \mu_i \in \text{bd}(C)\) and only if \(\text{if and only if } m(i,j) = M(i,j) = 0\).

(iii) We have both \(i \not\prec_C j\) and \(i \not\preceq_C j\) if and only if \(\mu_j - \mu_i \in C^c\) and only if \(\text{and if only if } m(i,j) = 0\) and \(M(i,j) > 0\). In particular, we have \(m(i,j) = 0\) or \(M(i,j) = 0\).

For each \(i \in [K]\), let \(\Delta_i^* := \max_{j \in P^*} m(i,j)\). By Proposition\(^3\)(iii), it is clear that \(\Delta_i^* = 0\) if \(i \in P^*\). We consider an \((\epsilon, \delta)\)-PAC (probably approximately correct) Pareto set identification setup under which the estimated Pareto set \(P \subseteq [K]\) returned by the learner needs to satisfy the conditions in the next definition.

**Definition 7.** Let \(\epsilon > 0\), \(\delta \in (0,1)\). A set \(P \subseteq [K]\) is called an \((\epsilon, \delta)\)-PAC Pareto set if the following success conditions hold with probability at least \(1 - \delta\):

(i) \(\forall i \in P^*\), \(\mu_i + (B(0,\epsilon) \cap C) \subseteq \bigcup_{j \in P^*} (\mu_j - C)\); (ii) for every \(i \in P\setminus P^*\), it holds \(\Delta_i^* \leq \epsilon\).

**Remark 3.** Note that condition (i) in Definition\(^1\) is equivalent to \((\hat{i}') \cup_{i \in P^*} (\mu_i + (B(0,\epsilon) \cap C)) \subseteq \{\mu_j \mid i \in P^*\}\). The implication \((i') \Rightarrow (i)\) is obvious. To see \((i') \Rightarrow (i)\), suppose that \((i')\) holds and let \(v \in \mu_i - C\) for some \(i \in P^*\). Then, by \((i')\), \(\mu_i \in \mu_j + (B(0,\epsilon) \cap C)\) for some \(j \in P\). Moreover, \(C + C = C\) since \(C\) is a convex cone. Hence, \(v \in \mu_j - C\) and \(\mu_j + (B(0,\epsilon) \cap C)\). This shows \((i)\). A similar covering condition has been introduced recently in \cite{Ararat et al., 2022}. Definition 3.5 in the context of deterministic convex vector optimization.

Condition (i) in Definition\(^1\) is an \(\epsilon\)-covering requirement for the Pareto set \(P^*\); in view of Remark\(^3\), it is equivalent to the following: for every \(i \in P^*\), there exist \(j \in P\) and \(u \in B(0,1)\cap C\) such that \(\mu_i \preceq_C \mu_j + u\). Roughly speaking, although \(P\) might not contain all Pareto optimal designs, it is required to include a close-enough design for each Pareto optimal design. Moreover, although some designs in \(P\) might be suboptimal, condition (ii) in Definition\(^1\) bounds the gaps of such designs; hence, it controls the quality of all returned designs.

## 4 NAÏVE ELIMINATION

In this section, we introduce the naïve elimination algorithm that is used for \((\epsilon, \delta)\)-PAC Pareto set identification. The algorithm operates in the same fashion as the naïve elimination algorithm used for \((\epsilon, \delta)\)-PAC best arm identification \cite{Even-Dar et al., 2006}. Naïve elimination takes as inputs \((\epsilon, \delta)\) and the polyhedral ordering cone \(C\) defined by matrix \(W\). It evaluates each design \(L\) times to form empirical means \(\mu_i, i \in [K]\), where \(L \geq 1\) is a positive integer that is used as the exploration parameter and it is set depending on \(\epsilon, \delta\) and \(K\). Hence, \(T = LK\) evaluations are made in total. Then, the algorithm computes and returns a random set \(P\) by using Definition\(^4\). This is done by checking for each design \(i\) whether there exists another design \(j\) with \(i \preceq_C |\{j\}|\), where \(\preceq_C|\{}\) is the random partial order that is defined by using \(\mu_i\) in place of \(\mu_i\), \(i \in [K]\), in the standard expression of \(\preceq_C|\{}\); see Definitions\(^3\) and\(^4\). (The random relations \(\preceq_C\) and \(\preceq_C|\{}\) are defined similarly.) Hence, we set \(P := \{i \in [K] \mid \exists j \in [K] : \bar{i} \preceq_C |\{j\}|\} \) for the rest of the paper.

## 5 SAMPLE COMPLEXITY ANALYSIS

Given \(i, j \in [K]\), let \(\hat{m}(i,j) := d(\mu_j - \mu_i, (\text{int}(C)) \cap (\mu_j - \mu_i - C))\) and \(M(i,j) := d(\mu_j - \mu_i, C \cap (\mu_j - \mu_i + C))\) represent the empirical estimates of \(m(i,j)\) and \(M(i,j)\), respectively. In the next lemma, we prove that the following conditions in terms of the gaps are sufficient for \((\epsilon, \delta)\)-PAC Pareto set identification.

**Condition 1.** For every \(i \in P^*\) and \(j \in [K] \setminus \{i\}\), \(M(i,j) > \epsilon\) implies that \(M(i,j) > 0\).

**Condition 2.** For every \(i \notin P^*\) and \(j \in P^*\), \(m(i,j) > \epsilon\) implies that \(m(i,j) > 0\).

**Lemma 1.** If Conditions 1 and 2 hold, then \(P\) is an \((\epsilon, \delta)\)-PAC Pareto set.

**Proof.** Assume that Condition 1 holds. To get a contradiction, suppose that success condition (i) in Definition\(^1\) does not hold. By Remark\(^3\), this implies that there exists \(i \in P^*\) such that \(\mu_i \notin \mu_j + (B(0,\epsilon) \cap (\mu_j - \mu_i + C))\) and \(\mu_j \notin \mu_i + (B(0,\epsilon) \cap (\mu_i - C))\). For each \(j \in P\). Hence, \(\mu_j - \mu_i \notin (B(0,\epsilon) \cap (\mu_j - \mu_i + C))\) and \(\mu_i - \mu_j \notin (B(0,\epsilon) \cap (\mu_i - C))\). Since \(B(0,\epsilon) \cap (\mu_j - \mu_i + C)\) is a compact set and \(C\) is a closed set, their Minkowski sum is closed. Therefore, for each \(j \in P\), we have \(d(\mu_j - \mu_i, (B(0,\epsilon) \cap (\mu_j - \mu_i + C)) + C) > 0\), and we also have

\[
\begin{align*}
&d(\mu_j - \mu_i, C \cap (\mu_j - \mu_i + C)) \geq d(\mu_j - \mu_i, C) \\
&\geq d(\mu_j - \mu_i, (B(0,\epsilon) \cap (\mu_j - \mu_i + C)) + C)
\end{align*}
\]

since \(C \cap (\mu_j - \mu_i + C) \subseteq C \subseteq (B(0,\epsilon) \cap (\mu_j - \mu_i + C)) + C\). Therefore, by Proposition\(^2\)(ii), we have \(M(i,j) = d(\mu_j - \mu_i, C \cap (\mu_j - \mu_i + C)) > 0\) for each \(j \in P\). Then, Condition 1 implies that \(M(i,j) > 0\) for each \(j \in P\). By Corollary\(^1\)(iii) applied to the random partial orders \(\preceq_C, \preceq_C|\{}\), we get \(i \preceq_C |\{j\}|\) for each \(j \in P\). Hence, we must have \(i \in P\). In particular, taking \(j = i\) gives \(\mu_i \notin \mu_i + (B(0,\epsilon) \cap C) - C\), which is a contradiction. Hence, success condition (i) holds.
Assume that Condition 2 holds. Let \( i \in P \setminus P^* \). Hence, there exists no \( j \in [K] \setminus \{i\} \) such that \( \hat{r}_{\xi_{ij}} \). By Corollary 1, \( \hat{r}_{\xi_{ij}} \) applied to the random partial orders \( \tilde{\xi}_{ij}, \tilde{\xi}_{ij} \), we have \( \hat{m}(i, j) = 0 \) for every \( j \in [K] \setminus \{i\} \), in particular, for every \( j \in P^* \). Then, Condition 2 implies that \( m(i, j) \leq \epsilon \) for every \( j \in P^* \). Hence, \( \Delta_i^* \leq \epsilon \), that is, success condition (ii) holds.

For each \( i, j \in [K] \) with \( i \neq j \), let us define \( \Delta_{ij} = \mu_j - \mu_i \). The next lemma shows that the following conditions in terms of the deviation of \( \Delta_{ij} \) from \( \Delta_{ij} \) are sufficient for (\( \epsilon, \delta \))-PAC Pareto set identification.

**Condition a.** For every \( i \in P^* \) and \( j \in [K] \setminus \{i\} \),
\[
d(\Delta_{ij}, C \cap (\Delta_{ij} + C)) > \epsilon \text{ implies that } ||\Delta_{ij} - \Delta_{ij}||_2 < d(\Delta_{ij}, C).
\]

**Condition b.** For every \( i \in P^* \) and \( j \in P^* \),
\[
d(\Delta_{ij}, (\text{int}(C)) \cap (\Delta_{ij} + C)) > \epsilon \text{ implies that } ||\Delta_{ij} - \Delta_{ij}||_2 < d(\Delta_{ij}, (\text{int}(C)) \cap (\Delta_{ij} + C)).
\]

**Lemma 2.** If Conditions a and b hold, then \( P \) satisfies the success conditions in Definition 2.

**Proof.** Assume that Condition a holds. We verify Condition 1. Let \( i \in P^* \) and \( j \in [K] \setminus \{i\} \) such that \( M(i, j) > \epsilon \), that is, \( d(\Delta_{ij}, C \cap (\Delta_{ij} + C)) > \epsilon \) by Proposition 1. Then, Condition a implies that \( ||\Delta_{ij} - \Delta_{ij}||_2 < d(\Delta_{ij}, C) \). Since \( d(\Delta_{ij}, C \cap (\Delta_{ij} + C)) > 0 \) and \( C \cap (\Delta_{ij} + C) \) is a closed set, we have \( \Delta_{ij} \notin C \cap (\Delta_{ij} + C) \). Hence, \( \Delta_{ij} \notin C \). We claim that \( \Delta_{ij} \notin C \). To get a contradiction, suppose that \( \Delta_{ij} \in C \). Then, we have \( ||\Delta_{ij} - \Delta_{ij}||_2 \geq \text{inf}_{\epsilon \in C} ||\Delta_{ij} - \epsilon||_2 = d(\Delta_{ij}, C) \), which is a contradiction. Hence, the claim holds, and we have \( \Delta_{ij} \notin C \cap (\Delta_{ij} + C) \). By Proposition 2, we obtain \( M(i, j) = d(\Delta_{ij}, C \cap (\Delta_{ij} + C)) > 0 \). Hence, Condition 1 holds.

Assume that Condition b holds. We verify Condition 2. Let \( i \notin P^* \) and \( j \in P^* \) such that \( m(i, j) > \epsilon \), that is, \( d(\Delta_{ij}, (\text{int}(C)) \cap (\Delta_{ij} - C)) > \epsilon \) by Proposition 1. Then, Condition b implies that \( ||\Delta_{ij} - \Delta_{ij}||_2 < d(\Delta_{ij}, (\text{int}(C)) \cap (\Delta_{ij} - C)) \). Moreover, since \( (\text{int}(C)) \cap (\Delta_{ij} - C) \) is a closed set, we have \( \Delta_{ij} \notin (\text{int}(C)) \cap (\Delta_{ij} - C) \) and hence \( \Delta_{ij} \in \text{int}(C) \). We claim that \( \Delta_{ij} \in \text{int}(C) \). Supposing otherwise that \( \Delta_{ij} \notin (\text{int}(C)) \cap (\Delta_{ij} - C) \), we get \( ||\Delta_{ij} - \Delta_{ij}||_2 \geq \text{inf}_{\epsilon \in (\text{int}(C))} ||\Delta_{ij} - \epsilon||_2 = d(\Delta_{ij}, (\text{int}(C)) \cap (\Delta_{ij} - C)) \), which is a contradiction. Hence, the claim holds, and we have \( \Delta_{ij} \notin (\text{int}(C)) \cap (\Delta_{ij} - C) \). By Proposition 1, we get \( \hat{m}(i, j) = d(\Delta_{ij}, C \cap (\Delta_{ij} + C)) > 0 \). Hence, Condition 2 holds.

For each \( i, j \in [K] \) with \( i \neq j \), the next lemma explains how \( \Delta_{ij} \) concentrates around \( \Delta_{ij} \) in \( L^2 \) norm as a function of the exploration parameter \( L \). Let us introduce the constant
\[
\theta_{ij} := \begin{cases} \frac{d(\Delta_{ij}, C \cap (\Delta_{ij} + C))}{d(\Delta_{ij}, (\text{int}(C)) \cap (\Delta_{ij} - C))} & \text{if } \Delta_{ij} \notin C, \\ \frac{d(\Delta_{ij}, (\text{int}(C)) \cap (\Delta_{ij} - C))}{d(\Delta_{ij}, (\text{int}(C)) \cap (\Delta_{ij} - C))} & \text{if } \Delta_{ij} \in \text{int}(C), \\ 1 & \text{if } \Delta_{ij} \in \text{bd}(C). \end{cases}
\]

**Lemma 3.** Suppose that \( L = g(\epsilon, \delta) := [(4\beta^2 c^2 a^2 / \epsilon^2) \log(4D/\delta)] \) noisy observations are evaluated for each design, where \( c > 0 \) is a constant. Then, there exists a choice of \( c > 0 \) (free of all problem parameters) such that, for each \( i, j \in [K] \) with \( i \neq j \), we have \( ||\Delta_{ij} - \Delta_{ij}||_2 \leq \epsilon \theta_{ij} \) with probability at least \( 1 - \delta/2 \).

**Proof.** By Jin et al. 2019 Corollary 7, there exists an absolute constant \( c > 0 \) such that, with probability at least \( 1 - \delta/2 \), we have
\[
L||\mu_i - \mu_i||_2 = L \left| \frac{\sum_{t=1}^{LK} X_i(I_t = i)}{L} - \mu_i \right|_2 \leq \sqrt{L \sigma^2 2 \log 4D / \delta},
\]
that is, \( ||\mu_i - \mu_i||_2 \leq c \sqrt{\frac{\sigma^2}{L}} \log \frac{4D}{\delta} \). Setting \( L = [(4\beta^2 c^2 a^2 / \epsilon^2) \log(4D/\delta)] \) ensures that \( ||\mu_i - \mu_i||_2 \leq \epsilon/(2\beta) \) with probability at least \( 1 - \delta/2 \). Applying a union bound, we obtain \( \mathbb{P}(||\mu_i - \mu_i||_2 \leq \epsilon/(2\beta)) \geq 1 - \delta/2 \). Noting that \( ||\Delta_{ij} - \Delta_{ij}||_2 = ||\mu_j - \mu_j + \mu_i - \mu_i||_2 \leq ||\mu_i - \mu_i||_2 + ||\mu_j - \mu_j||_2 \), we have \( \mathbb{P}(||\Delta_{ij} - \Delta_{ij}||_2 \leq \epsilon/(\beta)) \geq 1 - \delta \). If \( \Delta_{ij} \notin C \), then we have
\[
\frac{\epsilon}{\beta} \leq \frac{\epsilon}{\delta} \leq \frac{d(\Delta_{ij}, C \cap (\Delta_{ij} + C))}{d(\Delta_{ij}, (\text{int}(C)) \cap (\Delta_{ij} - C))} = \epsilon \theta_{ij} ;
\]
if \( \Delta_{ij} \in \text{int}(C) \), then we have
\[
\frac{\epsilon}{\beta} \leq \frac{\epsilon}{\delta} \leq \frac{d(\Delta_{ij}, (\text{int}(C)) \cap (\Delta_{ij} + C))}{d(\Delta_{ij}, (\text{int}(C)) \cap (\Delta_{ij} - C))} ;
\]
and if \( \Delta_{ij} \in \text{bd}(C) \), then we have \( \epsilon/\beta \leq \epsilon = \epsilon \theta_{ij} \); see 2 and 3 for the definitions of \( \beta_1 \) and \( \beta_2 \). Hence, the result follows.

The following theorem characterizes the sample complexity of naïve elimination for (\( \epsilon, \delta \))-PAC Pareto set identification.

**Theorem 1.** When naïve elimination is run with \( L = g(\epsilon, 2\delta/(K(K - 1))) \), the returned Pareto set \( P \) is an (\( \epsilon, \delta \))-PAC Pareto set.

**Proof.** With the given choice of \( L \), by Lemma 3, for every \( i, j \in [K] \) with \( i \neq j \), we have \( ||\Delta_{ij} - \Delta_{ij}||_2 \leq \epsilon \theta_{ij} \) with probability at least \( 1 - 2\delta/(K(K - 1)) \). The
application of union bound shows that with probability at least $1 - \delta$, $||\hat{\Delta}_{ij} - \Delta_{ij}||_2 \leq \epsilon \theta_{ij}$ simultaneously for all $i, j \in [K]$ such that $i \neq j$. Under this event, we verify Conditions a and b. Let $i \in P^*$ and $j \in [K] \setminus \{i\}$ such that $d(\Delta_{ij}, C \cap (\Delta_{ij} + C)) > \epsilon$. In particular, $\Delta_{ij} \notin C$. Hence, we have

$$
\|\hat{\Delta}_{ij} - \Delta_{ij}\|_2 \leq \epsilon \theta_{ij} = \frac{ed(\Delta_{ij}, C)}{d(\Delta_{ij}, C \cap (\Delta_{ij} + C))} < \frac{d(\Delta_{ij}, C)}{d(\Delta_{ij}, C)}.
$$

This shows that Condition a holds. Let $i \notin P^*$ and $j \in P^*$ such that $d(\Delta_{ij}, (\text{int}(C))^c \cap (\Delta_{ij} - C)) > \epsilon$. In particular, $\Delta_{ij} \in \text{int}(C)$. Hence, we have

$$
\|\hat{\Delta}_{ij} - \Delta_{ij}\|_2 \leq \epsilon \theta_{ij} = \frac{ed(\Delta_{ij}, (\text{int}(C))^c)}{d(\Delta_{ij}, (\text{int}(C))^c \cap (\Delta_{ij} - C))} < \frac{d(\Delta_{ij}, (\text{int}(C))^c)}{d(\Delta_{ij}, (\text{int}(C))^c)}.
$$

This shows that Condition b holds. Therefore, by Lemma 2 $P$ is an $(\epsilon, \delta)$-PAC Pareto set.

6 NUMERICAL RESULTS

We use SNW dataset from [Zuluaga et al. 2016]. It consists of 206 different hardware implementations of a sorting network. The objectives are the area and throughput of the network when synthesized on an FPGA ($D = 2$). Since we consider maximization problems, we use the negative of area as objective value. The mean rewards of designs are taken as the objective values in the dataset. The reward vector of a design is formed by adding independent zero mean Gaussian noise with variance $\sigma^2 = 1$ to the mean value of each objective of the design.

We consider the polyhedral cone $C_\theta$ described in Examples 2 and 3, which is parametrized by an angle $\theta \in (0, \pi]$. We use $C_{\pi/4}$, $C_{\pi/2}$ and $C_{3\pi/4}$ in our simulations (Figure 2). $P_\theta^*$ represents the true Pareto optimal set under the ordering induced by $C_\theta$. The Pareto sets for $C_{\pi/4}$, $C_{\pi/2}$ and $C_{3\pi/4}$ are shown in Figure 1. Some statistics of the gaps $\Delta_i^*$ of designs $i \in [K] \setminus P_\theta^*$ are given in Table 1.

As there is no work that considers vector optimization with stochastic bandit feedback, we do not compare with any other method. Instead, we illustrate how the performance of Naïve Elimination varies as a function of the number of samples from each design and shape of the ordering cone. We set $\delta = 0.01$ in all simulations. The reported results correspond to the average of 100 independent runs. As typically observed in the best arm identification literature, the theoretical value of $L$ is very large. For instance, for $\theta = \pi/2$, if $\epsilon = 0.1$, then $L \approx 38.8 \times 10^3$; if $\epsilon = 0.01$, then $L \approx 38.8 \times 10^5$. Therefore, instead of using theoretical values, we evaluate the results for different $L$ and $\epsilon$ values. The results are provided in Table 2. For fixed $L$ and $\epsilon$, success rate increases as $\theta$ increases. This happens because gaps increase as the cone becomes wider, and hence, the problem becomes easier. For fixed $\theta$ and $L$, success rate increases as $\epsilon$ increases, as both success conditions become easier to satisfy. For a fixed $\theta$ and $\epsilon$, success rate increases as $L$ increases, since more samples mean less noise in the estimates. For some $(\epsilon, \theta)$ pairs all runs were successful even when $L$ was much smaller than its theoretical value. Studying lower bounds on sample complexity is an interesting future research direction.

7 CONCLUSIONS

We proposed vector optimization problems with stochastic bandit feedback. We identified fundamental cone-dependent gaps that characterize the learning difficulty of the Pareto set. We derived sample complexity bounds for $(\epsilon, \delta)$-PAC Pareto set identification. Our introduction of noisy bandit feedback to vector optimization brings forth many interesting future research directions. In particular, the design of sample-efficient adaptive algorithms remains as an open problem that we seek to address in the future.

SUPPLEMENTAL PROOFS

Proof of a conjecture in Section 2

Recall the definition of $\beta_1$ in (2), which depends on the geometry of the ordering cone $C$. The following proposition verifies one of the conjectures stated in Section 2.

**Proposition 3.** Suppose that the ordering cone is at least as large as the positive orthant, i.e., $C \supseteq \mathbb{R}^D_+$. Then, $d(x, C \cap (x + C)) = d(x, C)$ for every $x \notin C$. In particular, $\beta_1 = 1$.

Proof. Let us fix $x \notin C$. Note that $C = \{ y \in \mathbb{R}^D \mid Wy \geq 0 \}$ and $x + C = \{ y \in \mathbb{R}^D \mid Wy \geq Wx \}$. Hence, $C \cap (x + C) = \{ y \in \mathbb{R}^D \mid Wy \geq (Wx)_+ \}$. Since $x \notin C$, there exists $n \in [N]$ such that $w_n^T x < 0$. Let $I(x) := \{ n \in [N] \mid w_n^T x \leq 0 \} \neq \emptyset$. We have $(w_n^T x)^+ = 0$ for each $n \in I(x)$ and $(w_n^T x)^- = w_n^T x > 0$ for each $n \in I(x)^c := [N] \setminus I(x)$. Hence, $d(x, C \cap (x + C))^2$ can be written as the optimal value of a quadratic optimization problem as follows:

$$
d(x, C \cap (x + C))^2 = \inf \{ \| y - x \|^2_2 \mid \forall n \in I(x): w_n^T y \geq 0, \forall n \in I(x)^c: w_n^T y \geq w_n^T x \}. \tag{9}$$

As this is a convex optimization problem with affine constraints and finite optimal value, the standard Karush-Kuhn-Tucker conditions are necessary and sufficient for optimality. Hence, a vector $y \in \mathbb{R}^D$ that satisfies the constraints of (9) is optimal if and only if there exists a Lagrange multiplier vector $\lambda \in \mathbb{R}^N_+$ such that the following conditions are satisfied:

$$
2(y - x) - \sum_{n \in [N]} \lambda_n w_n = 0, \tag{10}
$$

$$
\forall n \in I(x): \lambda_n w_n^T y = 0, \tag{11}
$$

$$
\forall n \in I(x)^c: \lambda_n (w_n^T y - w_n^T x) = 0. \tag{12}
$$

Here, condition (10) is the first order condition for the Lagrangian of (9) with respect to the primal variable $y$; conditions (11) and (12) are the complementary slackness conditions.

Let $y \in \mathbb{R}^D$ be an optimal solution of (9) with an associated Lagrange multiplier vector $\lambda \in \mathbb{R}^N_+$. We claim that $\lambda_n = 0$ for every $n \in I(x)^c$. To get a contradiction, suppose that $\lambda_n > 0$ for some $\bar{n} \in I(x)^c$. By (12), we have $w_{\bar{n}}^T (y - x) = w_{\bar{n}}^T y - w_{\bar{n}}^T x = 0$. On the other hand, $y - x = \frac{1}{2} \sum_{n \in [N]} \lambda_n w_n$ by (10). Combining these, we get

$$
\sum_{n \in [N]} \lambda_n w_{\bar{n}}^T w_n = 0. \tag{13}
$$

Note that $w_n \in C^+$ for each $n \in [N]$. Since $C \supseteq \mathbb{R}^D_+$, it follows from the definition in (5) that $C^+ \subseteq \mathbb{R}^D_+$. Hence, we have $w_{\bar{n}}^T w_n \geq 0$ for each $n \in [N]$. Then, (13) implies that $\lambda_n w_{\bar{n}}^T w_n = 0$ for each $n \in [N]$. In particular, taking $n = \bar{n}$ gives $\lambda_{\bar{n}} \| w_{\bar{n}} \|^2_2 = \lambda_{\bar{n}} = 0$, which is a contradiction. Therefore, the claim holds.

Thanks to the above claim, the pair $(y, \lambda)$ satisfies the system

$$
2(y - x) - \sum_{n \in [N]} \lambda_n w_n = 0,
$$

$$
\forall n \in [N]: \lambda_n w_n^T y = 0.
$$

Moreover, $w_n^T y \geq 0$ for each $n \in [N]$ by the feasibility of $y$ for (9). Hence, the Karush-Kuhn-Tucker conditions are established for the quadratic optimization problem

$$
d(x, C)^2 = \inf \{ \| y - x \|^2_2 \mid \forall n \in [N]: w_n^T y \geq 0 \} \tag{14}
$$

and we conclude that $y$ is optimal for (14). Therefore, $d(x, C) = d(x, C \cap (x + C)) = \| y - x \|_2$. \qed
Proof of Proposition 1

(i) To get a contradiction, suppose that \( m(i,j) = +\infty \). Hence, the set whose infimum is calculated in (7) is empty, that is, for every \( s \geq 0 \) and \( u \in B(0,1) \cap C \), we have \( \mu_i + su \in \mu_j - \text{int}(C) \). Since \( \{su \mid s \geq 0, u \in B(0,1) \cap C \} = C \), we have \( \mu_i + C \subseteq \mu_j - \text{int}(C) \subseteq \mu_j - C \). Hence, \( \mu_i - \mu_j + C \subseteq -C \) so that \( C \cap (-C) \subseteq C \cap (\mu_i - \mu_j + C) \). The latter intersection consists of all points \( x \in \mathbb{R}^D \) such that \( 0 \leq_C x \) and \( \mu_i - \mu_j \leq_C x \). Since \( C \) is a solid cone, there are infinitely many such points, which contradicts with \( C \cap (-C) = \{0\} \). Hence, \( m(i,j) < +\infty \).

(ii) Note that

\[
m(i,j) = \inf \{s \geq 0 \mid \exists u \in B(0,1) \cap C : \mu_i + su \in (\mu_j - \text{int}(C))^c \} = \inf \left\{ s \geq 0 \mid \exists u \in B(0,1) \cap C : \mu_i + su \in \mu_j - \text{int}(C) \right\} = \inf \left\{ s \geq 0 \mid \exists u \in B(0,1) \cap C : \mu_j - \mu_i = c = su \right\} = \inf \left\{ s \geq 0 \mid s = \frac{||\mu_j - \mu_i - c||}{2} \right\} = \inf \left\{ \mu_j - \mu_i, \text{int}(C)^c \cap (\mu_j - \mu_i - C) \right\}.
\]

(iii) Since \( \text{int}(C)^c \cap (\mu_j - \mu_i - C) \) is a closed set, by the well-known properties of distance function, we have \( \mu_j - \mu_i \in \text{int}(C)^c \cap (\mu_j - \mu_i - C) \) if and only if \( m(i,j) = d(\mu_j - \mu_i, \text{int}(C)^c \cap (\mu_j - \mu_i - C)) = 0 \). Since \( \mu_j - \mu_i \in \mu_j - \mu_i - C \) always holds, we have \( \mu_j - \mu_i \in \text{int}(C)^c \) if and only if \( m(i,j) = 0 \). Since the former condition precisely means that \( i \neq j \), the desired equivalence follows.

(iv) First, suppose that \( m(i,j) = 0 \), that is, \( \mu_j - \mu_i \notin \text{int}(C) \). By (1), there exists \( \bar{n} \in [N] \) such that \( w_n^T(\mu_j - \mu_i) \leq 0 \), that is, \( (w_n^T(\mu_j - \mu_i))^+ = 0 \). Hence, \( \min_{n \in [N]} (w_n^T(\mu_j - \mu_i))^+ / \alpha_n = 0 = m(i,j) \). Next, suppose that \( m(i,j) > 0 \), that is, \( \mu_j - \mu_i \in \text{int}(C) \). Note that we may write \( m(i,j) = \inf R \), where

\[
R := \{s \geq 0 \mid \exists u \in B(0,1) \cap C : \mu_i + su \notin \mu_j - C\}.
\]

We show that \( R \) is an interval that is unbounded from above. To that end, let \( s \geq 0 \) be such that \( \mu_i + su \notin \mu_j - C \) for some \( u \in B(0,1) \cap C \). Let \( s' > s \). We claim that \( \mu_i + s'u \notin \mu_j - C \). Suppose otherwise that \( \mu_i + s'u \in \mu_j - C \). Since \( \mu_i \in \mu_j - \text{int}(C) \subseteq \mu_j - C \) by supposition, and \( \mu_j - C \) is a convex set, we obtain

\[
\mu_i + su = \left(1 - \frac{s}{s'} \right) \mu_i + \frac{s}{s'} (\mu_i + s'u) \in \mu_j - C,
\]

which is a contradiction to the definition of \( s \). Hence, the claim holds. Since \( R \) is an interval in \([0, +\infty)\) that is unbounded from above, we have \( \inf R = \sup([0, +\infty) \setminus R) \). Therefore,

\[
m(i,j) = \sup\{s \geq 0 \mid \forall u \in B(0,1) \cap C : \mu_i + su \in \mu_j - C \} = \sup\{s \geq 0 \mid \forall u \in B(0,1) \cap C, \forall n \in [N] : w_n^T(\mu_j - \mu_i - su) \geq 0 \} = \sup\{s \geq 0 \mid \forall u \in B(0,1) \cap C, \forall n \in [N] : w_n^T(\mu_j - \mu_i) \geq s \sup_{u \in B(0,1) \cap C} w_n^T u \} = \sup\{s \geq 0 \mid \forall n \in [N] : w_n^T(\mu_j - \mu_i) \geq s \sup_{u \in B(0,1) \cap C} w_n^T u \} = \sup\{s \geq 0 \mid \forall n \in [N] : w_n^T(\mu_j - \mu_i) \geq s \min_{n \in [N]} \frac{1}{\alpha_n} \}
\]

which completes the proof.
Proof of Proposition 2

(i) We prove that the set whose infimum is calculated in (8) is nonempty. To get a contradiction, suppose that for every \( s \geq 0 \) and \( u \in B(0,1) \cap C \), we have \( \mu_j - \mu_i + su \notin C \), that is,

\[
\left( \mu_j - \mu_i + \bigcup_{s \geq 0} (B(0,s) \cap C) \right) \cap C = \emptyset.
\]

However, we have \( \bigcup_{s \geq 0} (B(0,s) \cap C) = C \); hence, we get a contradiction to the solidity of \( C \) as in the proof of Proposition 2(i). It follows that \( M(i,j) < +\infty \).

(ii) By elementary calculations, we have

\[
M(i,j) = \inf \{ s \geq 0 \mid \exists u \in B(0,1) \cap C, \exists c \in C: \mu_j + su = \mu_i + c \} = \inf \{ s \geq 0 \mid \exists u \in B(0,1) \cap C, M_j - M_i - c = -su \} = \inf_{c \in C} \{ s \geq 0 \mid s = \| \mu_j - \mu_i - c \|_2 \} = d(\mu_j - \mu_i, C \cap (\mu_j - \mu_i + C)).
\]

(iii) Since \( C \cap (\mu_j - \mu_i + C) \) is a closed set, we have \( M(i,j) = d(\mu_j - \mu_i, C \cap (\mu_j - \mu_i + C)) = 0 \) if and only if \( \mu_j - \mu_i \in C \cap (\mu_j - \mu_i + C) \). Since \( \mu_j - \mu_i \in \mu_j - \mu_i + C \) is always the case, these conditions are also equivalent to \( \mu_j - \mu_i \in C \), that is, \( i \leq C j \).

SUPPLEMENTAL NUMERICAL RESULTS

Table 3: Additional results for experiments conducted in Section 6: \( \theta \): cone angle in degrees. SR\( \theta \): success rate (in %) for \( C_\theta \). NF1\( \theta \): average number of designs in \( P_\theta \) that fail success condition (i) in Definition 7. NF2\( \theta \): average number of designs in \( P \setminus P_\theta \) that fail success condition (ii) in Definition 7. PM\( \theta \): \( \| P_\theta \| / \| P \| \) \times 100.
