(Dated: November 4, 2021)

The quantum metric is a central quantity of band theory but has so far not been related to many response coefficients due to its non-classical origin. However, within a newly developed Kubo formalism for fast relaxation, the decomposition of the dc electrical conductivity into both classical (intraband) and quantum (interband) contributions recently revealed that the interband part is proportional to the quantum metric. Here, we show that interband effects due to the quantum metric can be significantly enhanced and even dominate the conductivity for semimetals at charge neutrality and for systems with highly quenched bandwidth. This is true in particular for topological flat band materials of nonzero Chern number, where an upper bound exists for the resistivity due to the common geometrical origin of quantum metric and Berry curvature. We suggest to search for these effects in highly tunable rhombohedral trilayer graphene flakes.

I. INTRODUCTION

Recent experimental progress has made it possible to investigate new two-dimensional quantum materials with a highly quenched bandwidth, which exhibit a rich phase diagram including unconventional superconducting phases, correlated insulating states and a cascade of magnetic and non-magnetic flavor-ordered states [1–14]. While the most interesting phenomena in the ordered states are due to many-body effects, these findings have also ignited renewed interest in understanding the normal state of moiré-type and periodic lattice systems with vanishing Fermi velocity [15–18]. However, remarkably little is known about the effects of a quenched bandwidth on the electrical conductivity. In this work, we systematically investigate the interplay between band structure and conductivity using a non-interacting Kubo approach which allows to fully identify and quantify the various contributing factors.

The two paradigmatic flat band systems are twisted bilayer graphene (TBG), a van-der-Waals material where the second layer is put askew by a small angle [19,20]; and rhombohedral trilayer graphene (RTG), where three graphene monolayers are layered on top of each other without twist, with atomic positions in the sequence A-B-C [21–24]. Here, we will only discuss the latter material, because with the availability of high mobility samples, it offers a viable platform to study band structure effects. On the theoretical side, the implications of a highly quenched band width challenge the existing theories as, for instance, the superfluid stiffness should vanish in the limit of flat bands, which would forbid a superconducting state at finite temperature [25]. In this context, several indications have been found that a quantity known as the quantum metric provides the relevant contribution to the superfluid stiffness of the superconducting state [26–29]. The quantum metric has previously been connected to the size of a maximally localized Wannier state [30,31] and is crucial in the modern theory of polarization [32]. Only recently, its importance was noticed in other contexts [33–37].
momentum space for flatband systems.

We show that the new Kubo formalism for fast relaxation is capable to treat the different cases within one theory. The formalism is based on a phenomenological quasiparticle relaxation rate $\Gamma$ of arbitrary size. This regularizes the spectral occupation, which results in smooth conductivity formulas and allow for a systematic expansion in $\Gamma$. Since the previous formulation in Ref. [39] was limited to two bands, we present here a self-contained generalization to a general number of bands.

For semimetals at charge neutrality, the divergence of the quantum metric is compensated by a vanishing quasiparticle relaxation rate $\Gamma$. Since the previous formulation in Ref. [39] was limited to two bands, we present here a self-contained generalization to a general number of bands.

Flat band systems are particular interesting, since the vanishing quasiparticle velocity drastically reduces the intraband contribution. We therefore expect the quantum metric to prominently enter the dc conductivity in systems with highly quenched bandwidth. To this end, we calculate the normal state conductivity in the flat band limit for a band structure with arbitrary lifetime broadening. As expected, the interband term can become even larger than the Drude term. Additionally, the conductivity develops a plateau for an intermediate regime $W_{\text{flat}} < \Gamma < \Delta_{\text{gap}}$ of band broadening. Here, the lower limit of the plateau is given by the small bandwidth $W_{\text{flat}}$ of the quenched band, while the band gap $\Delta_{\text{gap}}$ to neighboring bands present the upper limit.

The quantum metric $g$ and the Berry curvature $\Omega$ are the real and imaginary part of the quantum geometric tensor, respectively, which is positive semi-definite [26]. This imposes a lower bound on their products $g^{\alpha\beta}$ and $\Omega^{\alpha\beta}$, which imposes a lower bound $\int p \, \text{tr} \, g \geq \int p |\Omega^{\alpha\beta}| \geq |C|/2\pi$ in two-dimensional systems [26,42,43], where $C$ is the Chern number. Based on the interpretation of the quantum metric as spread of the wave functions, this property is also known as "Wannier obstruction" [30,31,44]. In two-dimensional flat band systems in the regime $W_{\text{flat}} < \Gamma < \Delta_{\text{gap}}$ of band broadening, we find that the trace over the quantum metric contribution is proportional to $\int p \, \text{tr} \, g$ and, thus, bounded from below. This implies a new upper bound on the resistivity, which is unrelated to previous bounds which were suggested due to strong interactions and the related fast thermalization of quasiparticles [16,45–47]. We reemphasize that the bound is not a universal limit, because it only holds within a certain regime of relaxation rates.

We propose to use low-mobility RTG samples as a platform to search for the quantum metric effect experimentally. In particular, we suggest to study the temperature dependence of the conductivity and predict a conductivity minimum below room temperature as a result of decreasing classical (intraband) and increasing quantum metric (interband) contributions. In RTG both intraband and interband contributions are of similar size over the full temperature range in contrast to perfect flat band systems, where the energy scales are well separated. Nevertheless, we can clearly assign the conductivity minimum at the predicted temperatures to the quantum metric, since a conductivity upturn due to thermal activation of higher bands take place far beyond room temperature. We find the minimum for a broad range of tunable parameters.

The paper is structured as follows: We present the Kubo formalism for fast relaxation for a general multiband system and present our key formulas for the conductivity. The role of band broadening is discussed for metals, semimetals, and flat bands, where the bound on the resistivity is derived. The theory is then applied to a generic flat band model and RTG. We summarize our findings in the conclusions.

II. RESULTS

A. Conductivity formulas

We consider a non-interacting quadratic tight-binding Hamiltonian for an $N$-band system

$$H = \sum_p \Psi_p^\dagger \lambda_p \Psi_p,$$  

where the spinor $\Psi_p = (c_{p,1}, \ldots, c_{p,N})$ and its complex conjugate $\Psi_p^\dagger$ involve the fermionic annihilation and creation operators of the $N$ bands at (crystal) momentum $p$, respectively. $\lambda_p$ is the Hermitian $N \times N$ Bloch Hamiltonian matrix.

We calculate the dc conductivity given by

$$\sigma^{\alpha\beta} = -\lim_{\omega \to 0} \frac{1}{i\omega} \Pi^{\alpha\beta}(\omega),$$  

where $\alpha$ and $\beta$ denote the spatial directions of the current and the electric field, respectively, in $d$ dimensions. The following derivation generalizes the approach developed
The intraband contribution $v$ with fermionic Matsubara frequency $ip$ velocity (6) has both diagonal and off-diagonal contributions to the conductivity tensor (3) involving the generalized velocities, that is, the momentum derivatives of the Bloch matrix in Eq. (1), $\lambda^\alpha_p = \partial_\alpha \lambda_p$, and the Green’s function matrix

$$g_{ip_0,p} = [ip_0 + \mu - \lambda_p + i\Gamma \text{sign}(p_0)]^{-1} \quad (4)$$

with fermionic Matsubara frequency $ip_0$. We denote the trace over the $N$ bands as $Tr$. $T$ is the temperature and $V$ the volume of the Brillouin zone. The second term in Eq. (3) is the diamagnetic term, which is equal to the first term with $ip_0$ set to zero.

The key in the used approach is to consider a phenomenological relaxation rate $\Gamma > 0$, which is not restricted in size in the following derivation [39]. For simplicity, $\Gamma$ is assumed to be frequency- and momentum-independent as well as equal for all bands.

We diagonalize the Bloch Hamiltonian $\lambda_p$ by its $N$ eigenvectors $|n_p\rangle$ with corresponding eigenvalues $E_n^p$. The elements of the Green’s function and the generalized velocities in the eigenbasis then read

$$G^\alpha_{ip_0,p} = [ip_0 + \mu - E_n^p + i\Gamma \text{sign}(p_0)]^{-1}, \quad (5)$$

and

$$\lambda^\alpha_p E_n^p = \delta_{nm} v^{\alpha,n}_p + i(E_n^p - E_m^p)A^{\alpha,m}_n, \quad (6)$$

where we denote the quasiparticle velocities as $v^{\alpha,n}_p = \partial_\alpha E_n^p$ and the Berry connection as $A^{\alpha,n}_m = i\langle n_p | \partial_\alpha | m_p \rangle$. $\delta_{nm}$ is the Kronecker delta. Note that the quasiparticle Green’s function (5) is diagonal, whereas the generalized velocity (6) has both diagonal and off-diagonal contributions leading to both intraband and interband contributions to the conductivity tensor $\sigma^{\alpha\beta}$. Furthermore, we uniquely decompose $\sigma^{\alpha\beta}$ into its symmetric and antisymmetric parts under the exchange of $\alpha \leftrightarrow \beta$. After performing the Matsubara summation, analytic continuation, and the thermodynamic limit $1/V \sum_p \rightarrow \int d^d p/(2\pi)^d$ we obtain the decomposition

$$\sigma^{\alpha\beta} = \sigma^{\alpha\beta}_{\text{intra}} + \sigma^{\alpha\beta}_{\text{inter}} + \sigma^{\alpha\beta,a}_{\text{inter}}. \quad (7)$$

The intraband contribution $\sigma^{\alpha\beta}_{\text{intra}} = \sigma^{\alpha\beta}_{\text{intra}}$ is symmetric, whereas the interband contribution has both a symmetric part $\sigma^{\alpha\beta,a}_{\text{inter}} = \sigma^{\alpha\beta,a}_{\text{inter}}$ and an antisymmetric part $\sigma^{\alpha\beta,a}_{\text{inter}} = -\sigma^{\beta\alpha,a}_{\text{inter}}$. The three contributions read

$$\sigma^{\alpha\beta}_{\text{intra}} = \frac{e^2}{h} \int \frac{d^d p}{(2\pi)^d} \int df' \langle \epsilon \rangle \sum_n u^{n}_{p,\text{intra}}(\epsilon) v^{\alpha,n}_{p} v^{\beta,n}_{p}, \quad (8)$$

$$\sigma^{\alpha\beta}_{\text{inter}} = -\frac{e^2}{h} \int \frac{d^d p}{(2\pi)^d} \int df' \langle \epsilon \rangle \sum_{n,m} u^{n,m}_{p,\text{inter}}(\epsilon) A^{\alpha,m}_n A^{\beta,n}_m, \quad (9)$$

$$\sigma^{\alpha\beta,a}_{\text{inter}} = \frac{e^2}{h} \int \frac{d^d p}{(2\pi)^d} \int df' \langle \epsilon \rangle \sum_{n,m} u^{n,m,a}_{p,\text{inter}}(\epsilon) \Omega^{\alpha,m}_n \Omega^{\beta,n}_m, \quad (10)$$

where $f(\epsilon) = [\exp(\epsilon/k_BT) + 1]^{-1}$ and $f'(\epsilon)$ are the Fermi distribution and its derivative, respectively. The momentum integration is performed over the $d$-dimensional Brillouin zone. We discuss the different quantities in the following. The intraband contribution (8) involves a summation over all bands with their respective quasiparticle velocities $v^{\alpha,n}_p$. The two interband contributions (9) and (10) involve a summation over all pairs of bands with

$$g^{\alpha\beta}_{p,\text{nm}} = \text{Re}[A^{\alpha,n}_p A^{\beta,m}_n], \quad (11)$$

$$\Omega^{\alpha\beta}_{p,\text{nm}} = -2\text{Im}[A^{\alpha,n}_p A^{\beta,m}_n], \quad (12)$$

which are invariant under the $U(1)$ gauge freedom $|n_p\rangle \rightarrow e^{i\phi_p}|n_p\rangle$ for $n \neq m$ due to the particular combination of the Berry connections. The summation over $n \neq m$ $A^{\alpha,n}_p A^{\beta,n}_m$ yields the quantum geometric tensor $\mathcal{T}^{\alpha\beta,n}$, which decomposes into the symmetric real part $\sigma^{\alpha\beta,n}_{\text{sym}}$ and antisymmetric imaginary part $-\Omega^{\alpha\beta,n}_{\text{sym}}/2$, that is, the quantum (or Fubini-Study) metric and the Berry curvature, respectively [38].

$$\sum_{m \neq n} g^{\alpha\beta}_{p,\text{nm}} = \sum_{m \neq n} \sigma^{\alpha\beta}_{\text{inter}} = g^{\alpha\beta}_{p}, \quad (13)$$

$$\sum_{m \neq n} \Omega^{\alpha\beta}_{p,\text{nm}} = -\sum_{m \neq n} \Omega^{\alpha\beta}_{p,\text{nm}} = \Omega^{\alpha\beta}_{p}. \quad (14)$$

We emphasize that the interband contribution can be interpreted as a pure quantum geometrical quantity. For a two-band system, note that (11) and (12) are already the quantum metric and the Berry curvature, respectively. To highlight the geometric interpretation of the interband contributions, we refer to $\sigma^{\alpha\beta}_{\text{inter}}$ and $\sigma^{\alpha\beta,a}_{\text{inter}}$ as the quantum metric and the Berry curvature contribution, respectively, in the following.

The three contributions to the conductivity (8)-(10) involve three different spectral weighting factors

$$u^{n}_{p,\text{intra}}(\epsilon) = \pi A^{n}_p(\epsilon)^2, \quad (15)$$

$$u^{n,m,s}_{p,\text{inter}}(\epsilon) = \pi (E_n^p - E_m^p)^2 A^{n}_p A^{m}_n(\epsilon), \quad (16)$$

which are particular combinations of the quasiparticle spectral functions

$$A^{n}_p(\epsilon) = \frac{1}{\pi} \frac{\Gamma}{\Gamma^2 + (\epsilon + \mu - E_n^p)^2}. \quad (18)$$
We note that $w_{p,\text{inter}}^{n,s}(\epsilon) = w_{p,\text{inter}}^{n,s}(\epsilon) = 0$ for the diagonal components.

We close the general derivation by stressing that no assumptions on the size of $\Gamma$ were made during the calculation, so that the formulas for the conductivity in Eq. (7) and its contributions (8)-(10) are valid for $\Gamma$ of arbitrary size. However, the results crucially rely on the assumed simple form of the phenomenological relaxation rate $\Gamma$. A generalization, for instance, by using a frequency and momentum dependent $\Gamma(p, \omega)$ or a band dependent $\Gamma^{nm}$, is beyond the scope of this paper. Furthermore, $\Gamma$ is assumed without any specification of its physical realization, for instance, due to interaction, impurity scattering, or coupling to the environment, and potential vertex corrections are not taken into account in our calculation. The range of validity of our assumptions, thus, to be checked within the concrete application.

**B. Role of band broadening**

We discuss the dependence on the phenomenological relaxation rate $\Gamma$, which is captured by the spectral weighting factors (15)-(17). We distinguish three different cases: the clean limit for a metal, charge neutrality points in (higher-order) Dirac semimetals, and flat bands. We note that the scaling behavior for large $\Gamma$ and the (topological) properties of the Berry curvature contribution $\sigma_{\text{inter}}^{\alpha\beta,\lambda}$ were already discussed in Ref. [39] and will not be considered further here.

**a. Clean limit for a metal** In the following, we generalize the results for two-band systems given in Refs. [39,48]. We assume a $d-1$-dimensional Fermi surface. If $\Gamma$ is so small that for given directions $\alpha, \beta$, and bands $n, m$ the quantities $\epsilon_{p,n}^{\alpha,n,\beta,n,m}$, $\gamma_{p,n}^{\alpha,n,\beta,n,m}$, and $\Omega^{\alpha,n} p^{\beta,n,m}$ are almost constant in a momentum range in which the variation of $E_{p,n}^{\beta,n,m}$ is of the order of $\Gamma$, we can approximate the spectral weighting factors in Eqs. (15)-(17) by Dirac delta functions with a particular leading-order dependence on $\Gamma$: $w_{p,\text{inter}}^{n} \sim 1/\Gamma$, $w_{p,\text{inter}}^{n,s} \sim \Gamma$, and $w_{p,\text{inter}}^{n,m} \sim 1$. After performing the frequency integration and using (13) and (14), we see that the intraband, the quantum metric and the Berry curvature contributions further decompose into individual band contributions $\sigma_{\text{intra},n}^{\alpha\beta,\lambda} \sim \epsilon_{p,n}^{\alpha,n,\beta,n,m}$, $\gamma_{p,n}^{\alpha,n,\beta,n,m}$, and $\Omega^{\alpha,n} p^{\beta,n,m}$: respectively, involving the respective quasiparticle velocities, quantum metric, and Berry curvature. Thus, we recover the well-known semiclassical results for the intraband contribution [49] as well as the dissipationless anomalous Hall conductivity due to the Berry curvature [50,51]. The quantum metric contribution of the longitudinal conductivity is suppressed by $\Gamma^{2}/(E_{p,n}^{\alpha,n,\beta,n,m} p^{\beta,n,m})^{2}$ compared to the intraband contribution. It provides significant contribution only at small direct band gaps, for instance, at the onset of order at quantum critical points [48,52].

**b. Charge neutrality points in Dirac semimetals** We calculate the longitudinal conductivity explicitly for four different models of (higher-order) Dirac semimetals

\begin{align}
\lambda_{p}^{(I)} &= \frac{a}{2} p_{z} \sigma_{z} + b p_{y} \sigma_{y}, \\
\lambda_{p}^{(II)} &= \frac{a}{2} (p_{y} - p_{x}) \sigma_{x} + a p_{z} p_{y} \sigma_{y} + \frac{b}{2} |p|^{2} \sigma_{z}, \\
\lambda_{p}^{(III)} &= p_{x} \sigma_{x} + p_{y} \sigma_{y}, \\
\lambda_{p}^{(IV)} &= a p_{z} \sigma_{z} + b p_{y} \sigma_{y} + c p_{z} \sigma_{z},
\end{align}

with parameters $a, b, c > 0$. $\sigma_{\alpha}$ are Pauli matrices. The Hamiltonian (19) and (22) describe two- and three-dimensional Dirac cones. A quadratic band touching and a mixed linear and quadratic band touching in two dimensions are described by (20) and (21), respectively. We fix the chemical potential $\mu$ to the charge neutrality point, so that the Fermi surface reduces to a single momentum point. The former considerations do not apply since the quantum metric diverges at that momentum. We perform the momentum integration over $\mathbb{R}^{d}$ and at zero temperature.

The results are summarized in Table. I. We find that the intraband contribution and the quantum metric contribution are of the same order in $\Gamma$. For (19), (20), and (22) the conductivity is independent of $\Gamma$. For (21) we find an unconventional scaling of $1/\sqrt{\Gamma}$ in $x$ direction and $\sqrt{\Gamma}$ in $y$ direction. In all cases, the size of the quantum metric contribution is of the same order as the intraband contribution. For instance, both $\epsilon_{p,n}^{\alpha,n,\beta,n,m}$ and $\gamma_{p,n}^{\alpha,n,\beta,n,m}$ contribute equally to the longitudinal conductivity of a symmetric
two-dimensional Dirac cone (19) with \( a = b \), where we obtain again \( \sigma_{xx} = e^2/\pi \hbar \) for a Dirac cone. The ratio between the quantum metric and the intraband contribution is, however, non-universal as explicitly shown for (20) with \( \sigma_{xx}^{\text{int}}/\sigma_{xx}^{\text{intra}} = a^2/(a^2 + b^2) \) for arbitrary \( a, b > 0 \).

\[ c. \text{ Flat band geometry} \]

We study the intraband and the quantum metric contribution for a flat band system. For convenience, we relabel the bands such that the zeroth band is the momentum-independent flat band, \( E_p^0 = E_{\text{flat}} \). We fix the chemical potential at the flat band energy \( \mu = E_{\text{flat}} \). We assume that the flat band is isolated such that \( \Gamma \ll |E_p^0 - E_{\text{flat}}| \) for all bands \( n \neq 0 \) and momenta \( p \).

Note that the following arguments also hold for bands \( E_p^0 \) that are flat on the scale of \( \Gamma \), i.e., \( |\mu - E_p^0| \ll \Gamma \) for all momenta \( p \). For simplicity, we consider zero temperature in the following. The spectral weighting factors involving the flat band are

\[
\begin{align*}
\sigma_{\text{intra}}^{\alpha \beta}(0) & \approx \frac{1}{\pi} \int d^2 p \tilde{g}_p^{\alpha \beta,0} \\
\sigma_{\text{intra}}^{0n,s}(0) & = \sigma_{\text{intra}}^{0n,s}(0) \approx \frac{1}{\pi} \\
\end{align*}
\]

for \( n \neq 0 \). The higher-order terms and the other contributions with \( n, m \neq 0 \) are of order \( \mathcal{O}(\Gamma^2/(E_p^0 - E_{\text{flat}})^2) \) and, thus, suppressed. Using the formula in Eq. (9) we see that the quantum metric contribution is given by the mean spread of the Bloch wave functions of the flat band \([30,31,44,53]\).

We focus on a two-dimensional system in the following, which we assume to lie in the \( x-y \) plane. The trace of the quantum metric is bounded by the absolute value of the Berry curvature \([26,43,54]\), that is, \( g_p^{\alpha \beta,n} = |\langle n|\hat{r}_\alpha|n_p\rangle\langle n_p|\hat{r}_\beta|n\rangle - \langle n|\hat{r}_\alpha|n\rangle\langle n|\hat{r}_\beta|n_p\rangle| \) with position operator \( \hat{r}_\alpha = i\partial_\alpha \) we see that \( g_p^{\alpha \beta,n} \) for a chemical potential inside the flat band is given by the mean spread of the Bloch wave functions of the flat band \([30,31,44,53]\).

The quantum metric contribution in \( x \) and \( y \) direction is bounded from below, that is,

\[
\sigma_{\text{intra}}^{xx,n} + \sigma_{\text{intra}}^{yy,n} \geq \frac{2}{\pi} \frac{e^2}{\hbar} \int \frac{d^2 p}{(2\pi)^2} |\Omega_{xy,p}| \geq \frac{2}{\pi} \frac{e^2}{2\pi \hbar} |C_0|, \tag{26}
\]

where the Chern number is defined by \( C_n = 2\pi \int \Omega_{xy,p} d^2 p \in \mathbb{Z} \). We see that the quantum metric contribution and, thus, the longitudinal conductivity is always finite for systems with nonzero Berry curvature. In the next section we explore this bound for a topological flat band with nonzero Chern number, where it is particularly prominent.

The intraband contribution (8) involves the quasiparticle velocities, which are identically zero in a perfect flat band. Thus, the conductivity is entirely given quantum metric contribution. In almost flat bands, both intra- and interband processes contribute and it depends on the value of \( \Gamma \) which one is dominant. We can give an estimate on the crossover scale of \( \Gamma \) by setting \( \sigma_{xx}^{\text{intra}} + \sigma_{yy}^{\text{intra}} = \sigma_{xx}^{\text{intra}} + \sigma_{yy}^{\text{intra}} \), from which we conclude that the quantum metric related conductivity is dominant for values of the band broadening above a threshold \( \Gamma_c \), with

\[
\Gamma_c \lesssim \sqrt{\frac{\pi}{|C_0|} \left( |v_{\text{max}}^{x,0}|^2 + |v_{\text{max}}^{y,0}|^2 \right)} \tag{27}
\]

by using (23) and (26) and approximating the quasiparticle velocities by their upper bounds \( v_{\text{max}}^{x,0} \). However, note that a large estimate for \( \Gamma_c \) does not imply a negligible interband contribution for smaller \( \Gamma_c \), as we discuss in a moment using the example of rhombohedral trilayer graphene.

\[ \]

C. Flat band model

We apply our theory to a two-band model hosting a topological non-trivial flat lower and a dispersive upper band which was introduced in Ref. [55]. We show the band structure in Fig. 2. The complete Hamiltonian, the explicit form of the two bands \( E_p^\pm \) as well as the quantum metrics \( g_p^{xx,\pm} \) and \( g_p^{yy,\pm} \) are provided in the appendix. We use \( t \) as our unit of energy and set the lattice constant \( a = 1 \). We fix the chemical potential to the center of the lower band and analyze the longitudinal conductivity and its different contributions in the following. In Fig. 3 a) we show the total longitudinal conductivity \( \sigma_{\text{total}} = \sigma_{xx} + \sigma_{yy} \) (blue) calculated via (7) at zero temperature as a function of \( \Gamma/t \). We have \( \sigma_{xx} = \sigma_{yy} \) as expected by the C4 symmetry of the model. We clearly identify three different regimes with the crossover scales given by the band width of the flat band \( W_\pm/t = 0.036 \) and the band gap \( \Delta/t = 4 \). For small \( \Gamma \lesssim W_- \) the conductivity is dominated by the intraband contribution (8) (orange)
For an intermediate relaxation rate, flat band, $\mu$ at small $\Gamma$ the conductivity is dominated by the intraband with chemical potential fixed to the center of the lower and quantum metric can be calculated explicitly, yielding strongly suppressed. For large $\Gamma \gtrsim$ the total conductivity is dominated by the quantum metric and (26), respectively. Above the threshold $\Gamma \gtrsim \Delta$, we have $\sigma_{\text{intra,\pm}} \sim 1/\Gamma^2$ [39]. In the intermediate regime $W_- \ll \Gamma \ll \Delta$, we have $\sigma_{\text{intra,\pm}} \sim 1/\Gamma^2$ and $\sigma_{\text{inter}} \sim 1$ as expected by (23) and (24), respectively.

**D. Rhombohedral trilayer graphene**

We apply our theory to a realistic six-band low-energy model of the two-dimensional rhombohedral trilayer graphene in the regime of low carrier density where the fourfold flavor-symmetry in valley and spin is broken and only one flavor is occupied [11]. The full Hamiltonian and the parameters are summarized in the appendix. The material is highly tunable via an electrical displacement field, which introduces an energy gap $\Delta_1$. The band structure is shown in Fig. 2. Bands number 3 (orange) and 4 (blue) are almost flat within a momentum range of $|p|/a_0 \lesssim 0.05$, where $a_0$ is the lattice constant. In the following, we probe the longitudinal conductivity at the lower edge $\mu_{4,\min}$ of the nearly flat conduction band 4. The integration was performed on a square region up to a momentum cutoff $\pi a_0 \gg 0.05a_0$.

In Fig. 4 a) we show the obtained total conductivity $\sigma_{\text{total}} = \sigma_{xx} + \sigma_{yy}$ (blue) and its quantum metric (red) and intraband (orange) contribution as a function of $\Gamma$ at zero temperature. We fix $\Delta_1 = 40\text{ meV}$ and $\mu_{4,\min} = 1.4\text{ meV}$. Although the band structure is more complicated than for the flat band model, which we discussed previously, we find similar characteristic regimes. For intermediate relaxation rates between $\Gamma \approx 0.03...3\text{ eV}$ we find a large geometric interband contribution exceeding the lower bound (26) due to the Berry charges totaling $C_s = 3/2$ near the band bottom of the fourth band. For small values of $\Gamma$ the main part of the quantum metric contribution is due to the interband coupling of the close bands 3 and 4, i.e. $\sigma_{\text{inter}} \approx \sigma_{34}^{\text{inter}} + \sigma_{43}^{\text{inter}}$. For larger $\Gamma$ the quantum metric contribution of all other 28 interband couplings $\sigma_{\text{inter,other}}$ are required to exceed the lower bound. This might become important when using projections on a single band. Note that, in contrast to the flat band model discussed before, the intermediate regime cannot be easily connected to the characteristic energy scales of the system (vertical gray lines for the band width of the fourth band $W_4$ and the gaps to the third and fifth band $\Delta_{34}$ and $\Delta_{45}$, respectively). The main reason is based on the finite momentum range, in which the fourth band is flat: The relevant spectral weighting

due to the small but finite quasiparticle velocities with maximal values $v_{\text{max}}^x = v_{\text{max}}^y = 0.076t$ of the flat band (dashed orange). For an intermediate relaxation rate, $W_- \lesssim \Gamma \lesssim \Delta$, the quantum metric contribution (9) (red) is independent of $\Gamma$ and bounded from below by the finite Chern number $C_- = 2$ of the flat band according to (25) and (26), respectively. Above the threshold $\Gamma_c/t \approx 0.134$ the total conductivity is dominated by the quantum metric contribution. For large $\Gamma \gtrsim \Delta$ the total conductivity is strongly suppressed.

In this simple model, the integral of Eq. (25) over quantum metric can be calculated explicitly, yielding

$$\int \frac{d^2p}{(2\pi)^2} (g_{p}^{xx,-} + g_{p}^{yy,-}) = \frac{K(-1/8)}{\sqrt{2\pi}} \frac{|C|}{2\pi},$$

where $K(m) = \int_0^{\pi/2} 1(1 - m \sin^2 \theta)^{-1/2} d\theta$ is the complete elliptic integral of the first kind. The numerical value of Eq. (28) is 0.34, less than 10% above the threshold $1/\pi = 0.32$. We see that in a nearly perfect flat band, the bound holds tight.

In Fig. 3 b) we plot the logarithmic derivative of the different conductivity contributions as a function of $\Gamma/t$. For $\Gamma \ll W_-$ we have $\sigma_{\text{intra}} \sim 1/\Gamma$ and $\sigma_{\text{inter}} \sim \Gamma$ as expected for the clean limit behavior of a metal as discussed above. The intraband contribution of the upper band scales as $\sigma_{\text{intra,\pm}} \sim \Gamma^2$ [39]. For $\Gamma \gg \Delta$, we have $\sigma_{\text{intra,\pm}} \sim \sigma_{\text{inter}} \sim 1/\Gamma^2$ [39]. In the intermediate regime $W_- \ll \Gamma \ll \Delta$, we have $\sigma_{\text{intra,\pm}} \sim 1/\Gamma^2$ and $\sigma_{\text{inter}} \sim 1$ as expected by (23) and (24), respectively.
The maximal value of $\sigma_k^{\text{intra}}$ with $\Gamma = 4$ (red dashed) but all other 28 couplings contribute (purple dashed) significantly. Thus, the range of the momentum integration in the order of the band width of the flat band $W_k$ is much smaller than the smallest gap $\Delta_3 = 70 \text{meV}$ of the almost flat fourth band and the increase of the quantum metric contribution. It is important to notice that the temperature broadening by the Fermi function enhances the intraband contribution, in particular, of the fourth band (orange and dashed), which can be understood by the scaling argument $\sigma_{\text{intra}}^{\text{xx}} \sim 1/T \sim 1/T$. At high temperature, especially beyond $T \sim \Delta_3/k_B \approx 800 \text{K}$, the other bands contribute significantly (green and dashed). In an intermediate range the quantum metric contribution becomes crucial. We see that the temperature broadening by the Fermi function enhances the intraband contribution, whereas the quantum metric contribution is affected very little.

The conductivity $\sigma^{xx}$ exhibits a minimum at approximately $T_{\text{min}} \approx 170 \text{K}$. The decomposition into its contributions shown in Fig. 4 reveals the origin of this minimum. It is caused by the decrease of the intraband contribution of the almost flat fourth band and the increase of the quantum metric contribution. It is important to notice that the thermal activation of the other bands leading to further intraband contributions is not sufficient to a cause a minimum at such a low energy scale $k_BT_{\text{min}} \sim 15 \text{meV}$, which is much smaller than the smallest gap $\Delta_3 = 70 \text{meV}$. The intraband contributions of the other bands lead to a second kink at much higher temperature. Thus, we have identified a minimum of the longitudinal conductivity due to virtual processes, i.e. effects of the quantum metric in rhombohedral trilayer graphene.

In Fig. 5 we discuss the stability and trends of the minimum for different parameter values. In Fig. 5 a) we show $\sigma^{xx}$ (solid) and the corresponding intraband contribution (dashed) for different $\Delta_1$ at fixed $\Gamma = k_BT$ and corresponding finite quasiparticle velocities, the intraband contribution is nonzero over the full range of $\Gamma$, in particular, when $\Gamma$ exceeds the gaps to band 3 and 5 with $\Delta_{34} = 70 \text{meV}$ and $\Delta_{45} = 317 \text{meV}$. The upper scale is again given by the momentum cutoff.

The temperature dependence of the conductivity in RTG beyond 100K has not yet been investigated in detail, but the presence of flat bands and the emergence of superconducting phases at low temperatures suggests that the material offers a similar phenomenology to TBG. The latter has been shown to exhibit a very large linear-T resistivity, possibly making it a Planckian metal [17] in which the relaxation rate is close to a putative upper bound $O(k_BT)$. Therefore, for the discussion of the temperature dependence and possible experimental signatures in RTG, we feel it is justified to assume the ‘best case scenario’ for our purposes, where $\Gamma \sim k_BT$ with a coefficient close to 1. In Fig. 4 b) we show the conductivity $\sigma^{xx}$ (blue) and its quantum metric (red) and intraband (orange) contributions as a function of temperature. We used the same parameters for $\Delta_1$ and $\mu$ as in the upper figure and assumed a relaxation rate of $\Gamma = k_BT$, which can be understood by the scaling argument $\sigma_{\text{intra}}^{\text{xx}} \sim 1/T \sim 1/T$. At high temperature, especially beyond $T \sim \Delta_3/k_B \approx 800 \text{K}$, the other bands contribute significantly (green and dashed). In an intermediate range the quantum metric contribution becomes crucial. We see that the temperature broadening enhances the intraband contribution, whereas the quantum metric contribution is affected very little.
The quantum-metric induced conductivity minimum in trilayer graphene. (a) The total (solid) and the intraband (dashed) conductivity as a function of temperature for different $\Delta_1$ at fixed $\mu = 1.05\mu_{4,\text{min}}$ and $\Gamma = k_BT$. (b) The temperature of the minimal total (red filled and empty box) and intraband (blue star) conductivity for different parameters compared to $\mu = 1.05\mu_{4,\text{min}}$, $\Gamma = k_BT$, and $\Delta_1 = 40 \text{ meV}$ (empty box).

$\mu/\mu_{4,\text{min}} = 1.05$, that is $\mu - \mu_{4,\text{min}} = 1.4, 0.9, 0.4 \text{ meV}$ for $\Delta_1 = 40, 30, 20 \text{ meV}$. We see a pronounced minimum for all three parameter sets. The comparison to the intraband contribution clearly shows that this minimum is caused by virtual processes captured by the quantum metric and not by thermal activation of intraband processes. Only a small minimum at significiant higher temperature can be found for $\Delta_1 = 20 \text{ meV}$ (blue) and $\Delta_1 = 30 \text{ meV}$ (orange). We summarize the temperature of the conductivity minimum in Fig. 5 b) for these and further parameters of $\Gamma/k_BT$, $\mu/\mu_{4,\text{min}}$, and $\Delta_1$. The minimum found in Fig. 4 b) is taken as a reference (empty red box). We see that decreasing the temperature dependence of $\Gamma$ shifts the minimum to higher temperature. We understand this shift by both an increase of the intraband and a decrease of the quantum metric contribution by the following argument: The conductivity minimum at temperature $T_{\text{min}}$ satisfies $d\sigma^{xx}/dT = 0$. Assuming the scaling $\sigma^{xx}_{\text{intra}} \sim 1/ak_BT$ and $\sigma^{xx,s}_{\text{inter}} \sim ak_BT$ leads to $T_{\text{min}} \sim 1/a$ with $a = 0.4, 0.6, 0.8$, and 1.0. Note that the assumed scaling is only expected for small temperature. An increase of the chemical potential $\mu/\mu_{4,\text{min}} = 1.01, 1.05,$ and 1.1, that is $\mu - \mu_{4,\text{min}} = 0.3, 1.4,$ and $2.8 \text{ meV}$, respectively, increases the Fermi velocity on the Fermi surface [cf. Fig. 2]. This increases the intraband contribution (8), whereas the quantum metric contribution remains unchanged. Thus, the minimum shifts to higher temperatures. Modifying $\Delta_1$ decreases the gap between band 3 and 4, which increases the quantum metric. This and a decrease of the intraband contribution shifts the minimum to lower temperature. Whereas the full conductivity $\sigma^{xx}$ exhibits a conductivity minimum for all considered parameters, the intraband contribution $\sigma^{\text{xx}}_{\text{intra}}$ does not show any minimum in the reasonable temperature for most of the parameters.

We end with a discussion of the limitations of our approach. Since the formalism makes exclusive use of the band broadening parameter $\Gamma$, a legitimate concern is whether vector corrections and extrinsic scattering due to impurities can qualitatively affect the results presented here. While both these effects can indeed become problematic in semimetals which necessarily have a small density of states and a large Fermi velocity [50,56], for a flat band dispersion it is the opposite, as it has a large density of states and a vanishing quasiparticle velocity. It therefore behaves like ordinary metals with a large Fermi surface, where the quantum lifetime and the transport lifetime are identical and impurities effects are weak.

We also limited the analysis to the non-interacting case. Upon introducing interactions, additional interband processes become possible which are mediated by these interactions. Since this introduces additional virtual transitions, we expect it to increase both the effective $\Gamma$ and the effective $g$. As a result, it could be that the bound on resistivity is only weakly fulfilled. Since the bound is already only weakly fulfilled due to the finite residual Fermi velocity in RTG, it does not affect our main conclusions. A more serious complication is the possible presence of ordered states near charge neutrality. Experimentally, a correlated insulating state seems to emerge for carrier densities below $n_c = 0.05 \cdot 10^{12} \text{cm}^{-2}$, corresponding to a chemical potential of $1 - 2 \text{meV}$ above the band termination, which is comparable to the densities considered here. It is presently unclear whether such a state will also exist in samples of lower mobility.

III. CONCLUSIONS

We systematically explored the role of the quantum metric for the electrical conductivity for various semimetallic and metallic model systems, finding that it contributes at leading order both if the density of states vanishes at semimetallic band crossing points, but also when the density of states diverges in systems with quenched bandwidth and vanishing Fermi velocity. We reported an upper bound on the resistivity for flatband materials with nonzero Berry curvature and elucidated the range of validity and the limitations of this bound. As a platform to explore the resistivity bound, we suggested to employ...
rhombohedral trilayer graphene, and gave a detailed account of the various crossover scales which are expected in the system. After completion of this work, the simultaneously finished Ref. [57] was brought to our attention, who identified lower bounds to the quantum metric in flat band systems whose Wannier centers are obstructed from the atoms and which do not necessarily have a finite Berry curvature. This result suggests that the bound on the resistivity due to the quantum metric applies to a much broader class of materials as long as our other assumptions are fulfilled.

It is of timely relevance to explore how interactions will change the phenomenology reported here, in particular with respect to the quantum metric, a band structure parameter like the Berry curvature which is probably quite robust against interaction effects.

We are very grateful to Erez Berg, Laura Classen, Johannes Hofmann, and Elio König for valuable discussions.

IV. APPENDIX

In this appendix, we state the tight-binding Hamiltonians which were used in the numerical calculations for Figs. 3-5 of the main text.

A. Flat band model

As a toy model for topological flat bands we employ a square bipartite lattice where one band is flattened by longer-ranged hopping [55]. It reads explicitly,

$$\lambda_p/t = -\frac{1 - \sqrt{3}}{2} \left[ \cos \left(2(p_x + p_y)\right) + \cos \left(2(p_x - p_y)\right) \right] 1 - 2\sqrt{2} \sin(p_x) \sin(p_y) \sigma_z$$

$$-\sqrt{2} \left[ \cos(p_y) + \cos(p_x) \right] \sigma_x - \sqrt{2} \left[ \cos(p_y) - \cos(p_x) \right] \sigma_y.$$ (29)

The eigenvalues are

$$E_p^\pm = -(1 - \sqrt{2}) \cos 2p_x \cos 2p_y \pm \sqrt{6 + 2 \cos 2p_x \cos 2p_y}.$$ (30)

Numerically, we find for the energies where the bands terminate the values $E_{\text{max}}^+/t = 3.243$, $E_{\text{min}}^+/t = 1.586$, $E_{\text{max}}^-/t = -2.414$ and $E_{\text{min}}^-/t = -2.450$. We place the chemical potential in the middle of the flat band, at $\mu = (E_{\text{max}}^- + E_{\text{min}}^-)/2 = -2.432$. The quantum metric reads

$$g_{p^x,\pm}^{xx} = \frac{2(\sin p_y)^2 [1 + (\cos p_x)^2 (\cos p_y)^2] + (\cos p_y)^2 (\sin p_x)^2}{(3 + \cos 2p_x \cos 2p_y)^2},$$ (31)

$$g_{p^y,\pm}^{yy} = \frac{2(\sin p_x)^2 [1 + (\cos p_x)^2 (\cos p_y)^2] + (\cos p_x)^2 (\sin p_y)^2}{(3 + \cos 2p_x \cos 2p_y)^2}.$$ (32)

We have $v_{x,\pm}(p_x, p_y) = v_{y,\pm}(-p_y, p_x)$, $v_{y,\pm}(p_x, p_y) = -v_{x,\pm}(-p_y, p_x)$, and $g_{x,\pm}(p_x, p_y) = g_{y,\pm}(-p_y, p_x)$. Thus, it follows that $\sigma_{\text{intra}}^{xx} = \sigma_{\text{intra}}^{yy}$ and $\sigma_{\text{inter}}^{xx} = \sigma_{\text{inter}}^{yy}$.

B. Rhombohedral trilayer graphene

The six band model for trilayer graphene is adapted from [11]. It holds for each valley degree of freedom and both spin degrees of freedom, meaning that the total number of bands is 24. At low electron or hole density, the system spontaneously breaks the fourfold degenerate ground state symmetry and resides in a single flavor-polarized state.
where we used the shorthand $\pi = \xi p_x + i p_y$ with $\xi = \pm 1$ for the valley degree of freedom, it is (choosing $\xi = 1$),

$$
\lambda_p = \begin{pmatrix}
\Delta_1 + \Delta_2 + \delta & \gamma_2/2 & v_0 \pi_p^\dagger & v_4 \pi_p^\dagger & v_3 \pi_p & 0 \\
\gamma_2/2 & \Delta_2 - \Delta_1 + \delta & 0 & v_3 \pi_p & v_4 \pi_p & v_0 \pi_p \\
v_0 \pi_p & 0 & \Delta_1 + \Delta_2 & \gamma_1 & v_4 \pi_p^\dagger & v_0 \pi_p^\dagger \\
v_4 \pi_p & v_3 \pi_p & \gamma_1 & -2\Delta_2 & v_0 \pi_p & v_4 \pi_p \\
v_3 \pi_p^\dagger & v_4 \pi_p^\dagger & v_4 \pi_p & v_0 \pi_p & -2\Delta_2 & \gamma_1 \\
0 & 0 & v_4 \pi_p & \gamma_1 & \Delta_2 - \Delta_1 & 
\end{pmatrix}
$$

(33)

Using $\pi_p = \xi p_x + i p_y$ with $\xi = \pm 1$ for the valley degree of freedom, it is (choosing $\xi = 1$),

where we used the shorthand $v_i = \sqrt{3} a_0 \gamma_i/2$. The parameters take the following values [11]: $\gamma_0 = 3.1 \text{ eV}, \gamma_1 = 0.38 \text{ eV}, \gamma_2 = -0.015 \text{ eV}, \gamma_3 = -0.29 \text{ eV}, \gamma_4 = -0.141 \text{ eV}, \delta = -0.0105 \text{ eV},$ and $\Delta_2 = -0.0023 \text{ eV}$.
