A metastable amorphous intermediate is responsible for laser-induced nucleation of glycine

ABSTRACT: Laser-induced crystal nucleation through optical tweezing, and in particular polymorph selection through laser polarization, promises unprecedented control over crystallization. However, in the absence of a nearby liquid–liquid critical point, the origin of the required pre-nucleation clusters remains unclear. A number of recent studies of so-called nonclassical nucleation have suggested the presence of large amorphous clusters. Here we show that supersaturated aqueous glycine solutions form solid metastable intermediate particles on the pathway to crystal nucleation. Laser-induced crystal nucleation only occurs when the laser hits one of these particles. In situ low-frequency Raman spectroscopy is used to demonstrate their amorphous or partially ordered character and transformation to various crystal polymorphs. The requirement for solution aging in many previously reported laser-induced crystal nucleation experiments strongly suggests that the presence of amorphous intermediates is a general requirement.

Nucleation of crystals from solution is of great importance—ranging from the production of pharmaceutical drugs and chemical products to biological crystallography—but is difficult to control. In the mid-1990s, it was discovered that non-photochemical laser induced nucleation (NPLIN) can be used to nucleate crystals on demand and that the crystal polymorph could be selected by the polarization state of the laser. Since then, several groups have shown that pulsed lasers may be used to induce nucleation in supersaturated solutions, although the polymorph selection ability has been questioned. More recently, it has been shown that continuous-wave (CW) lasers can also induce crystal nucleation at the solution–air interface, which has been attributed to optical trapping of pre-nucleation clusters. However, unless the system is close to a liquid–liquid phase transition, there is no obvious physical reason for the presence of such pre-nucleation clusters. Moreover, the forces associated with optical trapping of sub-micron objects are expected to be negligible compared to thermal fluctuations. Therefore, the mechanism behind laser-induced crystal nucleation far away from any liquid–liquid critical points is still a mystery.

Could other supramolecular structures be involved in these laser-induced crystal nucleation phenomena? Previous work on tartaric acid solutions has indicated the presence of unidentified clusters of an intermediate form just before a crystal nucleates, while CaCO₃ is thought to crystallize by way of a nanosized liquid-like amorphous calcium carbonate phase. Light and small-angle x-ray scattering studies have shown the presence of ~250-nm glycine rich nanodroplets in saturated glycine solutions, while large subcritical clusters (> 700 nm) were detected by in situ dynamic light scattering (DLS) experiments. Despite the evidence of such nanometer-scale species in solution, very little about their state and structure is known.

Here, we investigate homogeneous and laser-induced crystal nucleation of glycine from solution using microscopy and broadband in situ Raman spectroscopy to provide detailed information on intermediates and their transformation to the crystalline form. The nucleation of glycine has been widely studied including the possible effects of stirring, non-photochemical laser-induced crystal nucleation and nucleation through CW optical trapping including polymorph control through laser polarization. We will show that supersaturated glycine solutions produce metastable amorphous intermediate particles whose relative stability impedes the spontaneous nucleation of a crystalline form. Irradiation of the intermediate particles with a laser induces rapid nucleation and formation of one of the polymorphs of glycine.

Nucleation experiments were carried out in a setup consisting of an inverted microscope allowing access by a high-power pulsed laser (1040 nm, 350 fs to 4 ps, 1 MHz repetition rate, ≤8 W) and a single-frequency Raman excitation laser (532 nm, 500 mW), and the collection of scattered light to provide Stokes and anti-Stokes Raman spectra with a minimum shift of about 10 cm⁻¹ (See Methods in SI and Figure S1). To minimize heating of the sample by the near-infrared laser, solutions were prepared in D₂O.

To investigate laser induced as well as homogeneous nucleation of glycine crystals in solution, thin film samples of glycine were prepared by placing 10 µL of a saturated solution onto the bottom of a glass petri dish that was covered with a lid. Additionally, 1 µL droplets of identical solution were placed on the side to slow down evaporation. In this setup, no spontaneous crystallization was observed over a period of 12 hours. As suggested in the literature, the laser was focused on the air/liquid interface to initiate nucleation. Despite many attempts using ≤1.0 W of the 1040 nm laser focused on the air/liquid interface for 20-30 minutes, no laser-induced nucleation was observed. However, it was observed that tiny particles (~1 µm diameter) formed in the solution. Bringing one of these particles into the laser focus reliably triggered their rapid transformation into crystals.
Figure 1. Laser-induced crystallization from a glycine particle in solution. Scale bars, 30 µm. (a) Micrometer sized glycine particle in solution, indicated by the arrow. The bright spot is scattered light from the laser focus; (b) The glycine particle is brought into laser focus by manually moving the stage instantly triggering crystallization; (c) A needle-like crystal grows rapidly while the laser has been switched off; (d) Prismatic crystal begins to grow out of the needles seconds later; (e) The needle-like habit is subsumed by the prismatic crystals habit gradually; (f) The needle-like habit eventually separates and re-dissolves, and the prismatic crystal clears its surface.

Figure 1 shows an example of a glycine particle transforming into a crystal induced by laser irradiation. Micrometer sized particles (an example indicated by the arrow in Figure 1(a)) formed in saturated glycine/D$_2$O solutions ($S = 1.0$) after laser irradiation for about 30 minutes. Once brought into the laser focus, the particle immediately starts to crystallize in a needle-like habit and continues to grow even when the laser is blocked, demonstrating that the solution has become super-saturated. After a few seconds, a crystal with a prismatic habit grows out on the needles and ultimately replaces the needle habit completely (see Supplementary Movie 1). Raman spectra of the two crystal habits (Figure S2) show distinct features in the low-frequency region, showing that the needle-like habit is the $\beta$ polymorph and the prismatic one the $\alpha$ polymorph of glycine consistent with previous observations.

Figure 2. Homogeneous crystal nucleation of glycine in D$_2$O solution monitored by broadband Raman spectroscopy. (a) Each represents a sum of 10 spectra with 1 s integration time. The inset on the left shows the 1410 cm$^{-1}$ peak intensity up to 2960 s. The inset on the right shows the spectral difference in the low frequency region after subtracting the Raman spectrum of pure D$_2$O. (b) Raman spectra of the glycine/D$_2$O solution in the few seconds before crystallization (integration time, 1 s). The inset shows the spectra in the fingerprint region with peak assignments.

Raman spectroscopic investigations of homogeneous crystallization of glycine from D$_2$O solution were performed to determine whether the appearance of particles in solution is a more general phenomenon. A droplet of 10 µL glycine/D$_2$O solution (starting saturation $S = 0.5$) was placed in a glass petri dish, with Drierite particles on the side, and covered. Broadband Raman spectra were recorded throughout the process. The measured power of the excitation laser (532 nm) at the sample was ~50 mW. Figure 2(a) shows the spectra at selected time points. By monitoring the intensity of the peak at 1410 cm$^{-1}$ (glycine CO$_2$ symmetric stretching; see inset of Figure 2(a) on the left), one can estimate that the glycine supersaturation quadruples from 0.5 (1.665 M) to 2 (6.66 M) just before
nucleation occurs. As the concentration increases, the double humped band peaking at ~60 cm\(^{-1}\) and 170 cm\(^{-1}\) (attributed to hydrogen-bond bending and stretching modes\(^{23}\)) flattens out. Subtracting the spectrum of pure D\(_2\)O reveals two hidden bands centered at ~70 cm\(^{-1}\) and 290 cm\(^{-1}\) (most likely due to glycine librations\(^{23}\)) and water in the solvation shell of glycine\(^{23}\)) emerging over time (see inset of Figure 2(a)). When the nucleation of a glycine crystal occurs at 2970 s, dramatic changes can be seen in the low-frequency region (see Figure 2(b)) by the appearance and growth of several sharp peaks near ~100 cm\(^{-1}\) due to lattice phonon modes of the \(\beta\) polymorph.\(^{22}\) From the difference spectra, it seems that the bands at 70 cm\(^{-1}\) and 290 cm\(^{-1}\) split into well-defined sharp peaks and upshift by about 30 cm\(^{-1}\) upon nucleation. It is worth to note that there was no sign of micro-particles in the solution before the homogeneous crystallization happened. The solution was subsequently dried, and the polymorph of the crystals determined using Raman spectroscopy. It was found that \(\alpha\) and \(\gamma\) polymorphs had formed from the initial \(\beta\) polymorph.

Single particles of glycine in solution were investigated by Raman spectroscopy to understand their formation and the role they play in the process of laser-induced crystallization. Glycine particles were observed in glycine/D\(_2\)O solution droplets placed in the petri dish with an initial saturation of \(S = 1.0\) and either aged overnight or irradiated with a 1 W (1040 nm) laser for 30 minutes. After this preparation stage, broadband Raman spectra were taken using the 532 nm laser at a sufficiently low power (50 mW) to slow down the process of particles transforming into crystals to allow study of the metastable particles.

Distinct features were observed in the low-frequency and finger-print region during the transition. An example is given in Figure 3 (also see Supplementary Movie 2). The spectral evolution shows that the particle experienced several stages before the transition to the crystal. The spectrum of the starting glycine/D\(_2\)O solution is shown for comparison (t = 16 s). The broad bands at ~500 cm\(^{-1}\) and 900 cm\(^{-1}\) are the background from the glass substrate. A particle was stabilized by the laser at t = 22 s, but changes in the spectrum can be only observed from t = 210 s. In the low-frequency region, it is very clear that a sharp peak at 105 cm\(^{-1}\) (due to a lattice phonon mode) appears from t = 210 s, gets stronger over time and peaks at t = 217 s (at which point significant morphological changes of the particle were observed by microscopy, see Figure 3(b)), then disappears for about 20 s before emerging again at t = 250 s, and finally dominates strongly from t = 283 s. A similar pattern is followed by the band at 60 cm\(^{-1}\) (see the difference spectra shown in Figure 3(b)) except that it vanishes from t = 283 s and splits into three peaks. Due to weak intensity, the 60 cm\(^{-1}\) band is not very clear before t = 218 s after subtraction of D\(_2\)O spectrum. By summing up multiple spectra, one can see a clear band at ~60 cm\(^{-1}\) despite the noise. This band is also observed from other particles in repeated experiments (for another example, see Figure S3). In the fingerprint region, peaks also get intense gradually but fluctuate over time, e.g., peaks at 483 cm\(^{-1}\) for CO\(_2\) rocking and 1410 cm\(^{-1}\) for CO\(_2\) symmetric stretching. The latter downshifted 10 cm\(^{-1}\) at t = 283 s, which implies a weakening of the CO\(_2\) double bond on formation of the final structural form. The sudden disappearance of the 2063 cm\(^{-1}\) peak and appearance of 2198 cm\(^{-1}\) peak at t = 282 s can be attributed to the polarization dependence.

Figure 3. Spectral evolution due to intermediate stages between microscopic particle and a fully-fledged crystal. (a) Raman spectra taken during transitions of glycine particles in D\(_2\)O; (b) Selected difference Raman spectra (with the spectrum at t = 16 s subtracted) in the low-frequency region at key times, along with the time-matched microscopy images. Scale bars, 5 \(\mu\)m; (c) Temporal evolution of Raman peak intensities in the low-frequency region for the 60 (blue), 105 (red), and 483 cm\(^{-1}\) (black) bands.
of N–D symmetric and antisymmetric stretching vibrations in crystalline glycine (see Figure S4 for polarized Raman spectra of glycine crystals) combined with the slow rotation of the crystal.

The stochastic temporal changes of the Raman peaks in the low-frequency region (see Figure 3(c)) show that the particle goes through intermediate phases before finally becoming fully crystalline at $t = 283$ s. The two bands in the low-frequency region ($60 \text{ cm}^{-1}$ and $105 \text{ cm}^{-1}$) followed the same pattern, while the trace of the $483 \text{ cm}^{-1}$ peak was slightly different, but they all stabilized at $283$ s. The strong fingerprint Raman bands but broad phonon-like peaks hidden in the $60 \text{ cm}^{-1}$ band suggest that the solid structure was in an amorphous state before $t = 282$ s. The relatively sharp peak at $105 \text{ cm}^{-1}$ is a sign of a structure that has partial ordering. Similar behavior has been observed in repeat experiments, while transitions from the $\beta$ polymorph to the $\alpha$ or $\gamma$ polymorph could be observed in some cases. Low-frequency Raman spectroscopy on randomly selected crystals after drying of the solution reveals that $38\%$ (8 out of 21) are $\gamma$-glycine with the rest being $\alpha$-glycine (see Figure S5).

Liquid-like clusters or droplets (hundreds of nanometers in diameter) in aqueous glycine solutions have been reported previously.$^{16,28}$ However, the physical reason for the presence of such pre-nucleation clusters is still unclear. Hidden liquid–liquid critical points could be the cause for concentration fluctuations leading to such clusters,$^{10,28}$ but such a critical point is yet to be found for aqueous glycine solutions. It has been reported that aging is required for nanodroplets to form in glycine/H$_2$O solution$^{30}$ and that these nanodroplets are a requirement for non-photoc hemical laser induced nucleation (NPLIN) to occur.$^{28}$ This is consistent with our observations: microscopic particles appear after aging or irradiation, and nucleation can only be induced when the particles are hit by the laser. Such a requirement for aging to improve the effectivity of NPLIN has also been reported for urea,$^{12}$ L-histidine,$^{13}$ hen egg white lysozyme,$^{14}$ and glucose isomerase,$^{15}$ suggesting that it is a general phenomenon.

Time-resolved broadband Raman spectroscopy demonstrates that the intermediate structures go through several stages before stabilizing the structure in the final crystalline state. Bands in the lattice phonon region show changes from a broad unstructured band to sharp split peaks, showing that the intermediate structure experienced transitions from amorphous or partially ordered to crystalline. The phonon–region band of the amorphous particles is distinct from that seen in highly concentrated solutions, showing it is a different phase. The amorphous state observed here is also different from the one detected at low temperature ($T = -60^\circ C$) in previous work,$^{22,31}$ where the latter has 7 water molecules for each glycine molecule. The amorphous state observed here has no significant OD-stretch Raman intensity (at $2392 \text{ cm}^{-1}$ and $2486 \text{ cm}^{-1}$) when amorphous glycine is detected, which implies little or no water is involved. For the same reason, it can be ruled out that the detected intermediate state is glycine dihydrate.$^{33}$ Therefore, the intermediate states detected here are amorphous glycine, and the glycine dihydrate phase is bypassed at room temperature in solution.

Several mechanisms have been proposed for NPLIN such as the optical Kerr effect, dielectric polarization, optical trapping, and heating, but no single theory can explain all the experimental observations. The temporal changes of the Raman peak intensity (Figure 3(c)) in our experiments show that there are a number of intermediates before crystallization. This is reminiscent of the process of pre-nucleation and redissolution characteristic of the classical Gibbs model of nucleation except here in an amorphous (or partially ordered) phase and under the influence of a laser field. The electric field of the laser may facilitate the crystallization from amorphous phase by reducing the free-energy barrier through an effect such as the optical Kerr effect, which may now operate on a micrometer-sized structure (as opposed to individual molecules) allowing the laser polarization to have an effect on polymorph selection. Early experiments on aqueous glycine solutions reported that the $\gamma$ polymorph was favored in NPLIN while the $\alpha$ polymorph was always produced in spontaneous nucleation.$^{30}$ This is consistent with our finding that $38\%$ of crystals produced in the NPLIN experiments are $\gamma$ polymorph. In contrast, crystals formed in a control sample (solution dried out naturally, without laser irradiation) turned out to be all $\alpha$ polymorph.

It is generally understood that (and indeed in homogeneous nucleation experiments we observe that), at room temperature, the least stable polymorph, $\beta$ glycine, is nucleated first and then transforms into the $\alpha$ or $\gamma$ polymorph depending on the amount of water present. However, in the single particle experiments, this Ostwald-rule route is not always followed, and the $\alpha$ or $\gamma$ polymorph could be seen to form directly from amorphous phase. There are two possible explanations: One is that the $\beta$ polymorph was short lived (less than the 1-s integration time used for Raman spectroscopy) and could not be temporally resolved or that the electric field of the laser indeed affects the alignment of glycine molecules and the $\alpha$ or $\gamma$ polymorph is directly formed.

There is mounting evidence for the existence of amorphous intermediates on the path from supersaturated solution to crystal. Similar to the case of sodium thiosulfate pentahydrate reported recently,$^{32}$ in aqueous glycine solutions the amorphous intermediate—detected here for the first time, using in situ low-frequency Raman spectroscopy—is metastable to such an extent that it inhibits crystal nucleation for more than 12 hours. However, it is also found here that the same amorphous intermediate is key to the process of non-photoc hemical laser induced nucleation (NPLIN) in glycine solutions. The requirement for “aging” strongly suggests that a similar mechanism is at work in other examples of NPLIN.

Supporting Information-A metastable amorphous intermediate is responsible for laser-induced nucleation of glycine

Zhiyu Liao, Klaas Wynne
School of Chemistry, University of Glasgow, G12 8QQ, UK

METHODS

Sample preparation. Glycine (PlusOne Glycine, GE Healthcare, 99.7%) and D$_2$O (Sigma-Aldrich, 99.9%) were used as received without any further purification. Saturated glycine/D$_2$O solution was prepared by dissolving 0.22 g of glycine in 1 g of D$_2$O in a clean glass vial. The solution was shaken at 60°C for 8 hours at a speed of 500 rpm, then gradually cooled down to room temperature. For the samples used for microscopy and Raman spectroscopy, a droplet of 10 µL saturated solution was placed on the glass window of a petri dish (12 mm Glass Based Dish, Thermo Scientific), along with 1 mL of the same solution on the side to slow evaporation. The dish was covered with a lid during the experiments.

Microscopy and Raman setup. The setup for microscopy and Raman spectroscopy was home-built on a double-deck inverted microscope (Olympus IX73), a schematic is depicted in Figure S1. Phase contrast microscopy images and videos were captured by using a 60×/0.7 N.A. objective (Olympus, UCPlanFL N Ph2) and a CMOS camera (Teledyne Dalsa, Genie Nano-1GigE). Two laser sources were aligned into the microscope objective simultaneously, as the high power 1040 nm laser (Spectra-Physics, Spirit One, 8 W) intended for optical tweezing and trapping, and the 532 nm laser with linear polarization (Laser Quantum, gem 532, 500 mW) for Raman excitation. BragGrate™ bandpass and notch filters (OptiGrate) were used to achieve ultra-low frequency Raman spectroscopy, it allows Raman detection as low as 10 cm$^{-1}$. For detection, a spectrometer (Andor, Shamrock 500i with 600 groove/mm grating) and a CCD camera (Andor, iDUS 401) were employed. An optical fiber with 50 µm core size was used for Raman collection. The spectral resolution of the system is ~ 2 cm$^{-1}$.

DATA PROCESSING

Raman spectra obtained from glycine/D$_2$O solution, pure D$_2$O and glycine micro-particles in solution in the low frequency region (10 - 500 cm$^{-1}$) were Bose-Einstein corrected to remove the temperature dependence of the vibrations. The processing was done in MATLAB (MathWorks) by applying the Bose-Einstein factor to the raw spectra ($I/(1+n)$) after background subtraction (dark counts of CCD detector), where $n = 1/(e^{\hbar \omega/(kT)} - 1)$, $\omega$ is the frequency, and $I$ the Raman amplitude at $\omega$.

Figure S1. Schematic of the optical tweezing and broadband Raman spectroscopy system based on an inverted double-deck microscope.
Figure S2. Low-frequency Raman spectra obtained from a crystal with a needle-like habit (blue) and one with a prismatic habit (red) shown in Figure 1(f).

Figure S3. Another example of spectral evolution due to intermediate stages between microscopic particle and a fully-fledged crystal, time-matched microscopy images shown on the right. The spectra are subtracted by spectrum of D$_2$O taken at $t = 2$ s when the particle was not present in the laser focus.
