Fractons are particles with restricted mobility. We give a symmetry-based derivation of effective field theories of gapless phases with fractonic topological defects, such as solids and supersolids, using a coset construction. The resulting theory is identified as the Cosserat elasticity theory, which reproduces the conventional symmetric elasticity theory at low energies. The construction can be viewed as a dynamical realization of the inverse Higgs mechanism. We incorporate topological defects such as dislocations and disclinations, which are nontrivially related by the Bianchi identities of defect gauge fields. The origin of the fractonic nature of defects in those systems can be traced back to the semi-direct product structure of translational and rotational groups. The construction is immediately extendable to higher dimensions and systems with broken translational symmetries, such as solids, supersolids, and vortex crystals. We identify Wess-Zumino terms in supersolids, which induce quasiparticle scatterings on topological defects.

Introduction. – Fracton phases are a new class of quantum phases that host excitations with mobility restrictions \cite{Qi2018, Park2017}. These excitations cannot move at all, or their motions are restricted in subdimensional spaces. Such fracton phases were first discussed in exactly solvable lattice models \cite{Affleck1987, Haldane1988, Levin2007, Reading2015, Bonderson2008}. It has been realized that symmetric tensor gauge theories \cite{Rozali2015, Short2016, Fidkowski2016, Chamon2018} can encode mobility restrictions through the conservation laws of multipole moments. The elasticity theory of two-dimensional crystals was shown to be dual to a symmetric tensor gauge theory, and disclinations in solids are fractonic \cite{Hirono2017}. Similar dualities can also be formulated for other systems such as supersolids \cite{Hirono2018b} and vortex crystals \cite{Crossley2018}.

The relation between the immobility of a particle and the conservation of multipole moments \cite{Hirono2017, Park2017} can be seen as follows. Suppose that there is a particle number current \( j_\mu (x) \), which is conserved, \( \partial^\mu j_\mu = 0 \). If we define the dipole current by \( (J^a)_\mu (x) = x^a j_\mu \), where \( a \) is a spatial index, its divergence reads

\[
\partial^\mu (J^a)_\mu = j^a. \tag{1}
\]

This relation means that the flow of a current should be accompanied by the creation/destruction of dipoles. Therefore, if the dipole current is conserved, \( \partial^\mu (J^a)_\mu = 0 \), the particle number current vanishes, \( j^a = 0 \), which means that a particle is immobile.

In the case of a solid in \( 2+1 \) dimensions, disclinations and dislocations correspond to \( j_\mu \) and \((J^a)_\mu\), respectively. When the dipole excitations (dislocations) are gapped, the conservation of dipoles is energetically enforced, and disclinations are immobile. In this way, the relation (1) plays a key role in realizing fractons.

In this work, we discuss the construction of the effective field theories of gapless phases with fractonic topological defects, such as solids and supersolids, in which the translational symmetry is spontaneously broken. We employ a coset construction \cite{Park2016, Balachandran2018}, which is a systematic method of writing down the effective Lagrangian of low-energy theory associated with a spontaneously symmetry breaking (SSB). Topological defects appear as a result of an SSB, and they can be incorporated in the effective theory. In this approach, the relations between the defect currents (1) can be traced back to the underlying structure of the symmetry group and its breaking pattern. The geometric origin of the fractonic feature becomes transparent, and Eq. (1) reflects the fact that the rotational symmetry acts nontrivially on the translational symmetry. Its origin is the same as the the Bianchi identities of the torsion and curvature of the Riemann-Cartan spacetime. The coset construction clarifies this connection.

Coset construction and the Cosserat elasticity. – A coset construction is a method for constructing the effective theory of Nambu-Goldstone (NG) modes associated with an SSB. The obtained effective theories are universal, in the sense that their forms are dictated by the symmetry breaking patterns, and microscopic details are encoded in the values of phenomenological parameters. Although it was invented for the breaking of internal symmetries, it allows for a number of generalizations, such as spacetime symmetries \cite{Park2016b, Nishino2016, Park2017b, Hirono2018a} and higher-form symmetries \cite{Park2018, Hirono2018c}.

We here perform a coset construction for solids and supersolids in \( D = d + 1 \) spacetime dimensions. We consider non-relativistic systems and the underlying spacetime symmetry is the Galilean group. This symmetry is spontaneously broken because of the formation of solids or supersolids. In the case of supersolids, we have an additional \( U(1) \) symmetry, which is also spontaneously broken. In a coset construction, we first parametrize the coset space, and for each broken generator we have a NG field, which is a degree of freedom of the low-energy theory.

Solids are realized as a result of the SSB of the Galilean group, \( \text{Gal}(d) \), down to \((\mathbb{Z}^d \rtimes \mathcal{G}) \times \mathbb{R}\), where \( \rtimes \) is the semi-direct product, \( \mathbb{R} \) is the time translation, \( \mathbb{Z}^d \subset \mathbb{R}^d \) is the remaining discrete translational symmetries, and \( \mathcal{G} \subset \text{SO}(d) \) is a discrete subgroup of \( \text{SO}(d) \) unbroken in the ground state. Under the formation of a solid, the broken generators are spatial translations \( Q_a \), rotations \( L_{ab} \), and Galilean boosts \( B_\mu \). We denote the corresponding NG fields as \( u^a (x) \), \( \theta^a_\mu (x) \), and \( v^a (x) \). The field \( u^a \) represents the deviation of the material coordinate from its equilibrium position, and is called...
the displacement field in the elasticity theory. In the case of supersolids, we have an additional charge, $Q_0$, and its corresponding NG field, $u^0$, which can be identified as the fluctuating part of the $U(1)$ phase of the condensate (divided by the mass $m_0$ of a particle). The coset space is parametrized by the NG fields as

$$\Omega = e^{iux} \tilde{P}_u e^{iu(x)} B_u e^{iu(x)} Q_0 e^{iu(x)} Q_0 e^{i\omega^{ab}(x)L_{ab}}.$$  

(2)

The building blocks of the low-energy theory is provided by the Maurer-Cartan (MC) form, $\omega = -i\Omega^{-1}d\Omega$. The MC form can be expanded by generators as

$$\omega = \omega^a_P A^a + \omega^{ab}_J J_{ab} + \omega^0 Q_0 + \omega^a_Q Q_a + \omega^a_L L_{ab} + \omega^a_B B_a.$$  

(3)

From the components proportional to broken generators, we can read off the covariant derivatives of NG fields, with which we can write down the invariant Lagrangian.

A subtlety for the broken spacetime symmetry is that, unlike the case of internal symmetries, there is no one-to-one correspondence between a broken symmetry generator and a gapless NG mode [19]. This is because of the nontrivial commutators among the generators, which are reflected in the covariant derivatives of NG fields. Indeed, the leading order covariant derivative of the translational NG fields $u^a$ reads

$$d_\theta u^a \equiv du^a - \theta^a_b \wedge dx^b.$$  

(4)

The NG fields $u^a$ and $\theta^a_b$ are transformed under the infinitesimal a translation and rotation as

$$u^a \mapsto u^a - \alpha^a - \beta^a_b x^b, \quad \theta^a_b \mapsto \theta^a_b - \beta^a_b,$$  

(5)

where $\alpha^a$ and $\beta^a_b$ are transformation parameters for the translation and rotation, respectively. Equation (4) is indeed invariant under those transformations. Intuitively speaking, the reason why the covariant derivative of $u^a$ include $\theta^a_b$ is that the translational NG field $u^a$ is nontrivially transformed under rotations. In such cases, one may eliminate certain NG fields. Imposing $\partial_b u^a - \theta^a_b = 0$ eliminates the antisymmetric part of $\partial_b u^a$, which results in the conventional elasticity theory [25-31] written by the symmetric part $\partial_b u^a \equiv (\partial_b u^a + \partial_a u^b)/2$. However, whether one should impose the constraint depends on the microscopic details of the system [32]. This choice leads to the differences in the number of gapped physical modes.

Here, we choose not to eliminate the rotational NG fields. After the elimination of boost NG fields through an inverse Higgs constraint, the effective Lagrangian for solids, to the leading order, is written in terms of both translational and rotational NG fields as

$$L = -\frac{1}{2} C^{ab} d_\theta u^a \wedge \star d_\theta u^b - \frac{1}{2} C^{abcd} \star d\theta^{ab} \wedge \star d\theta^{cd},$$  

(6)

where $\star$ is the Hodge star operator. This Lagrangian can be identified with that of the Cosserat elasticity theory [33, 34]. The Cosserat theory is a generalization of the conventional elasticity theory, and it contains rotational degrees of freedom, in addition to the displacement field. Such a generalization is necessary to explain the properties of porous materials [35, 36] or mechanical metamaterials [37]. Because of the nontrivial covariant derivative (4), the rotational NG field $\theta^a_b$ has a mass term. This introduces characteristic scales in the theory, which are absent in the conventional elasticity. If we consider the long-wavelength limit, the mass term is dominant compared to the kinetic term for $\theta^a_b$, and its EOM is $\theta^a_b = \partial_b u^a$, where $[\cdots]$ indicates antisymmetrization. At sufficiently low energies, those gapped modes can be ignored, and the remaining part for $\partial_b u^a$ is the symmetric part. Then, the Lagrangian (6) reduces to the classical elasticity theory. Thus, we have shown that the Cosserat theory arises naturally from the coset construction, and it can be understood as a dynamical realization of the inverse Higgs phenomenon [19, 38].

Fractonic topological defects.– Let us introduce topological defects. In a crystal, there are two kinds of defects, dislocations and disclinations. The former are associated with the translational symmetry breaking $\mathbb{R}^d \to \mathbb{Z}^d$, and the latter are due to the broken rotational symmetry. Dislocations and disclinations can be identified with the multivalued [39] parts of the fields $u^a$ and $\theta^a_b$, respectively. We decompose the covariant derivatives of phonon fields into continuous part and singular part as

$$d_A u^a = du^a - \theta^a_b \wedge dx^b + A^a, \quad d_A \theta^a_b = d\theta^a_b + A^a_b,$$  

(7)

where we have introduced $A^a \equiv d u^a_{(s)}$ and $A^a_b \equiv d \theta^a_{(s)}$, and the subscript (s) indicates the singular part.

---

1 We normalize $Q_0$ as the total mass, which is the particle number times the mass $m_0$ of a particle.

2 See Supplemental Material for the derivation of effective theories.

3 We have chosen elastic constants $C_{iajb} = C_{ab}\delta_{ij}$, $C_{iabjcd} = C_{abcd}\delta_{ij}$. More general cases can be considered straightforwardly.
The way the defect fields, \( A^a \) and \( A_b^a \), enter is the same as that of gauge fields. We can promote the translational and rotational transformations to local ones, \( \alpha^a \rightarrow \alpha^a(x) \) and \( \beta^b \rightarrow \beta^b(x) \), by simultaneously transforming \( A^a \) and \( A_b^a \) as
\[
A^a \rightarrow A^a + d\alpha^a + d\beta^b \partial_b^a, \quad A_b^a \rightarrow A_b^a + d\beta^a_b.
\]
The gauge-invariant field strengths of the defect gauge fields are given by
\[
\star J^a \equiv dA^a + A_{ab} \wedge dx^b, \quad \star J^a_b \equiv dA_a^b.
\]
We can identify \( \star J^a \) as the dislocation current, and \( \star J^a_b \) as the disclination current. The integration of \( \star J^a \) over a surface \( S \) gives the Burgers vector, \( b^a = \int_S \star J^a \). By taking the exterior derivative of Eq. (9), we obtain the following relations,
\[
d \star J^a = \star J^{ab} \wedge dx^b, \quad d \star J^{ab} = 0.
\]
The divergence of the dislocation current is equal to the disclination current. This relation corresponds to Eq. (1) and hence represents the fractonic feature of the defects. In this derivation, the geometric origin [40] of the fractonic behavior is manifest: the inter-relation between the defect currents can be traced back to the semi-direct product structure of the translational and rotational groups. The origin of those relations the same as are the Bianchi identities of torsion and curvature in a Riemann-Cartan spacetime [41, 42].

Let us make several comments. We have shown that the inclusion of rotational NG field, which is a gapped mode, gives rise to the Cosserat elasticity theory, and the currents of dislocations/disclinations, which are defects associated with translations/rotations, satisfy the Bianchi identities (10). This construction depends only on the symmetry breaking pattern, and is generalizable to situations where translations and rotations are spontaneously broken, such as supersolids and vortex crystals. For each of those systems, we can construct a Cosserat-type theory via the inclusion of gapped rotational NG fields. The present derivation is for \( D \)-dimensional spacetime, where \( J^a \) and \( J^a_b \) are both \( (D-2) \)-form, and the dislocations and disclinations are \( (D-3) \)-dimensional objects. They are extended objects in general and the motions of disclinations are constrained by the relation (10). In \( 3+1 \) dimensions, those defects are lines [43].

Dual gauge theory. —We can perform a duality transformation of the Cosserat elasticity theory [44, 45]. In the dual gauge theory, NG fields couple to the topological defects electrically. For notational simplicity, let us here take the elastic constants to be of the form, \( C_{ab} = c\delta_{ab}, \, C_{abcd} = c'\delta_{ac}\delta_{bd} \). The Lagrangian of the dual gauge theory reads
\[
L_{\text{dual}} = -\frac{c}{2} f^a \wedge \star f_a - \frac{c'}{2} f^{ab} \wedge \star f_{ab},
\]
where the gauge-invariant field strengths are defined as
\[
f^a \equiv da^a, \quad f^{ab} \equiv da^{ab} + \tilde{c} dx^b \wedge a^a,
\]
with \( \tilde{c} \equiv c/c' \). The gauge fields are related to the original fields by \( da^a = \star d\rho^a, \, da_b^a = \star d\beta_{ab} \). In the presence of topological defects, we also have source terms, \( L_a = a^a \wedge \star J_a + a^{ab} \wedge \star J_{ab} \). A dislocation sources translational gauge field \( a^a \), and a disclination sources rotational gauge field \( a^{ab} \). The field strengths (116) are invariant under the gauge transformations,
\[
a^a \rightarrow a^a + d\lambda^a, \quad a^{ab} \rightarrow a^{ab} + d\rho^{ab} + \tilde{c} dx^b \wedge \lambda^a,
\]
where \( \lambda^a \) and \( \rho^{ab} \) are \( (D-3) \)-form transformation parameters. By varying the dual action with respect to the gauge fields, we obtain a type of Maxwell’s equations,
\[
d^\dagger f^a + \star^{-1}(\star f^{ab} \wedge dx^b) = J^a, \quad d^\dagger f^{ab} = J^{ab},
\]
where \( d^\dagger \) is the codifferential. By applying an exterior derivative on \( f^a \) and \( f^{ab} \) in Eq. (116), we obtain the Bianchi identities,
\[
d f^a = 0, \quad df^{ab} + \tilde{c} dx^b \wedge f^a = 0.
\]
Those equations correspond to the conservation of momentum and angular momentum, respectively. Equations (119) and (15) constitute the set of equations of motion in the presence of dislocations and disclinations.

\[\text{4} \] The derivation and equations of motion in terms of electric and magnetic fields are given in Supplementary Material.
To understand its dynamics, let us focus on $D = 2 + 1$ and rewrite the equations using electric and magnetic fields, which are introduced for each of $f^a$ and $f^{ab}$ by
\begin{equation}
 f^a = \epsilon^a_b \left( (E^b)_i dx^j \wedge dx^0 + \frac{1}{2} \epsilon_{ij} B^b dx^i \wedge dx^j \right), \tag{16}
\end{equation}
\begin{equation}
 f^{ab} = \epsilon^{ab} \left( \omega dx^j \wedge dx^0 + \frac{1}{2} \epsilon_{ij} B^a dx^i \wedge dx^j \right). \tag{17}
\end{equation}
Using the Maxwell’s equations and Bianchi identities, we can derive closed equations for the translational electric fields $(E^a)_i$,
\begin{equation}
 (\partial_0)^2 (E^a)_i = \partial_i \partial^j (E^a)_j + \epsilon^a_b \partial_j (E^j)_k - \frac{c}{2} \epsilon^a \epsilon^b \epsilon^c (E^c)_j, \tag{18}
\end{equation}
where $\partial_i \equiv \epsilon_{ij} \partial^j$ is the derivative in the transverse direction. If we see this in the momentum space, in the long-wavelength limit, $k \to 0$, the antisymmetric part of the translational electric fields $(E^a)_i$ satisfies $(\omega^2 - \bar{c}) \epsilon^a_i (E^a)_i = 0$, where $\omega$ is the frequency. Thus, the antisymmetric part is gapped and its gap is given by $\sqrt{\bar{c}}$. At low energies, this part can be dropped, and the symmetric tensor gauge theory [10, 11] is reproduced.

Cosserat-type theory for supersolids– The current construction can be straightforwardly extended to supersolids. A supersolid is a phase of matter with both crystalline and superfluid orders, which correspond to the spontaneous breaking of translational symmetries and a $U(1)$ symmetry [46]. Using a coset construction, the low-energy effective Lagrangian of supersolids to the quadratic order in fields is given by
\begin{equation}
 L = - \frac{c_0}{2} C_{ab} dx^a \wedge *dx^b - \frac{c}{2} C_{abcd} dx^a \wedge *dx^b \wedge *dx^c - \frac{c_0}{2} f^a \wedge *dx^b - g f^a \wedge *f^b \wedge *f^c + \overline{\theta}_a, \tag{19}
\end{equation}
where $u^0$ is the fluctuating part of the $U(1)$ phase divided by $m$, and $\overline{\theta}_a = \epsilon_{a_1 a_2} dx^{a_1} \wedge \cdots \wedge dx^{a_2}$ is a constant $(D - 2)$-form. The last term [47] arises as a Wess-Zumino term, as we discuss later. This effective theory contains a gapped rotational NG mode $\theta^a_b$, and is a Cosserat-type theory for supersolids. In the low-energy limit, it reduces to the conventional effective theory for supersolids [12]. The dual gauge theory for supersolids is given by
\begin{equation}
 L_{\text{dual}} = - \frac{c_0}{2} f^0 \wedge *f^0 - \frac{c}{2} f^a \wedge *f^a - \frac{c'}{2} f^{ab} \wedge *f^{ab} - g * f^0 \wedge *f^a \wedge \overline{\theta}_a. \tag{20}
\end{equation}
If we introduce the electric and magnetic fields for superfluid phonons by
\begin{equation}
 f^0 = e_i \omega dx^i \wedge dx^0 + \frac{1}{2} \epsilon_{ij} b dx^i \wedge dx^j, \tag{21}
\end{equation}
the last term of Eq. (20) is written as
\begin{equation}
 - g \left[ \bar{b} (E^a)_a + e_a B^a \right] dx^0 \wedge dx^1 \wedge dx^2. \tag{22}
\end{equation}
These are mixed $E \cdot B$-type terms and are responsible for a generalized Witten effect [13]. By varying the dual action (20) with respect to the gauge fields, one obtains the corresponding Maxwell’s equations,
\begin{equation}
 d^\dagger \left( f^0 + g_0 * f^0 \wedge \overline{\theta}_a \right) = J^0, \tag{23}
\end{equation}
\begin{equation}
 d^\dagger \left( f^a - \bar{g} * f^0 \wedge \overline{\theta}_a \right) + *^{-1}(* f^{ab} \wedge dx^b) = J^a, \tag{23}
\end{equation}
\begin{equation}
 d^\dagger f^{ab} = J^{ab}, \tag{23}
\end{equation}
where we set $g_0 \equiv g/c_0$ and $\bar{g} \equiv g/c$.

Wess-Zumino terms for supersolids.–The effective Lagrangian can contain terms which are varied by total derivatives under symmetry transformations. Such terms arise when the Lie algebra of the symmetry group allows for nontrivial central extensions. These contributions are called Wess-Zumino terms [48, 49], and are necessary to capture the quantum anomalies in the UV theory. They can be identified by finding invariant and closed $(D + 1)$-forms made out of MC forms. Corresponding to the centrally extended algebra,
\begin{equation}
 [B_a, P_b] = -i \delta_{ab} Q_0. \tag{24}
\end{equation}

$^5$ We provide the derivation of the terms and computation of cross sections in Supplementary Material.
we have the following term,

\[ L_{D=3}^{WZ} = \frac{\kappa}{2} \epsilon_{abc} v^a dv^b \wedge \star j_m, \quad (28) \]

where the boost NG field \( v^a \) is written by the \( U(1) \) NG field as \( v^a = \partial^a u^0 \) after imposing an inverse Higgs constraint.

The Wess-Zumino terms (25) and (28) are total derivatives and do not affect the EOM in the absence of topological defects. However, they change the identifications of Noether currents, and when topological defects are present, these terms induce nontrivial scattering effects. The elastic scattering of lattice phonons off superfluid vortices through Eq. (25) is studied in Ref. [47]. Because of the fact that they are Wess-Zumino terms, the coupling constants for the processes induced by those terms are fixed by the symmetry algebra, and are model independent.

Let us consider examples of such processes. The presence of a dislocation leads to the singular part of \( u^a \) of the form, \( \epsilon_{ijk} \partial^i \partial^j u^a = b^a \delta_k(x_T) \), where \( b^a \) is the Burgers vector, and \( \delta_k(x_T) \) is the transverse delta function. The term (25) leads to the following Lagrangian density,

\[ -\rho_0 u^0 \epsilon_{abc} b^a \hat{u}^b \delta^i(x_T) + O(u^3). \quad (29) \]

Thus, a superfluid phonon with energy/momentum \( (\omega, k) \) can be converted to a lattice phonon with \( (\omega', k') \) and polarization \( \epsilon' \) via a scattering off a dislocation. The infinitesimal cross section of this process by a line element \( d\ell \) of the dislocation is

\[ d\sigma = \frac{1}{2 \omega v_s} |\mathcal{M}|^2 \left( \frac{d\theta}{4\pi v^2} \right) d\ell = \frac{\rho_0}{\rho_s} \frac{\omega}{2\pi v_s v^2} |(b \times \epsilon') \cdot n| d\theta d\ell, \quad (30) \]

where \( n \) is the unit tangent vector to the dislocation, \( \theta \) is the scattering angle, and \( v \) and \( v_s \) are the velocities of transverse elastic phonons and superfluid phonons, respectively. The cross section is determined by the relative orientations of the Burgers vector \( b \), the polarization \( \epsilon' \) of the final-state lattice phonon, and the direction \( n \) of the dislocation. For example, for a screw dislocation, \( b \propto n \), the cross section vanishes. We also note that the cross section is enhanced at small superfluid densities.

The Wess-Zumino term (28) leads to scattering processes on superfluid vortices. In 2+1 dimensions, a vortex is a point-like object. If we consider a vortex placed at the origin, we have \( \epsilon_{abc} \partial^a \partial^b u^0 = \frac{2\pi}{m} \delta(x) \), where \( \delta(x) \equiv \delta(x)\delta(y) \). The term (28) is written in the presence of a vortex as

\[ \frac{2\pi}{m} \kappa \rho_0 \delta(x) \left( u^0 \nabla \cdot u - u^a \partial_a u^0 + O(u^3) \right). \quad (31) \]

This indicates that superfluid phonons and lattice phonons can be converted via the scatterings off a superfluid vortex. Let us consider the process of a transverse lattice phonon with \( (\omega, k) \) and polarization \( \epsilon \) converted on a vortex into a superfluid phonon with \( (\omega', k') \). The matrix element of the this process is

\[ i\mathcal{M} = \frac{2\pi\kappa}{m} \sqrt{\rho_0 \rho_s} \omega k' \cdot \epsilon, \quad (32) \]

and the differential cross section is given by

\[ \frac{d\sigma}{d\theta} = \frac{\pi \rho_0}{2 \rho_s m^2 v_s^2} \frac{\kappa^2}{kk' \sin^2 \theta}, \quad (33) \]

where \( \theta \) is the scattering angle.
Conclusions.—We derived effective field theories of gapless phases with fractons, such as solids and supersolids, using a coset construction. A dynamical realization of the inverse Higgs phenomenon naturally leads to the Cosserat theory of elasticity. The topological defects appear as the singular parts of the NG fields, and the corresponding currents obey the relation (10), which plays a key role so that the disclinations behave as fractons. The derivation clarifies the geometric origin of the fractonic nature: it comes from the semi-direct product structure of the translational and rotational groups. The current construction can be applied to systems where translational symmetry is broken, and we can understand why fractons appear in solids, supersolids, vortex crystals, and so on. We identified Wess-Zumino terms in supersolids, which result in nontrivial scattering process involving topological defects. When superfluid density is small, the coupling constants of these processes are fixed by the algebra [Eq. (24) and (27)], and hence are model independent.

I. SUPPLEMENTARY MATERIAL

A. Derivation of effective Lagrangians via a coset constructions

Here we give the details of the derivations of the low-energy effective theories for solids and supersolids using a coset construction. Below, $d$ indicates the spatial dimension, and $D = d + 1$ denotes the spacetime dimension. We use the mostly-plus convention for the Minkowski metric, $\eta_{\mu\nu} = (-1,+1,\ldots,+1)$.

1. Symmetry and its breaking pattern

Galilean group is the spacetime symmetry group of non-relativistic systems. The generators of the Galilean group in $d$-spatial dimensions, Gal$(d)$, satisfy the Galilean algebra $\mathfrak{gal}(d)$, whose non-vanishing commutation relations are

$$
[J^{ab}, J_{cd}] = -4i\eta^{[a}_{[c} J^{b]}_{d]}, \quad [J_{ab}, P_c] = 2i\eta_{[a} P_{b]}^c, \\
[J_{ab}, B_c] = 2i\eta_{[a} B_{b]}^c, \quad [B_a, H] = iP_a,
$$

where $J_{ab}$, $P^a$, and $B^a$ are the generators of rotation, spatial translation, and Galilean boost, respectively, and $H$ corresponds to the non-mass energy. The Bargmann algebra $\mathfrak{b}(d)$ is a central extension of the Galilean algebra $\mathfrak{gal}(d)$ with the following relation,

$$
[B_a, P_b] = -i\eta_{ab} Q_0,
$$

where $Q_0$ represents the total mass, which can be written as $Q_0 = -mQ$ where $m$ is the mass of a particle, and $Q$ is the particle number. Since $Q$ is a $U(1)$ charge and commute with every other generator, this is a central extension. The Bargmann algebra can be obtained as the non-relativistic limit of the Poincaré algebra [51]. For $d \geq 3$, this is the only central extension. In the case of two spatial dimensions, Galilean group Gal$(2)$ admits another central extension. In addition to Eq. (35), we have the following non-vanishing commutation relations,

$$
[B_a, B_b] = -i\epsilon_{ab}^c Q_0.
$$

In addition to $m$, there is another parameter $\kappa$, which can be interpreted as the spin of a particle [50].

The realization of supersolids spontaneously breaks those symmetries,

$$
\mathrm{Gal}(d) \times U(1) \rightarrow (\mathbb{Z}^d \rtimes \mathcal{G}) \times \mathbb{R},
$$

where $\times$ is the semi-direct product and $\mathcal{G} \subset \mathrm{SO}(d)$ is a discrete subgroup of $\mathrm{SO}(d)$, $\mathbb{R}$ is the time translation and $\mathbb{Z}^d$ represents discrete spatial translations. The low-energy behavior of solids can be described by a $d$-dimensional field $\phi^a(t, x)$. The field $\phi^a(t, x)$ can be regarded as the comoving coordinate of the material. The action of internal rotational and translational symmetries are given by

$$
\phi^a \rightarrow \xi^a_b \phi^b, \quad \xi^a_b \in \mathrm{SO}(d), \\
\phi^a \rightarrow \phi^a + c^a, \quad c^a \in \mathbb{R}^d.
$$
For supersolids, to describe the $U(1)$ symmetry breaking, we introduce an additional scalar field $\phi^0(t, x)$, which is shifted by the $U(1)$ symmetry,

$$
\phi^0 \mapsto \phi^0 + c^0, \quad c^0 \in \mathbb{R}/2\pi \mathbb{Z} \simeq U(1).
$$

(39)

The action of the $U(1)$ symmetry and the translations can be combined into a four-vector notation,

$$
\phi^A \mapsto \phi^A + c^A,
$$

(40)

where $c^A$ are constants with index $A = (0, a)$. Correspondingly, we introduce a four-vector notation $Q_\mu = (Q_0, Q_a)$.

When the supersolid or solid is in the ground state, we can choose the comoving coordinates $\phi^A$ to coincide with the spacetime coordinates $x^A = (x^0, x^a) = (-t, \delta^i_a x^i)$,

$$
\langle \phi^a \rangle = x^a, \quad \langle \phi^0 \rangle = x^0.
$$

(41)

The fields $\phi^a$, $\phi^0$ can be written as

$$
\phi^a = x^a + u^a, \quad \phi^0 = x^0 + u^0,
$$

(42)

where $u^a$ is the displacement field, $\phi^0$ (or $u^0$) is related to the $U(1)$ phase $\varphi$ of the superfluid order parameter by $\phi^0 = \varphi/m$.

Let us summarize the unbroken and broken generators for supersolids:

\begin{align*}
\text{unbroken} & : \bar{P}_\mu = P_\mu + Q_\mu, \quad \text{spacetime translation} \\
& \hspace{1em} J_{ab} = J_{ab} + L_{ab}, \quad \text{spatial+internal rotation} \\
\text{broken} & : Q_\mu = (Q_0, Q_a), \quad \text{internal } U(1) \times \mathbb{R}^d \\
& \hspace{1em} L_{ab}, \quad \text{internal rotation} \\
& \hspace{1em} B_a, \quad \text{Galilean boost}
\end{align*}

(43)

Note that the ground state is invariant under the combinations of spacetime and internal translations/rotations [20]. The combined generators are written, for translation, as $\bar{P}_\mu = (-H - mQ, P_\mu + Q_\mu)$.

2. Computations of covariant derivatives

The low-energy degrees of freedom are the coordinate of the coset space associated with the symmetry breaking (37). In the following, we call those fields as Nambu-Goldstone (NG) fields. We can parametrize the coset space as

$$
\Omega = e^{i\omega' P_\mu e^{i\nu'(x)} B_a e^{i\nu'(x)} Q_\mu e^{i\theta^{ab}(x)} L_{ab}},
$$

(44)

where $\nu'(x)$, $\nu'(x)$ and $\theta^{ab}(x)$ are the NG fields of Galilean boosts, $U(1)$ and internal translations, and internal rotations, respectively. The building blocks of the low-energy theory can be obtained from the Maurer-Cartan (MC) form,

$$
\omega \equiv -i\Omega^{-1} d\Omega.
$$

(45)

The MC form can be expanded by generators as

$$
\omega = \omega^A \bar{P}_A + \omega^{ab} J_{ab} + \omega^\mu Q_\mu + \omega^{ab}_L L_{ab} + \omega^a B_a.
$$

(46)

The coefficients of the unbroken combined translation and rotational generator, $\bar{P}_A$, $J_{ab}$ give the vielbein and spin connection,

$$
\omega^A_\mu = e^A_\mu dx^\mu, \quad \omega^{ab}_\mu = \omega^{ab}_\mu dx^\mu.
$$

(47)

The 1-forms proportional to the broken generators give the covariant derivatives $D_A$ of NG fields,

$$
\omega^\nu_Q = e^A_\mu D_A u^\nu dx^\mu, \\
\omega^{ab}_L = e^A_\mu D_A \theta^{ab} dx^\mu, \\
\omega^a_B = e^A_\mu D_A \phi^a dx^\mu.
$$

(48)

By using the commutation relations, we have

$$
\begin{align*}
& e^{-iv'B_a} P_a e^{iv'B_c} = P_a - v_a Q_0, \\
& e^{-iv'B_a} P_0 e^{iv'B_c} = P_0 - v_a P_a + \frac{1}{2} v^2 Q_0, \\
& e^{-i\theta'q_A} \bar{P}_\mu e^{i\theta'q_A} L_a = (\bar{P}_0, P_a + \xi_a q_B),
\end{align*}
$$

(49)
where \( \xi^a_b \in SO(d) \) is the rotational matrix associated with \( \theta \),

\[
\xi^a_b = (e^{i\theta L})^a_b.
\]  

(50)

Using those relations, we can identify the components of MC 1-forms as

\[
\begin{align*}
\omega^0_\mu & = dx^\mu, \\
\omega^a_\mu & = dx^a - v^a dx^\mu, \\
\omega^0_Q & = du^0 - v_a dx^a + \frac{1}{2} v^2 dx^0 - \frac{\kappa}{2} v^a v^b \epsilon_{ab}, \\
\omega^a_Q & = d\phi^b \xi^a_b - dx^a + v^a dx^0, \\
\omega^a_B & = dv^a.
\end{align*}
\]

(51)

The term proportional to \( \kappa \) in \( \omega^0_Q \) can exist only in \((2 + 1)\)-dimensional spacetime. The part proportional to the rotational generator \( L_{ab} \) is written as

\[
\omega^a_{\mu L} L_{ab} = -ie^{-i\theta^a L_{ab}} d e^{i\theta^b L_{ab}}.
\]

(52)

From the \( \omega^A_\mu \), we can read off the vielbein,

\[
e^A = \left( \frac{dx^0}{dx^a - v^a dx^0} \right).
\]

(53)

In terms components,

\[
e^A_\mu = \delta^A_\mu - \delta^a_\mu v^a, \quad e^A_\mu \equiv (e^A_\mu)^{-1} = \delta^A_\mu + \delta^0_\mu v^0,
\]

with \( v^\mu = (0, v^a) \). They satisfy \( e^a_\mu v^\mu = 0 \). We can read off the components of \( \omega^0_Q, \omega^a_Q, \) and \( \omega^0_B \) as

\[
\begin{align*}
(\omega^0_Q)_\mu & = \partial_\mu u^0 - v_a \delta^a_\mu + \frac{1}{2} v^2 \delta^0_\mu - \frac{\kappa}{2} \epsilon_{ab} v^a \partial_\mu v^b, \\
(\omega^a_Q)_\mu & = \partial_\mu \phi^b \xi^a_b - \delta^a_\mu + \delta^0_\mu v^a, \\
(\omega^0_B)_\mu & = \partial_\mu v^a.
\end{align*}
\]

(54)

Accordingly, the covariant derivatives of the NG fields are given by

\[
egin{align*}
D_A u^0 & = e^A_\mu (\omega^0_Q)_\mu = \partial_A u^0 - \delta^a_\mu v_a + \delta^0_\mu v^2 - \frac{\kappa}{2} \epsilon_{ab} v^a \partial_A v^b + \delta^a_\mu v^c \left( \partial_c u^0 - v_c - \frac{\kappa}{2} \epsilon_{ab} v^a \partial_c v^b \right), \\
D_A u^a & = e^A_\mu (\omega^a_Q)_\mu = \partial_A \phi^b \xi^a_b - \delta^a_\mu + \delta^0_\mu v^a + \delta^a_\mu v^c (\partial_c \phi^b \xi^a_c - \delta^a_c), \\
D_A v^a & = e^A_\mu (\omega^0_B)_\mu = \partial_A v^a + \delta^0_\mu v^a \partial_A v^a.
\end{align*}
\]

(56)

Let us list the temporal and spatial components of the covariant derivatives separately:

\[
\begin{align*}
D_0 u^0 & = \partial_0 u^0 + v^a \partial_a u^0 - \frac{1}{2} v^2 - \frac{\kappa}{2} \epsilon_{ab} v^a \partial_0 v^b - \frac{\kappa}{2} \epsilon_{ab} v^a v^c \partial_0 v^b \equiv D_0 u^0 - \frac{1}{2} v^2 - \frac{\kappa}{2} \epsilon_{ab} v^a D_0 v^b, \\
D_0 u^a & = \partial_0 \phi^b \xi^a_b \equiv D_0 \phi^b \xi^a_b, \\
D_0 v^a & = \partial_0 \phi^b \xi^a_b - \delta^0_a, \\
D_0 v^a & = \partial_0 v^a + v^b \partial_b v^a \equiv D_0 v^a, \\
D_0 v^a & = \partial_0 v^a, \\
D_0 v^a & = \partial_0 v^a + v^b \partial_b v^a \equiv D_0 v^a,
\end{align*}
\]

(57)

where we defined the convective time derivative \( D_0 \) by\(^6\) \( D_0 \equiv \partial_0 + v^a \partial_a \). The covariant derivatives (57) are the building blocks of the effective Lagrangian.

---

\(^6\) Under the action of a Galilean boost,

\[
\begin{align*}
x^a & \rightarrow x'^a = x^a + \beta^a t, \\
t & \rightarrow t' = t, \\
v^a & \rightarrow (v^a)' = v^a + \beta^a,
\end{align*}
\]

(58)

the derivatives are transformed as

\[
(\partial_0)' = \partial_0 - \beta^a \partial_a, \quad (\partial_a)' = \partial_a.
\]

(59)
3. Effective Lagrangian for supersolids and solids

For the broken spacetime symmetry, not every NG field leads to a physical gapless mode. Namely, there can be a redundancy in the parametrization of the modes and some of them can be expressed in other fields. Suppose that the commutator of the unbroken generator \( \hat{P}_\mu \) with a broken generator \( X \) contains another broken generator \( X' \),

\[
[\hat{P}_\mu, X] \sim X' + \cdots.
\]

(65)

If we denote the NG fields for \( X \) and \( X' \) as \( \pi \) and \( \pi' \), we can impose the inverse Higgs constraint of the form \( D_\mu \pi' = 0 \), to express \( \pi' \) via the derivative of \( \pi \). However, whether one should impose the constraint depends on the microscopic details of the system [32]. This choice leads to the differences in the number of gapped physical modes.

Because of the algebra \([\hat{P}_\mu, B_\mu] = i \delta_{\mu \nu} Q_0\), we can express the boost NG field \( \nu^a \) in terms of \( u^0 \). By imposing the inverse Higgs constraint \( D_\mu u^0 = 0 \), the velocity field \( u^a \) is expressed as (in the absence\(^7\) of \( \kappa \))

\[ v_a = \partial_a u^0. \]

(68)

Namely, we can identify \( v_a \) as the superfluid velocity. Since \([\hat{P}_\mu, L_{bc}] = -2i \eta_{\mu \nu} Q_{c l} \), it is possible to impose the IHC \( D_\mu u^0 = 0 \). Here, we choose not to, and this leads to the Cosserat theory of elasticity. Substituting Eq. (68) to Eq. (57), the covariant derivatives are

\[
\begin{align*}
D_0 u^0 &= \partial_0 u^0 + \frac{1}{2} (\partial_a u^0)^2, \\
D_0 u^a &= (\partial_0 \phi^b + \partial^a u^0 \partial_c \phi^b) \xi_b^a, \\
D_i u^0 &= \partial_0 \phi \xi_c^a - \delta_b^a, \\
D \theta^{ab} &= \partial \theta^{ab} + \partial \theta^a \theta^b + O(\theta^3).
\end{align*}
\]

(69)

In the absence of rotational NG fields, i.e., \( \xi_b^a = \delta_b^a \), the first two coincide with the Galilean invariant building blocks of the supersolid effective Lagrangian discussed in Ref. [47].

To the leading order in the numbers of fields and derivatives, the covariant derivatives are written as

\[
\begin{align*}
D_0 u^0 &\simeq \partial_0 u^0, \\
D_0 u^a &\simeq \partial_0 u^a, \\
D_i u^0 &\simeq \partial_0 u^a + \theta^a, \\
D \theta^{ab} &\simeq \partial \theta^{ab}.
\end{align*}
\]

(70-73)

To the quadratic order in the number of fields and to the lowest order in derivatives, the effective Lagrangian for supersolids can be written in the form

\[
L = \frac{1}{2} K (\partial_0 u^0)^2 - \frac{1}{2} K_i j \partial^i u^0 \partial^j u^0 + \frac{1}{2} C_{ab} \partial_0 u^a \partial_0 u^b - \frac{1}{2} C_{\delta a \delta b} (\partial_i u^a + \theta_i^a) (\partial_j u^b + \theta_j^b) + \frac{1}{2} C_{iajb} (\partial \theta^i \theta^a + \theta_i^b + \theta_i^b) \theta^{cd}
\]

(74)

where \( C_{iajb} \) are elastic constants. There is an additional term,

\[
L^{WZ} = \rho_0 d u^0 \wedge d u^a \wedge \bar{e}_a,
\]

(75)

The vielbeins \( (53) \) are transformed covariantly under Galilean transformation \( (58) \),

\[
(dx^a)' = dx^0, \quad (dx^a - i\phi dx^0)' = dx^a - i\phi dx^0.
\]

(60)

The convective derivative \( \mathcal{D}_0 \) is Galilean-invariant,

\[
(\mathcal{D}_0)' = (\partial_0)' + (i\phi)'(\partial_0') = \partial_0 - \beta \partial_a + (\phi' + \beta \phi) \partial_a = \mathcal{D}_0
\]

(61)

Note that the field \( u^0 \) is shifted under a Galilean boost (in the absence of \( \kappa \)) as

\[
(u^0)' = u^0 + \beta \cdot x + \frac{1}{2} \beta^2 t.
\]

(62)

We can explicitly check that the covariant derivative \( D_0 u^0 \) is indeed invariant under a Galilean boost:

\[
\begin{align*}
(\partial_0 u^0 + \frac{1}{2} (\partial_0 u^0)^2)' &= (\partial_0 - \beta \cdot \nabla) (u^0 + \beta \cdot x + \frac{1}{2} \beta^2 t) + \frac{1}{2} (\partial_0 u^0 + \beta u^0)^2 \\
&= \partial_0 u^0 + \frac{1}{2} \beta^2 - \beta \cdot \nabla u^0 - \beta^2 + \frac{1}{2} (\partial_0 u^0 + \beta u^0)^2 \\
&= \partial_0 u^0 + \frac{1}{2} (\partial_0 u^0)^2.
\end{align*}
\]

(63)

The field \( u^a \) is shifted under a Galilean boost as

\[
(u^a)' = u^a - \beta^a t.
\]

(64)

and \( (\phi^a)' = \phi^a \).

\(^7\) In 2 + 1 dimensions and \( \kappa \neq 0 \), the condition \( D_0 u^0 = 0 \) is written as

\[
\partial_0 u^0 - \partial_0 - \frac{\kappa}{2} \epsilon_{bc} \theta^b \partial_a \phi^c = 0.
\]

(66)

If we solve this for \( v_a \) perturbatively in the number of derivatives,

\[
v_a = \partial_a u^0 - \frac{\kappa \epsilon_{bc}}{2} \partial_0 \partial_a \phi^c + O(\partial^3).
\]

(67)
where \( \tilde{e}_a \equiv \epsilon_{a_{a_2}...a_d}dx^{a_2} \wedge \cdots \wedge dx^{a_d} \) is a constant \((D - 2)\)-form. This term \((75)\) appears as a Wess-Zumino term, and its derivation is discussed in the following subsection.

The effective Lagrangian for solids can be obtained by setting \( u^0 = 0 \),
\[
L = \frac{1}{2} C_{ab} \partial_0 u^a \partial_0 u^b - \frac{1}{2} C_{iaj b}(\partial_i u^a + \theta_i^a)(\partial_j u^b + \theta_j^b) + \frac{1}{2} C_{iaj b} \partial_0 \theta_i^a \partial_0 \theta_j^b - \frac{1}{2} C_{iaj b e} \partial_0 \theta_i^a \partial_0 \theta_j^b \partial_0 \theta_e^b \partial_0 \theta^{cd}.
\]
(76)

We note that this is the Lagrangian of the Cosserat elasticity theory. By choosing the elastic constants as
\[
C_{iaj b} = C_{ab} \delta_{ij}, \quad C_{iaj b e} = C_{ab e} \delta_{ij},
\]
we consider the low-energy limit and do not consider the rotational NG fields \( \theta_i^a \). The effective Lagrangian can also contain Wess-Zumino terms, which are invariant only up to total derivatives. Below, we consider the low-energy effective Lagrangian of solid with the translational and rotational NG fields, to the quadratic order, can be written in differential form as
\[
L = -C_{ab} \partial_0 u^a \wedge \ast \partial_0 u^b - C_{a_b c_d} \partial \theta^{ab} \wedge \ast \partial \theta^{cd},
\]
(78)
where we have defined
\[
\partial_0 u^a = \partial u^a - \theta_i^a dx^i.
\]
(79)

4. Wess-Zumino terms for supersolids

The Lagrangian built from the covariant derivatives \((57)\) are exactly invariant under the symmetry transformations. The effective Lagrangian can also contain Wess-Zumino terms, which are invariant only up to total derivatives. Below, we consider the low-energy limit and do not consider the rotational NG fields \( \theta_i^a \). We also consider the case where the superfluid density is small, which is typically the case \([47]\). We first note that the Maurer-Cartan forms satisfy the following equations,
\[
\begin{align*}
\partial \omega^0_P &= 0, & \partial \omega^0_P &= \omega^0_P \wedge \omega^0_B, & \partial \omega^0_B &= 0, \\
\partial \omega^0_Q &= \omega^0_P \wedge \omega^0_B - \frac{\kappa}{2} \epsilon_{a b} \omega^a_B \wedge \omega^b_B, \\
\partial \omega^a_Q &= -\omega^0_P \wedge \omega^a_B = -\partial \omega^a_P.
\end{align*}
\]
(80)
where the term proportional to \( \kappa \) exists only in \( 2 + 1 \) dimensions.

To look for a Wess-Zumino term, we have to find an invariant and closed \((D + 1)\)-form. Let us define the mass current \( j_m \) in \( d \)-spatial dimensions by
\[
\ast j_m = \frac{\rho_0}{\partial t} \epsilon_{a_1...a_d} \partial \phi_{a_1} \wedge \cdots \wedge \partial \phi_{a_d},
\]
(81)
where \( \rho_0 \) is the mass density in the ground state. The current is trivially conserved, \( d \ast j_m = 0 \). Note that \( d \phi^a = \omega^a_Q + \omega^a_P \).

We have the following closed \((D + 1)\)-form,
\[
\Omega_{D+1} = \omega^a_B \wedge (\omega^a Q)_a \wedge \ast j_m = -\omega^a_B \wedge (\omega^a P)_a \wedge \ast j_m,
\]
(82)
where the latter equality follows from \( d \phi^a \wedge d \phi_{a_1} \wedge \cdots \wedge d \phi_{a_d} \epsilon_{a_1...a_d} = 0 \). The closedness of \( \Omega_{D+1} \) can be checked using Eq. \((80)\). The \((D + 1)\)-form \( \Omega_{D+1} \) can be written as
\[
d\omega^a \wedge (dx_a - v_a dx^0) \wedge \ast j_m = d \left[ (v^a dx_a - v^2/2 dx^0) \wedge \ast j_m \right]
\]
(83)
Therefore, we can write down the corresponding Wess-Zumino term in \( D \)-dimensions as
\[
L_{D}^{WZ} = (v^a dx_a - v^2/2 dx^0) \wedge \ast j_m.
\]
(84)

Note that it can be written as
\[
L_{D}^{WZ} = (du^0 - \omega^0_Q) \wedge \ast j_m.
\]
(85)
The one-form \( \omega^0_Q \) is exactly invariant under Galilean boosts. Thus, the term proportional to \( \omega^0_Q \) should be already taken into account by the coset construction. Thus, we can adopt the following form instead of Eq. \((85)\),
\[
L_{D}^{WZ'} = du^0 \wedge \ast j_m.
\]
(86)

\( ^8 \) The coefficient \( \rho_0 \) may slightly deviate for as an effect of non-zero superfluid fraction.
This expression is consistent with the interpretation of $j_\mu$ as the mass current. This term was introduced in Ref. [47]. It is a total derivative, and does not affect the equations of motion. Still, this term changes the identification of the Noether current, and is needed to reproduce the centrally extended algebra, $[B_\alpha, P_\beta] = -i\delta_{\alpha\beta}Q_0$. In the presence of vortices, the term induces the interactions of vortices with lattice phonons. Under a Galilean boost, $L_D^{WZ'}$ is transformed as

$$\delta L_D^{WZ} = \delta L_D^{WZ} = (\beta^a dx_a + \frac{\beta^2}{2} dx^0) \wedge \star j_\mu = d \left[ (\beta^a x_a + \frac{\beta^2}{2} x^0) \wedge \star j_\mu \right],$$

which is a total derivative.

In $2+1$ dimension, the Galilean algebra allows for another central extension parameterized by $\kappa$. Correspondingly, we have another invariant 4-form,

$$\Omega_4' = \frac{K}{2} \epsilon_{ab} \omega_B^a \wedge \omega_B^b \wedge \star j_\mu.$$  

(87)

It produces the following Wess-Zumino term,

$$L_{D=3}^{WZ} = \frac{K}{2} \epsilon_{ab} v^a dv^b \wedge \star j_\mu.$$  

(89)

Under a Galilean boost, this term is shifted by a total derivative,

$$\delta L_{D=3}^{WZ} = \frac{K}{2} \epsilon_{ab} \beta^a dv^b \wedge \star j_\mu = d \left[ \frac{K}{2} \epsilon_{ab} \beta^a v^b \wedge \star j_\mu \right].$$  

(90)

If we use the IHC $v_\mu = \partial_\mu u^0$, the term (89) also is a total derivative, and the EOMs are not affected in the absence of topological defects.

Wess-Zumino terms change the identification of the currents. The term (86) leads to the following additional contribution to the boost current,

$$(\star j_B^a)_{WZ} = \frac{\partial L_{WZ}}{\partial u^0} \delta^a u^0 = x^a(\star j_\mu),$$

where $\delta^a u^0$ indicates the variation of $u^0$ under a Galilean boost in the $a$-th direction. The boost current is written as

$$\star j_B^a = -t(\star p^a) + x^a(\star j_\mu),$$

where $p^a$ denotes the translational current. With this contribution, we can reproduce the centrally extended algebra,

$$\langle [P_a, B^b] \rangle = \langle [P_a, \int_{\mathbf{V}} \star j_B^b] \rangle = \langle \int_{\mathbf{V}} (-i\partial_\mu (x^b \star j_\mu)) \rangle = -i\delta^b_a \langle \int_{\mathbf{V}} \star j_\mu \rangle = -i\delta^b_a \langle Q_0 \rangle.$$  

(93)

5. Scattering of quasiparticles off topological defects

Although the Wess-Zumino terms (86) and (89) are total derivatives, they induce nontrivial interactions in the presence of topological defects. Here, we discuss such processes induced by Eqs. (86) and (89). Since their coefficients are determined by the symmetry algebra, the coupling constants of those processes are model independent.

Let us first discuss the consequence of Eq. (86). We here consider a vortex in a $3+1$-dimensional supersolid located along the $z$-direction at $x = y = 0$. Such a vortex configuration can be expressed by $\epsilon_{abc} \phi^a \phi^b \phi^c u^0 = (2\pi/m)\delta(x)$, where $\delta_c(x_T) \equiv n_c \delta(x) \delta(y)$, is the transverse delta function and $\mathbf{n} = \hat{z}$ is the unit tangent vector along the vortex. In the presence of a superfluid vortex, the Lagrangian density can be written as

$$L_D^{WZ'} = -\frac{\rho_0}{3m} \epsilon^{\mu\nu\rho\sigma} \epsilon_{abc} \partial_\mu \phi^a \partial_\nu \phi^b \partial_\rho \phi^c$$

$$= -\frac{\rho_0}{m} \epsilon_{abc} u^a u^b \delta^c(x_T) + O(u^3).$$  

(94)

The leading-order term describes elastic scatterings of lattice phonons off superfluid vortices in a supersolid. We denote the energy/momentum and polarization of the incoming/scattered particles as $\{\omega, \mathbf{k}, \epsilon\}$ and $\{\omega', \mathbf{k}', \epsilon'\}$, respectively. For definiteness, we consider the incoming lattice phonon that is incident perpendicularly to the vortex, $\mathbf{k} \cdot \mathbf{n} = 0$, and assume that it is transversely polarized, $\mathbf{k} \cdot \epsilon = 0$. We also assume that the scattered phonon is also transversely polarized, and the polarization vectors of the initial and scattered phonons are in the plane perpendicular to the vortex, $\epsilon \cdot \mathbf{n} = \epsilon' \cdot \mathbf{n} = 0$. 

11
The current collision geometry reduces the problem effectively to two-spatial dimensions. The matrix element of this elastic scattering process is

$$iM = 2 \cdot \frac{1}{\rho_0} \frac{\pi \rho_0}{m} \left( \epsilon_{abc} \epsilon^a n^c = \frac{2\pi}{m} \omega (\epsilon \times \epsilon') \cdot n = \frac{2\pi}{m} \omega \sin \theta, \right)$$

where $\theta$ is the angle between $k$ and $k'$. We here assume that the supersolid is isotropic. The 1-body final state phase space is given by

$$d\Pi_b = 2\pi \delta(\omega - \omega') \frac{1}{2\omega_b (2\pi)^2}$$

Since the superfluid vortex does not break time translations, the scattering conserves the energy, $\omega = \omega'$, which is reflected in the phase-space delta function, $2\pi \delta(\omega - \omega')$. The infinitesimal cross section a vortex line element $d\ell$ is given by

$$d\sigma_{a \rightarrow b} = \frac{1}{2\omega \upsilon_a} |M_{a \rightarrow b}|^2 d\Pi_b d\ell,$$

$$= \frac{1}{2\omega \upsilon_T} \left( \frac{4\pi^2}{m^2} \omega^2 \sin^2 \theta \right) \left( \frac{d\theta d\ell}{4\pi \upsilon_T^2} \right)$$

$$= \frac{\pi}{2} \frac{\omega}{m^2 \upsilon_T^2} \sin^2 \theta d\theta d\ell,$$

where $\upsilon_T$ is the velocity of transverse phonons. The differential cross section per unit vortex length is written as

$$\frac{d^2\sigma}{d\theta d\ell} = \frac{\pi}{2} \frac{k}{m^2 \upsilon_T^2} \sin^2 \theta,$$

which is obtained in Ref. [47]. The cross section is linearly proportional to the momentum $k$ and it is largest when the scattering angle is $\pi/2$. This is the dominant elastic scattering process of lattice phonons off vortices when the superfluid density is small.

Let us now consider the presence of a dislocation in a $(3+1)$-dimensional supersolid. The term $d\upsilon^0 \wedge \star j_m$ leads to the conversion of lattice phonons and superfluid phonons on a dislocation. The existence of a dislocation leads to the following multivalued part of $u^a$,

$$\epsilon_{ijk} \delta^i_j \delta^j_i u^a = b^a \delta_k(x_T),$$

where $b^a$ is the Burgers vector. The interaction Lagrangian is written as

$$L_{WZ}^{(4)} = \frac{\rho_0}{3!} d\upsilon^0 \wedge \delta \phi^a \wedge \delta \phi^b \wedge \delta \phi^c \epsilon_{abc} = -\frac{\rho_0}{2} d\upsilon^0 \wedge d^2 \phi^a \wedge \delta \phi^b \wedge \delta \phi^c \epsilon_{abc} = -\rho_0 u^a \epsilon_{abc} b^a u^b \delta^c(x_T) d\upsilon^0 \wedge dx^1 \wedge dx^2 \wedge dx^3 + O(u^3).$$

This results in the conservation of a superfluid phonon with energy/momentum $(\omega, k)$ to a lattice phonon $(\omega', k')$ with polarization $\epsilon'$ via the scattering off a dislocation. The matrix element of this process is

$$iM = \frac{1}{\sqrt{\rho_s \sqrt{\rho_0}}} \rho_0 i \omega' b^a \epsilon^b \epsilon_{abc} n^c = \sqrt{\frac{\rho_0}{\rho_s}} \omega'(b \times \epsilon') \cdot n.$$

The infinitesimal cross section is

$$d\sigma = \frac{1}{2\omega \upsilon_s} |M|^2 \left( \frac{d\theta}{4\pi \upsilon_T^2} \right)$$

$$= \frac{\rho_0}{\rho_s} \frac{k}{8\pi \upsilon_T^2} |(b \times \epsilon') \cdot n|^2 d\theta,$$

where $\upsilon_s$ and $v$ are the velocities of superfluid phonons and lattice phonons, respectively. The cross section is determined by the relation of the Burgers vector, the polarization of the final-state lattice phonon, and the direction of the dislocation. For example, the cross section vanishes for a screw dislocation, for which $b$ is parallel to $n$.

---

9 In the computation of scattering amplitudes [52], we need to take into account of the non-canonical normalization of the kinetic term,

$$L = \frac{\rho_0}{2} [(\partial^a \upsilon ^a)^2 - \upsilon ^2 (\partial_i n^a)^2] + \frac{\rho_0}{2} (\upsilon^a)^2 + \ldots$$

(95)
Next, let us consider the Wess-Zumino term (89), which can exist in 2+1 dimensions. In the presence of vortices, this term induces nontrivial interactions among NG fields. If we consider a vortex placed at the origin, \( \epsilon_{ab}\frac{\partial^2}{\partial\theta^2}u^0 = \frac{2\pi}{m}\delta(x) \), and we have the following term,

\[
\frac{2\pi \kappa \rho_0}{m} \delta(x) \left( \dot{u}^0 \nabla \cdot u - \dot{u}^a \partial_a u^0 + O(u^3) \right).
\]  

(104)

This indicates that superfluid phonons and lattice phonons can be converted via the scatterings off a superfluid vortex. We here consider the conversion process of a transverse lattice phonon with energy/momentum \((\omega, k)\) and polarization \(\epsilon\) into a superfluid phonon with \((\omega', k')\). The matrix element is

\[
iM = \frac{1}{\sqrt{\rho_0 \rho_s}} \frac{2\pi \kappa \rho_0}{m} \left[-(-i\omega)(-i\epsilon)^2 \right] = \frac{2\pi \kappa}{m} \sqrt{\rho_0 \rho_s} \omega k' \cdot \epsilon.
\]  

(105)

The infinitesimal cross section is computed as

\[
d\sigma = \frac{1}{2\omega v} |M|^2 d\Pi_b,
\]

\[
= \frac{1}{2\omega v} \left( \frac{4\pi^2 \kappa^2 \rho_0}{m^2 \rho_s} \omega^2 (k' \cdot \epsilon)^2 \right) \left( \frac{d\theta}{4\pi v_s^2} \right)
\]

\[
= \frac{\pi \rho_0 \kappa^2}{2 \rho_s m^2 v_s^2} kk' \sin^2 \theta d\theta,
\]  

(106)

where \(\theta\) is the angle between \(k\) and \(k'\).

Finally, let us emphasize that the coupling constants associated with the Wess-Zumino terms are fixed by the symmetry algebra, and the cross sections associated with those terms are model independent prediction of the effective theory.

\section{II. Dual Gauge Theories}

In this section, we provide the derivation of dual gauge theories of the effective Lagrangians of solids and supersolids. We also derive the corresponding Maxwell’s equations written in terms of electric and magnetic fields, and discuss their dynamical properties.

\subsection{A. Derivation of dual gauge theories}

In this section, we give the derivation of the dual gauge theories for solids and supersolids. Since the gauge theory of solids can be obtained from that of supersolids, we here discuss supersolids. We start with the partition function of supersolids \(Z = \int [D\theta_{ab}] [D\theta_{ab}^c] [\bar{u}^a, \theta^{ab}, u^a] \), where the action is given by

\[
S[u^0, u^a, \theta^{ab}] = -\int_{M_D} \left[ \frac{1}{2} C_{abcd} \delta \dot{u}^a \ast \delta \dot{u}^b + \frac{1}{2} C_{abcd} \theta^{ab} \ast \delta \theta^{cd} + \frac{1}{2} C_{00} \delta u^0 \ast \delta u^0 + g \delta u^0 \ast \delta u^0 \right],
\]  

(107)

where \(M_D\) is a \(D\)-dimensional spacetime manifold. For notational simplicity, we organize \(u^0\) and \(u^a\) as a four vector as \(u^A = (u^0, u^a)\), and the constants are also organized accordingly. We write the action as

\[
S[u^A, \theta^{ab}] = -\int_{M_D} \left[ \frac{1}{2} C_{AB} \delta \dot{u}^A \ast \delta \dot{u}^B + \frac{1}{2} C_{abcd} \theta^{ab} \ast \delta \theta^{cd} + g \delta u^0 \ast \delta u^0 \right].
\]

(108)

By introducing auxiliary fields, \((\tau^A, \sigma^{ab})\), the partition function can be written as \(Z = \int [D\tau^A][D\sigma^{ab}][D\theta_{ab}^c][\bar{u}^a, \theta^{ab}, \tau^A, \sigma^{ab}]\), where the action is given by

\[
\int_{M_D} \left[ \frac{1}{2} C_{AB}^{-1} \tau^{AB} \ast \tau^B + \tau^A \ast \delta \dot{u}^A + \frac{1}{2} C_{abcd}^{-1} \sigma^{ab} \ast \delta \sigma^{cd} + \sigma^{ab} \ast \delta \theta_{ab} - g \delta u^0 \ast \delta u^0 \right],
\]

(109)

By doing a variation with respect to \(\tau^a\) and \(\sigma^{ab}\), we obtain

\[
-C_{AB}^{-1} \tau_B = \delta \dot{u}^A, \quad -C_{abcd}^{-1} \sigma_{cd} = \delta \theta^{ab}.
\]

(110)

The path-integration of (the smooth part of) \(u^A\) and \(\theta^{ab}\) leads to the following equations of motion,

\[
d \ast \tau^A = 0, \quad d \ast \sigma^{ab} + dx^b \ast \tau^a = 0,
\]

(111)
which are conservation laws of $U(1)$ charge ($\tau^0)_0$, momentum density ($\tau^a)_0$ and angular momentum density ($\sigma^{ab})_0$, respectively. The equations above can be solved explicitly by introducing $(D - 2)$-form gauge fields $a^A, a^{ab}$ as

$$\ast \tau_A = -C_{AB}da^B, \quad \ast \sigma_{ab} = -C_{abcd}da^{cd} - C_{ac}dx_b \wedge a^c.$$  \hfill (112)

By comparing with Eq. (110), we obtain the relation between the dual gauge fields and the original fields as

$$da^A = \ast du^A, \quad da^{ab} = \ast d\theta^{ab}.$$  \hfill (113)

Substituting Eq. (112) to Eq. (109) the following dual effective Lagrangian,

$$L_{\text{dual}} = -\frac{1}{2}C_{AB}f^A \wedge \ast f^B - \frac{1}{2}C_{abcd}f^{ab} \wedge \ast f^{cd} - g \ast f_0 \wedge \ast f^a \wedge \bar{e}_a.$$  \hfill (114)

To simplify the expression, let us choose isotropic elastic constants as $C_{ab} = c\delta_{ab}$ and $C_{abcd} = c^\prime \delta_{ac} \delta_{bd}$, and $C_{00} = c_0$. Then, we have $\ast \tau_a = -da_a$, and $\ast \sigma_{ab} = -da_{ab} - \bar{c} dx_b \wedge a_a$ with $\bar{c} \equiv c/c^\prime$. In this case, the dual Lagrangian reads

$$L_{\text{dual}} = -\frac{c_0}{2} f^0 \wedge \ast f^0 - \frac{c}{2} f^a \wedge \ast f_a - \frac{c^\prime}{2} f^{ab} \wedge \ast f^{ab} - g \ast f_0 \wedge \ast f^a \wedge \bar{e}_a,$$  \hfill (115)

where the field strengths are defined as\(^{10}\)

$$f^A \equiv da^A, \quad f^{ab} \equiv da^{ab} + \bar{c} dx^b \wedge a^a.$$  \hfill (116)

The field strengths (116) are invariant under the following gauge transformations,

$$a^A \mapsto a^A + d\lambda^A, \quad a^{ab} \mapsto a^{ab} + d\rho^{ab} + \bar{c} dx^b \wedge \lambda^a,$$  \hfill (117)

where $\lambda^A$ and $\rho^{ab}$ are $(D - 3)$-form gauge parameters. Note that the rotational gauge field is shifted by the transformation parameter of translational gauge field. Accordingly, the field strengths satisfy the following Bianchi identities,

$$df^A = 0, \quad df^{ab} + \bar{c} dx^b \wedge f^a = 0.$$  \hfill (118)

Topological defects enter as sources to the dual gauge fields, $L_a = C_{AB}a^A \ast J^B + C_{abcd}a^{ab} \ast J^{cd}$. By varying the dual action with respect to the gauge field $a^A$ and $a^{ab}$, we obtain the equations of motion as

$$d^\dagger \left( f^0 + g_0 \ast f^a \wedge \bar{e}_a \right) = J^0,$$

$$d^\dagger \left( f^a - \bar{g} \ast f^0 \wedge \bar{e}_a \right) + \ast^{-1}(\ast f^{ab} \wedge dx^b) = J^a$$  \hfill (119)

where we set $g_0 \equiv g/c_0$ and $\bar{g} \equiv g/c$. The equations of motion (119) together with Bianchi identities (118) describe the dynamics of superfluid phonons, translational phonons, and rotational phonons in $D$ spacetime dimensions in the presence of vortices, dislocations, and disclinations.

### B. Equations of motion in terms of electric and magnetic fields

Let us rewrite the EOMs using electric and magnetic fields. We here consider $2+1$ dimensions. Electric and magnetic fields for superfluid phonons, lattice phonons, and rotational phonons are introduced by

$$f^0 = e_i dx^i \wedge dx^0 + \frac{1}{2} \epsilon_{ij} b dx^i \wedge dx^j,$$  \hfill (120)

$$f^a = e_a^b \left( E^b_j dx^j \wedge dx^0 + \frac{1}{2} \epsilon_{ij} B^b dx^i \wedge dx^j \right),$$  \hfill (121)

$$f^{ab} = e^{ab} \left( E_a dx^i \wedge dx^0 + \frac{1}{2} \epsilon_{ij} b dx^i \wedge dx^j \right).$$  \hfill (122)

\(^{10}\) In the general case, $f^a \equiv da^a$ and $f^{ab} \equiv da^{ab} + (C^{-1})^{cd} C_{ce} dx^d \wedge a^e$. 

---

14
The topological term can be written as

\[- g \star f_0 \wedge \star f^a \wedge \epsilon_a = - g \left[ b (E^a)_a + \epsilon_a B^a \right] dx^0 \wedge dx^1 \wedge dx^2. \tag{123} \]

Those are crossed \( E \cdot B \)-type terms and are responsible for the generalized Witten effect.

Maxwell’s equations for superfluid phonons are now written as

\[
\partial^i e_i - g_0 \partial^i B_i = -(J_0)_i, \tag{124}
\]

\[
\partial_0 e_i - \tilde{\partial}_i b + g_0 \partial_0 (E^a)_a - \partial_0 B_i = -(J_0)_i, \tag{125}
\]

where \( \tilde{\partial}_i \equiv \epsilon_{ij} \partial^j \). Equation (124) indicates that a vortex acquires a magnetic charge of the translational gauge field because of the topological term, which means that a vortex carries a crystalline angular momentum.

Maxwell’s equations for translational phonons are:

\[
\partial^i (E^a)_i + \tilde{g} \partial^a b - \epsilon^a_b (J^b)_0 = 0. \tag{126}
\]

\[- \tilde{\partial}_i B^a + \partial_0 (E^a)_i + \tilde{g} \left( \partial^a_i \partial_0 b - \tilde{\partial}_i e^a \right) - \epsilon_a \hat{a} = \epsilon^a_b (J^b)_i. \tag{127} \]

Maxwell’s equations for rotational phonons are:

\[
\partial^i \mathcal{E}_i = - \frac{1}{2} \epsilon_{ab} (\mathcal{J}^{ab})_0, \tag{128}\]

\[- \tilde{\partial}_i \mathcal{B}^i + \partial_0 \mathcal{B} = - \frac{1}{2} \epsilon_{ab} (\mathcal{J}^{ab})_i. \tag{129}\]

Bianchi identities are written as

\[- \tilde{\partial}_i e_i + \partial_0 b = 0, \tag{130}\]

\[- \tilde{\partial}_i (E^a)_i + \partial_0 B^a = 0, \tag{131}\]

\[- \tilde{\partial}_i \mathcal{E}_i + \partial_0 \mathcal{B} + \frac{\tilde{c}}{2} \epsilon_i (E^c)_i = 0. \tag{132}\]

\[\text{C. Excitations in solids}\]

Let us look at the properties of excitations in solids in terms of the dual gauge theory. The EOMs for solids can be obtained by setting \( f^0 = 0 \). In the absence of topological defects, The EOMs are written as follows:

- Maxwell’s equations for translational phonons:

\[
\partial^i (E^a)_i - \epsilon^a_b = 0, \tag{133}\]

\[- \tilde{\partial}_i B^a + \partial_0 (E^a)_i - \epsilon_a \hat{a} = 0, \tag{134}\]

- Bianchi identity for translational phonons

\[- \tilde{\partial}_i (E^a)_i + \partial_0 B^a = 0, \tag{135}\]

- Maxwell’s equations for rotational phonons:

\[
\partial^i \mathcal{E}_i = 0, \tag{136}\]

\[- \tilde{\partial}_i \mathcal{B} + \partial_0 \mathcal{E}_i = 0. \tag{137}\]

- Bianchi identity for rotational phonons:

\[- \tilde{\partial}_i \mathcal{E}_i + \partial_0 \mathcal{B} + \frac{\tilde{c}}{2} \epsilon_i (E^c)_i = 0. \tag{138}\]

Let us write the EOM in term of electric fields. The translational electric fields \( (E^a)_i \) have four components. Because of the Gauss law, \( \partial_0 \partial^i (E^a)_i = 0 \), there are three physical degrees of freedom. The EOM for \( (E^a)_i \) can be derived as

\[
(\partial_0)^2 (E^a)_i = \tilde{\partial}_i \partial_0 B^a + \epsilon^a_b \partial_0 \mathcal{B}^i
\]

\[
= \tilde{\partial}_i \partial^j (E^a)_j + \epsilon^a_b \left[ \tilde{\partial}_i \mathcal{E}^j - \frac{\tilde{c}}{2} \epsilon_i (E^c)_j \right] \tag{139}\]

\[
= \tilde{\partial}_i \partial^j (E^a)_j + \epsilon^a_b \tilde{\partial}_j \partial_0 (E^b)_j - \frac{\tilde{c}}{2} \epsilon_i \epsilon^a_b (E^c)_j. \]
To discuss the nature of linear excitations, let us write the EOM in the momentum space,

$$\omega^2(E^a)_i - k^2 \tilde{n}_i(E^a)_j \tilde{n}^j - k^2 \epsilon^a_i \epsilon_j(E^a_j) \tilde{n}^j - \frac{\tilde{c}}{2} \epsilon^a_i \epsilon_j(E^a_j) = 0$$  \hspace{1cm} (140)

where \( k \equiv \sqrt{k_i k^i} \), \( \tilde{k}_i \equiv \epsilon_{ij} k^j \) is the transverse vector (to \( k_i \)), and \( n_i \equiv k_i/k \), \( \tilde{n}_i \equiv \tilde{k}_i/k \) are unit vectors in the longitudinal and transverse directions, respectively. In the long-wavelength limit, \( k \to 0 \), the antisymmetric part of the translational electric fields \( (E^a)_i \) satisfies

$$\left( \omega^2 - \tilde{c} \right) \epsilon^a_i(E^a)_i = 0.$$ \hspace{1cm} (141)

Hence, as a result of the coupling to the rotational electric and magnetic fields, the antisymmetric part, \( \epsilon^a_i(E^a)_i \), acquires a gap, and its gap is given by \( \omega = \sqrt{\tilde{c}} \). Other two modes are gapless. Because of the gap, the antisymmetric part \( \epsilon^a_i(E^a)_i \), can be dropped at low energies [44], and the remaining electric field is symmetric. The symmetric tensor gauge theory [12] is reproduced in this way.

To obtain the modes at finite \( k \), let us project \( (E^a)_i \) to the longitudinal and transverse directions for each index. We have the following projected components,

$$TT \equiv \tilde{n}_a(E^a)_i \tilde{n}^i, \quad LT \equiv n_a(E^a)_i \tilde{n}^i, \quad TL \equiv \tilde{n}_a(E^a)_i n^i.$$ \hspace{1cm} (142)

As we stated earlier, \( LL = 0 \) because of the Gauss law. Using the relation \( \epsilon_{ij} = \tilde{n}_i n_j - n_i \tilde{n}_j \), we can write the antisymmetric part as \( \epsilon^a_i(E^a)_i = TL - LT \). The EOMs are written in the matrix form as

$$\begin{pmatrix}
\omega^2 - k^2 - \frac{\tilde{c}}{2} & k^2 + \frac{\tilde{c}}{2} & 0 \\
0 & \omega^2 - k^2 - \frac{\tilde{c}}{2} & 0 \\
0 & 0 & \omega^2 - k^2
\end{pmatrix}
\begin{pmatrix}
LT \\
TL \\
TT
\end{pmatrix} = 0.$$ \hspace{1cm} (143)

The transverse-transverse sector is decoupled and represents a gapless mode. There is a mixing between longitudinal-transverse and transverse-longitudinal sectors. As a result, there will be one gapless and one gapped modes from this sector.

Instead of electric fields, we can write the EOMs using the magnetic fields as follows:

$$\begin{gathered}
(\partial_0)^2 b = \tilde{\partial}^a \partial_0 e^a_i \partial_0 (E^a)_i \\
= \tilde{\partial}^a \partial_0 b - \frac{\tilde{c}}{2} e^a_i (\tilde{\partial}^a B^a + e^a_i b) \\
= \tilde{\partial}^a \partial_0 b - \tilde{c} b + \frac{\tilde{c}}{2} \tilde{\partial}^a b^a,
\end{gathered}$$ \hspace{1cm} (144)

$$\begin{gathered}
(\partial_0)^2 (\partial_a B^a) = \tilde{\partial}^i \partial_0 (E^a)_i \\
= \tilde{\partial}^i \partial_0 [\tilde{\partial}^a B^a + e^a_i b] \\
= \partial^2 \partial_a B^a - \tilde{\partial}^2 b^a,
\end{gathered}$$ \hspace{1cm} (145)

$$\begin{gathered}
(\partial_0)^2 (\tilde{\partial}_a B^a) = \tilde{\partial}^i \tilde{\partial}_0 (E^a)_i \\
= \tilde{\partial}^i \tilde{\partial}_a [\partial_0 B^a + e^a_i b] \\
= \tilde{\partial}^i \tilde{\partial}_a (\tilde{\partial}_a B^a) \\
= \partial^2 (\tilde{\partial}_a B^a).
\end{gathered}$$ \hspace{1cm} (146)

Those equations can be written in the momentum space in the following matrix form,

$$\begin{pmatrix}
\omega^2 - k^2 - \tilde{c} & \tilde{c}/2 & 0 \\
k^2 & \omega^2 - k^2 & 0 \\
0 & 0 & \omega^2 - k^2
\end{pmatrix}
\begin{pmatrix}
\frac{b}{n_a B^a} \\
n_a B^a \\
\tilde{n}_a B^a
\end{pmatrix} = 0.$$ \hspace{1cm} (147)

The longitudinal part of \( B^a \) is mixed with the rotational magnetic field \( b \). The transverse part of \( B^a \) is decoupled and stays gapless.
