Abstract. Although tremendous achievements have been made toward inertial confinement fusion, laser plasma instabilities (LPIs) remain to be the inevitable problem for current drive schemes. To mitigate these instabilities, here we propose the design of polychromatic drivers for the generation of multicolor beams based upon optical parametric amplification and frequency conversion technologies. Each polychromatic light has four colors of monochromatic beamlets with a full spectrum width of 3%, and the beamlet colors of any two adjacent flanges are different. The suppression effects of such polychromatic lights have been investigated via particle-in-cell simulations, which indicate that more than 35% of the incident energies can be saved from the LPIs compared with monochromatic lasers for the direct drive scheme, or high-density filled target for the indirect drive scheme. The proposed polychromatic drivers are based on the matured technologies, and thus may pave the way towards realization of stable and high-efficiency fusion ignition.

1. Introduction

Achieving nuclear fusion energy on the Earth has long been a challenging scientific campaign since the idea of laser confinement fusion was proposed in the 1970s [1]. Recently, the fusion energy yield of 1.3MJ has been achieved at the National Ignition Facility (NIF) [2], which represents a new milestone towards the realization of inertial confinement fusion (ICF). The enhancement of the beam-target coupling efficiency remains a critical issue for achieving high-efficiency ignition. Laser plasma interaction is an inevitable process in ICF [3, 4, 5], where a target containing deuterium and tritium fuel is directly (direct drive) or indirectly (indirect drive) compressed by megajoule laser beams [6, 7, 8, 9, 10]. Laser plasma instabilities (LPIs) can be fully developed at the 10 picosecond scale in the interactions of high-power lasers and large scale plasmas [11]. The uncontrollable LPIs, such as stimulated scattering instabilities and two-plasmon
decay (TPD), are among the major obstacles to achieving ignition, causing laser energy loss [12, 13], asymmetric and insufficient compression [14, 15, 16], and target preheating [17, 18, 19]. Stimulated scattering instabilities including stimulated Raman scattering (SRS) and stimulated Brillouin scattering (SBS) are the decay of incident lasers into scattered lights via induced plasma density perturbations, which cause tremendous incident energy loss and modulate the pump envelope [20]. As an example for indirect drive, the minimum laser energy required for ignition scale is inversely proportional to the hohlraum-to-capsule coupling efficiency [21, 22]. Therefore, mitigation of LPIs will contribute to the high efficiency and stable ignition performance. A few ideas have been proposed to inhibit LPIs, such as laser smoothing techniques [23, 24, 25], broadband lasers [26], a spike train of uneven duration and delay [27], and near-vacuum hohlraum [28], etc.

Suppression of LPIs via broadband lasers has been investigated from the early 1970s [26, 29]. Both the theoretical model and numerical simulation indicate that the linear growth of LPIs can be reduced when the laser bandwidth is much larger than the growth rate [30, 31]. Therefore, typically the bandwidth scale $\gtrsim 1\% \omega_0$ ($\gtrsim 3.51$nm for the triple-frequency lasers) is required for the LPI inhibition, where $\omega_0$ is the central frequency. However, the phase matching condition required in the frequency conversion of broadband lasers is hard to be satisfied due to the dispersion of materials [32, 33, 34]. As a result, the bandwidth of the available ultraviolet laser is extremely limited, and the conversion efficiency is greatly reduced [34, 35].

Different from conventional broadband lasers, in this article we propose the design of polychromatic drive beams with multiple colors of monochromatic beamlets propagating in the same direction. The polychromatic driver generates the wide spectrum multicolor lights based upon the optical parametric amplification (OPA) and frequency conversion technologies, which skirts the low conversion efficiency of the broadband triple frequency. The LPIs developed by the polychromatic lights have been studied via theory and simulations, which show better inhibition effects than continuous broadband lasers at a long time scale [36, 37].

2. Theoretical model for LPI inhibition via polychromatic light

The fundamental requirements for the development of LPIs are the wave-vector matching condition $\vec{k}_0 = \vec{k}_p + \vec{k}_s$ and the frequency matching condition $\omega_0 = \omega_p + \omega_s$, where $\vec{k}_0$, $\vec{k}_p$ and $\vec{k}_s$ respectively are the wave-vectors of incident light, plasma wave and scattering light, and $\omega_p$ and $\omega_s$ are the frequencies of plasma wave and scattering light, respectively. The frequency difference detunes the phase matching of the three-wave coupling. However, the incident beams can still be coupled via the overlap of the instability regions in phase space, i.e., there is an applicable finite bandwidth for the satisfaction of the matching conditions. The beams are decoupled as long as the frequency difference is larger than the bandwidth threshold.

We first consider the beamlet decoupling threshold of the polychromatic light
interaction with homogeneous plasmas. The wavenumber width of the SRS instability region developed by a monochromatic laser with frequency $\omega_0$ is

$$\Delta k_L = a_0 k_L \sqrt{\frac{\omega_{pe}(\omega_0 - \omega_{pe})}{\omega_0^2 - 2\omega_{pe}\omega_{pe}}},$$

(1)

where $k_L = k_0 + \frac{c^{-1}}{\sqrt{\omega_0^2 - 2\omega_0\omega_{pe}}}$, and $a_0 = \sqrt{I_0(W/cm^2)[\lambda(\mu m)]^2}/1.37 \times 10^{18}$ is the amplitude of the incident laser. The phase matching condition of a two-color beam is detuned by the frequency difference $\delta k_L = k_{L1} - k_{L2} \neq 0$, which can be simplified to

$$\delta k_{LC}/\omega_0 = \left(\frac{1}{\sqrt{1 - \omega_{pe}^2/\omega_0^2}} + \frac{1 - \omega_{pe}/\omega_0}{\sqrt{1 - 2\omega_{pe}/\omega_0}}\right) \frac{\delta \omega_0}{\omega_0},$$

(2)

In general, the two beams are decoupled when their instability regions are completely separated by the frequency difference, i.e., $\delta k_{LC} \geq \sqrt{2} \Delta k_L$. The simplified decoupling threshold in the underdense plasma $\omega_{pe} \ll \omega_0$ is

$$\delta \omega_0/\omega_0 \gtrsim 3\Gamma/\omega_0,$$

(3)

where $\Gamma = k_L c a_0 \sqrt{\omega_{pe}/16(\omega_0 - \omega_{pe})}$ is the growth rate of backward SRS. Analogously, the decoupling threshold for SBS can also be obtained from the SBS dispersion relation, which is always less than Eq. (3) owing to the lower growth rate of SBS.

Under the same incident energy, the amplitude of each polychromatic beamlet is $a_i = a_0/\sqrt{N}$, where $N$ is the beamlet number. Note that each beamlet independently develops LPIS in homogeneous plasmas, when the decoupling threshold is satisfied. Therefore, LPISs are effectively mitigated when the intensities of decoupled beamlets do not satisfy the driving threshold in strongly damped plasmas.

Now we consider the convective amplification in an inhomogeneous plasma with density profile $n_e = n_0(1 + x/L)$, where $L$ is the density scale length and $x$ is the longitudinal axis. The saturation coefficient of convective SRS developed by a two-color beam is $\frac{2\pi \Gamma^2}{v_s v_p K_0} \left[1 + \cos\left(\frac{4L\omega_0 v_p^2 \omega_L^2}{n_0 c(\omega_0^2 - \omega_{pe}^2)^{3/2}} \delta \omega_0\right)\right],$$

(4)

where $v_s$, $v_p$ and $\nu_p$ are the group velocity of scattering light and plasma wave, and the damping of plasma wave, respectively. $K_0 = k_0 - k_s - k_L$ denotes the wavenumber mismatch. Based on Eq. (4), we know that the saturation level of electron plasma wave is reduced by the frequency difference $\delta \omega_0 \neq 0$. Therefore, the common Langmuir wave shared by the monochromatic lasers at $n_e/n_c \leq \cos^4 \theta_e/4$ is divided into multiple weakly coupled modes by the polychromatic lights with a broad spectrum $\Delta \omega_0 \gtrsim 3\% \omega_0$. The scattering lights of the polychromatic beams are also detuned from each other when the frequency difference satisfies $\delta \omega_0 \sim 10^{-2} \omega_0$. Assume that each polychromatic light has $N$ beamlets, and every beamlet shares different common modes with all other polychromatic beamlets, i.e., there are $N^2$ backscattered common waves. The amplification coefficient for the polychromatic lights can be estimated as $\alpha_p = N^2 \exp(1),$
and that for the monochromatic lasers with the same energy is \( \alpha_n = \exp(N) \) based on \( a_i = a_0 / \sqrt{N} \). The amplification ratio \( \alpha_p/\alpha_n \) is found to be less than one when \( N > 3 \), and the energy fraction \( \alpha_p^2/\alpha_n^2 < 1 \) is always satisfied for any \( N > 1 \). Therefore, polychromatic lights with \( \Delta \omega_0 \geq 3\% \omega_0 \) and beamlet number \( N \leq 4 \) can effectively control the intensity and saturation level of SRS in inhomogeneous plasmas.

Different from the convective SRS, the absolute SRS always develops in the density range \([ (\omega_0/2 - a_0 k_0 c/4)^2, (\omega_0/2 + a_0 k_0 c/4)^2 ] \) \([38, 42]\), where the multiple beams share the same scattering light. Analogously, the dispersion relation also indicates that TPD occurs in the same density region as absolute SRS. Therefore, the beamlets are decoupled from each other when the frequency differences satisfy

\[
\delta \omega_0 / \omega_0 \geq 0.866 a_i. \tag{5}
\]

The bandwidth of SBS scattering light is \( \Delta \omega_s \sim \Delta (k_i c_s) + \Delta u_L \), where \( \Delta k_i c \lesssim 2 \omega_0 \) and \( \Delta c_s \sim 10^{-3} c \) respectively are the scales of ion-acoustic wavenumber and velocity, and \( \Delta u_L \sim 10^{-3} c \) is the scale of ion flow velocity. Therefore, the frequency difference \( \delta \omega_0 \gtrsim 0.5\% \omega_0 \) is sufficient to inhibit SBS and CBET.

### 3. Optical design of the polychromatic light generation

In general, a polychromatic driver is able to generate numerous polychromatic beamlets with whole spectrum width larger than \( 40\% \omega_0 \) \([44, 45]\). However, the actual color numbers should be determined according to the cost and complexity of the project, as well as the LPI inhibition effect. Here we propose a typical design example of polychromatic driver with total 16 colors of monochromatic beamlets, where the full spectrum width is \( \Delta \omega_0 = 7.5\% \omega_0 \), and the difference between every two adjacent frequencies is constant \( \delta \omega_0 = 0.5\% \omega_0 \). The four-color beamlets with adjacent frequency difference \( \delta \omega_0 = 1\% \omega_0 \) are synthesized to form a single polychromatic beam with a spectrum width \( \Delta \omega_0 = 3\% \omega_0 \). Therefore, each laser entrance flange is injected with a four-color beam, and the polychromatic lights of any two adjacent flanges have total eight different color beamlets as shown in Fig. 1. The collective LPIs are also mitigated by the adjacent polychromatic beams, such as the mitigation of cross-beam energy transfer (CBET) due to the frequency detuning \( \delta \omega_0 \gtrsim 0.5\% \omega_0 \) \([38, 46, 47]\).

Based on the polychromatic driver scheme, the duration of the multicolor beamlets is on the order of nanoseconds with a narrow bandwidth of each beamlet. Therefore, the type-I SHG process can be described by the following Eqs. (6)-(7) on the slowly varying envelope of plane waves \([49, 50, 51]\).

\[
\frac{\partial A_1}{\partial x} = \frac{i \omega_1}{n_1 c} d_{\text{eff}} A_2 A_1^* \exp(i \Delta k_1 x) + \frac{i}{2k_1 c} \nabla^2 A_1, \tag{6}
\]

\[
\frac{\partial A_2}{\partial x} = \frac{i \omega_2}{2n_2 c} d_{\text{eff}} A_1 A_1 \exp(-i \Delta k_1 x) + \frac{i}{2k_2 c} \nabla^2 A_2 + \tan \rho \frac{\partial A_2}{\partial z}, \tag{7}
\]

where \( A \) is the complex amplitude of optical field, \( n \) and \( k \) respectively are the refractive index and wave vector in the nonlinear crystal, \( \rho \) is the walk-off angle of
the extraordinary light, \( d_{\text{eff}} \) is the effective nonlinear coefficient, and \( \Delta k_1 \) is the phase mismatch \( \Delta k_1 = k_{2e} - 2k_{1o} \). The subscripts \( o \) and \( e \) represent the ordinary light and extraordinary light, and 1 and 2 are the fundamental wave and the corresponding second harmonic, respectively. \( \nabla_\perp^2 = \partial_y^2 + \partial_z^2 \), where \( y \) and \( z \) are the transverse Cartesian coordinates in the plane orthogonal to the \( x \) direction of propagation.

Type-II phase matching is used for the OPA and THG processes, and the corresponding nonlinear coupling equations are as follows

\[
\frac{\partial A_1}{\partial x} = \frac{i\omega_1}{n_{1e}c}d_{\text{eff}}A_3A_2^*\exp(i\Delta k_\Pi x) + \frac{i}{2k_{1e}}\nabla_\perp^2A_1 + \tan \rho_{1e}\frac{\partial A_1}{\partial y},
\]

\[
\frac{\partial A_2}{\partial x} = \frac{i\omega_2}{n_{2o}c}d_{\text{eff}}A_3A_1^*\exp(i\Delta k_\Pi x) + \frac{i}{2k_{2o}}\nabla_\perp^2A_2,
\]

\[
\frac{\partial A_3}{\partial x} = \frac{i\omega_3}{n_{3e}c}d_{\text{eff}}A_1A_2\exp(-i\Delta k_\Pi x) + \frac{i}{2k_{3e}}\nabla_\perp^2A_3 + \tan \rho_{3e}\frac{\partial A_3}{\partial y},
\]

where \( \Delta k_\Pi = k_{3e} - k_{2o} - k_{1e} \). The subscripts 1, 2, and 3 refer to the fundamental, second and third harmonics in the THG process, and refer to the signal light, idler light and pump light in the OPA process, respectively.

The optical scheme for the efficient generation of high-power polychromatic laser is based upon the OPA and frequency conversion technologies indicated above, and an example for the generation of a four-color beam is exhibited in Fig. 1. The two-color light generator, including a main laser and the other different color signal light, is a unit of the polychromatic system, where a two-color beam with the fundamental frequency is obtained via the OPA process. The two-color beamlets are then separated due to their
distinct polarizations, and each monochromatic beamlet is triple-frequency converted independently. The other two-color light is generated in the same way. Finally, the four-color beamlets are synthesized into a single beam with all the beamlets propagation in the same direction, and the polarization of each beamlet can be controlled by adding the plasma electrode Pockels cell [48]. In the process of beam combination, reflective optical structures of the third-harmonic lights are utilized to reduce the damage.

The spatiotemporal shaping Nd:glass laser (1053nm) with an aperture of 350mm, 8kJ energy, and 3ns pulse duration is the fundamental wave pulse, and its second harmonic is the pump source to generate and amplify the polychromatic light [52, 53, 54, 55]. Two beams with wavelengths 1035nm and 1047nm are the signal lights, and both of them are pre-amplified to 50J via multistage OPA using the 526.5nm laser. The amplification and frequency-conversion processes of the 1047nm and 1059nm lasers are presented as examples in Figs. 2(a) and 2(b). The second harmonic of 1053nm laser

**Figure 2.** Numerical simulations for the generation of polychromatic ultraviolet beam. The laser energies varied with the crystal length in the processes of (a)-(b) generation of the two-color light with 1047nm and 1059nm, (c)-(d) SHG and THG of the 1047nm laser, and (e)-(f) SHG and THG of the 1059nm laser, respectively.
with an energy of 6.8kJ is produced by a 20-mm-thick deuterated potassium dihydrogen phosphate (DKDP) crystal, which is then used to amplify the 1047nm laser via the OPA process. As a result, the 1047nm laser is amplified to 2.9kJ though a 25-mm-thick DKDP crystal, and a 1059nm laser with an energy of $\sim2.85$kJ is generated in the meanwhile.

In order to obtain the third-harmonic light efficiently, the efficiency of the SHG should be around 66.7%, so that the fraction of the fundamental photon numbers and the second harmonic photon numbers is 1:1, and therefore the corresponding energy ratio is 1:2 according to Ref. [51]. Under our design scheme, 20-mm- and 15-mm-thick DKDP crystals are used for the SHG and third-harmonic generation (THG) of 1047nm laser, respectively, as indicated in Figs. 2(c) and 2(d). The other two DKDP crystals with almost the same thickness are used for the SHG and THG of 1059nm laser, as displayed in Figs. 2(e) and 2(f). The obtained two-color beamlets with wavelengths 349nm and 353nm have an equal energy of $\sim2.4$kJ. Therefore, the total energy conversion efficiency from the Nd:glass laser to polychromatic ultraviolet light is about 60%. The generation, amplification, and frequency conversion mechanisms for the lasers with wavelengths of 1035nm and 1071.6nm are the same to the above examples. Finally, one obtains a polychromatic ultraviolet beam with total energy $\sim9.6$kJ, 3ns pulse duration, and four different wavelengths 345nm, 349nm, 353nm, and 357.2nm, where the difference of two adjacent frequencies is $\delta\omega_0 \approx 1.1\%\omega_0$ regarding the central wavelength 351nm.

A polychromatic direct-drive system with 60 incident beams is presented as an example in Fig. 3, which describes the overall structure of the polychromatic light generation, transmission and focusing based upon the single beam diagram in Fig. 1. The equal optical paths of all the laser beamlines are realized by employing the baseline algorithm and symmetrical operations [56, 57], and the switchyard in the target area is
displayed in Fig. 3. The optical units used in the processes of reflection and focusing are reflective to reduce the optic component damage. The third-harmonic beams injected into the target chamber are obtained by filtering the fundamental and second-harmonic frequency components with the multiple color separation mirrors. Note that the basic optical technologies and designs can also be applied to the indirect-drive scheme.

4. Particle-in-cell simulations for LPI mitigation via polychromatic lights

4.1. Suppression of LPIs with polychromatic lights under the indirect-drive scheme

All the PIC simulations have been carried out using the OSIRIS code [58, 59]. Soft X-rays, generated by laser irradiation on the hohlraum wall, compress the target under the indirect-drive configuration. To demonstrate the suppression effects of LPIs with polychromatic lights, two dominant parameter intervals of laser plasma interactions are investigated here including the plasma at the entrance hole and the ionized gas in hohlraum as shown in Fig. 4(a). We first consider the inhomogeneous plasma at the entrance hole of the hohlraum [40, 60]. The third-harmonic laser intensity is $I_0 = 1.1 \times 10^{15}$ W/cm$^2$. Under the same incident energy, the beamlet intensity of the polychromatic light is $I_i = 2.75 \times 10^{14}$ W/cm$^2$ with beamlet number $N = 4$ and spectrum width $\Delta \omega_0 = 3\% \omega_0$. Figure 4(b) presents the spectra of the two polychromatic lights, where the black and red lines respectively correspond to the two pump beams with incident angles $\theta_1 = 26^\circ$ and $\theta_2 = -26^\circ$, i.e., the angle between the two beams in vacuum is $\theta_v = \theta_1 - \theta_2 = 52^\circ$. Each polychromatic light has four-color beamlets with whole spectrum width $\Delta \omega_0 = 3\% \omega_0$, and the difference between every two adjacent frequencies of the two beams is $\delta \omega_0 = 0.5\% \omega_0$ according to Fig. 4(b). The inhibition mechanism of the LPIs via polychromatic lights is displayed in Fig. 4(c), where one of the daughter waves developed by a pump beamlet will not be amplified by the other beamlets when the pumps are decoupled. Consequently, the instability growth rate and saturation level are effectively reduced by a polychromatic beam as compared to those developed using a monochromatic laser.

Pump laser pulses are incident from the two transverse boundaries in the 2D simulations for the stimulated scattering instabilities. The coupling term of incident light and scattering light is $\vec{a}_0 \cdot \vec{a}_s = a_0 a_s \cos(\phi)$, where $a_s$ is the amplitude of scattered light. It should be noted that $\cos(\phi) = 1$ is always satisfied for the s-polarized (the electric field of light is perpendicular to the plane) incident beams. Therefore, the beams are all s-polarized in our 2D simulations for the stimulated scattering instabilities, which normally lead to relatively larger growth rates than p-polarized (the electric field of light is parallel to the plane) ones [41]. The transverse width of the plasmas is $44\lambda$, and the resolutions are $dx/\lambda = dy/\lambda = 0.0286$ with 25 particles per cell. The ion mass is $m_i = 3672m_e$ with an effective charge $Z = 1$ for all the simulations. In our two-dimensional (2D) simulations, the longitudinal plasma density profile is $n_e/n_c = 0.06(1 + x/500)$ with the density range of $0.06n_c \leq n_e \leq 0.172n_c$, where
Figure 4. Comparison of simulation results of LPIs developed by monochromatic lasers and polychromatic lights under the indirect-drive scheme. (a) Configuration of indirect drive with LPI regions considered in the simulations. (b) Spectra of the two incident polychromatic beams in the 2D simulations. (c) Inhibition mechanism of LPIs with polychromatic light. Transverse wavenumber evolutions of the electrostatic field developed by (d) monochromatic lasers $I_0 = 1.1 \times 10^{15}$W/cm$^2$ and (e) polychromatic lights with each $I_i \times 2.75 \times 10^{14}$W/cm$^2$, where the longitudinal wavenumber is summated from $k_x c = 1.1 \omega_0$ to $k_x c = 1.45 \omega_0$. (f) Comparison of electron hot tail developed by monochromatic lasers and polychromatic lights at $t = 6000 \tau$. $N_e$ is the relative number of electrons. (g)-(h) 1D simulation results of the incident beam interaction with the filled gas in hohlraum. (g) Transmission rate of incident energies at $t = 6000 \tau$. (h) Electron energy distributions heated by monochromatic laser and polychromatic light at $t = 15000 \tau$ under $n_e = 0.07 n_c$. 
was the critical density of the pump beam. The electron and ion temperatures are $T_e = 2\text{keV}$ and $T_i = 0.8\text{keV}$, respectively. The temporal evolutions of electrostatic fields developed by multibeam SRS are exhibited in Figs. 4(d) and 4(e), which are obtained by summing the wavenumber distributions along the longitudinal direction $1.1\omega_0 \leq k_x c \leq 1.45\omega_0$. Multibeam SRS has been strongly developed at $t = 500\tau$ for the monochromatic lasers on the basis of Fig. 4(d), where $\tau$ is the light period. However, weak SRS signals can be found later at $t = 1500\tau$ for the polychromatic lights according to Fig. 4(e). The SRS reflectivity of the monochromatic lasers is reduced by a factor of more than three using polychromatic lights, which mitigates the electron hot tail as displayed in Fig. 4(f). The transmission efficiency of the incident energy is enhanced from 80.4% to 91.4% by polychromatic lights. Therefore, polychromatic drivers can save at least 11% of the incident energy from the stimulated scattering instabilities at the entrance hole.

Different from the plasma at the entrance hole, the gas filled in hohlraum is almost homogeneous, where the electron density is always less than $0.07n_c$ \cite{61, 62}. According to Eq. (3), the decoupling threshold of SRS is found to be around $0.75\%\omega_0$ at $n_e = 0.07n_c$ under the beamlet amplitude $a_i = 0.005$. Therefore, the beamlets of the polychromatic light are decoupled from each other. In order to investigate LPI development inside the hohlraum, comparative one-dimensional (1D) simulations for monochromatic laser and polychromatic light interaction with different density plasmas have been carried out as shown in Figs. 4(g)-4(h). A laser pulse with a plateau of $15000\tau$ and two edges of $25\tau$ at the front and end is incident from the left boundary of the simulation box. We have taken 100 cells per wavelength and 100 particles per cell. Large-scale plasmas with a whole length of $3000\lambda$ are set in the simulations to include the convective effects, where $\lambda$ is the wavelength of incident laser in vacuum. The electron and ion temperatures are $T_e = 2.5\text{keV}$ and $T_i = 1\text{keV}$, respectively. Figure 4(g) indicates that the transmission efficiency of the incident energy varied with the plasma density. Polychromatic light can save at least 8.8% of the incident energy from LPIs compared with the monochromatic laser at $n_e = 0.05n_c$. The energy-saving ratio of polychromatic light increases with the plasma density, which is up to 29.57% at $n_e = 0.07n_c$. Electron energy distributions developed by different pump beams are displayed in Fig. 4(h). A saturated hot electron tail with $T_e = 52.2\text{keV}$ can be found for the monochromatic laser at $t = 19000\tau$ (i.e., 22.3ps). However, the electrons have not been obviously heated at this time for the polychromatic light.

4.2. Suppression of LPIs with polychromatic lights under the direct-drive scheme

Lasers directly irradiate on the target under the direct-drive scheme, and interact with the the large scale plasma formed by the ablation. Figures 5(a)-5(d) present the comparative simulation results of stimulated scattering instabilities, where the longitudinal plasma density profile is $n_e/n_c = 0.12\exp(x/1000)$ with the density range $0.12n_c \leq n_e \leq 0.254n_c$, and the incident beams are $s$-polarized. Linear ion flow

(a)-(d) Simulation results of stimulated scattering instabilities with s-polarized incident beams. (a) Transmission rate of incident energies for different incident angles with density range of $0.12n_c \leq n_e \leq 0.254n_c$. (b)-(c) Simulation example at $\theta_\nu = 110^\circ$ of (a). Transverse wavenumber evolutions of ion acoustic waves stimulated by the crossing of (b) monochromatic lasers and (c) polychromatic lights, where the longitudinal wavenumber is summed from $k_xc = -0.05\omega_0$ to $k_xc = 0.05\omega_0$. (d) Transient transmission efficiencies of incident lights in a larger scale plasma with $0.12n_c \leq n_e \leq 0.5n_c$ and $\theta_\nu = 110^\circ$. (e)-(g) Comparative results for multibeam TPD at plasma density $n_e \approx 0.232n_c$. The incident angle between the two p-polarized beams is $\theta = 59^\circ$ in plasma. Wavenumber distributions of electrostatic field summarized from $t = 1000\tau$ to $t = 6000\tau$ for (e) monochromatic lasers and (f) polychromatic lights. The intersections of the white curves show the most intense TPD growing regions in the wave-vector space. (g) Temporal evolutions of the fraction of incident laser energy $E_{en} = \Sigma |E_z(t)|^2$ converted into electrostatic energy $\Sigma \left( |E_L(x, y)| \omega_L / \omega_0 \right)^2$. 
velocity has been considered here as $v_f/c = -0.0035 + 6.84 \times 10^{-4}x/1000$. The plasma temperatures are the same as those in the 2D simulations in Fig. 4. Figure 5(a) shows the transmission rate of the incident energy under different angles between the two beams, which indicates that polychromatic lights can save at least 10% of the incident energy from LPIs in the SRS developing regime. As an example, the SRS reflectivity at $\theta_v = 110^\circ$ is reduced from 5.1% to 1.83% by polychromatic lights. The inhibition of SRS weakens the intensity of the electrostatic field, and therefore reduces hot electron generation. The hot electrons with kinetic energies $\geq 50$keV developed by polychromatic lights is greatly reduced compared to monochromatic lasers, where the total energy of the former is only 6.7% of that of the latter. The cross beams transfer energies through the stimulated ion acoustic waves, where one of the pump beams is a seed light to develop SBS via beating with the other one. Temporal evolutions of the CBET ion mode developed by different types of incident lights are displayed in Figs. 5(b) and 5(c). An intense CBET mode can be observed for monochromatic lasers near $\vec{k}_i \approx \vec{k}_1 - \vec{k}_2$, i.e., $k_{iy}c \approx 1.5\omega_0$ and $k_{iz}c \approx 0$ in Fig. 5(b). However, the instability has not been clearly developed using polychromatic lights according to Fig. 5(c). To investigate the mitigation of stimulated scattering instabilities at a wide density range by polychromatic lights, a large scale plasma with density region $0.12n_c \leq n_e \leq 0.5n_c$ is considered in the simulation example at $\theta_v = 110^\circ$, and the result is shown in Fig. 5(d). The transient transmission efficiency is reduced marginally at $t = 2000$ for the polychromatic lights. However, a dramatic reduction in the transient transmission efficiency is found at $t = 1000\tau$ for the monochromatic lasers. In addition, the total efficiency of the energy transfer has been enhanced by 35.86% with using polychromatic lights.

Unlike the stimulated scattering instabilities, the TPD instability is the decay of a laser into two equal-frequency Langmuir waves near $0.25n_c$. Therefore, in the simulations we only consider the density region $0.225n_c \leq n_e \leq 0.242n_c$ with longitudinal profile $n_e/n_c = 0.225\exp(x/1000)$. The beamlet amplitude of the polychromatic light in our simulations is $a_i = 0.005$, which satisfies the decoupling threshold for TPD $0.433\%\omega_0 < 1\%\omega_0$ according to Eq. (5). The transverse width of the plasmas is 94$\lambda$. The electron and ion temperatures are $T_e = 2$keV and $T_i = 1$keV, respectively. The angle between the two incident beams is $\theta_p = 59^\circ$ in the plasma. The other laser parameters are unchanged. Compared with the monochromatic lasers, the instability regions of the collective TPD modes are broadened and weakened by the polychromatic lights according to Figs. 5(e) and 5(f). The submodes of the electrostatic fields developed by different color beamlets are weakly coupled in the phase space. Therefore, the total saturation level is reduced by the wavenumber detuning. The fraction of incident laser energy converted into electrostatic energy can directly indicate the TPD development as displayed in Fig. 5(g). The maximum energy fraction is approximately 0.32% at $t = 6000\tau$ for the polychromatic lights. However, the electrostatic energy developed by the monochromatic lasers increases with time without saturation even at $t = 6000\tau$, and the peak is about eight times higher than that of polychromatic lights. The total energy of the hot electrons with kinetic energies $\geq 50$keV is reduced by 86.3% via using
polychromatic lights.

5. Summary

We have proposed the design of polychromatic driver and evaluated the LPI inhibition effects via particle-in-cell (PIC) simulations. The polychromatic lights not only delay the growth of LPIs, but also significantly reduce the LPI saturation levels. A clear enhancement of the laser transmission efficiency and hot electron reduction can be found for the polychromatic lights under both indirect-drive and direct-drive schemes. The collective behaviors, such as multibeam SRS, TPD, and CBET, are all effectively suppressed by the wavenumber detuning of the polychromatic beamlets. The results confirm the significant potential of polychromatic beams to enhance the laser-target coupling efficiency for inertial fusion energy.

Two dominant refitments on the existing facility are sufficient to generate polychromatic lights as shown in Fig. 1. The polychromatic generation module is installed in the upstream of switchyard, and the focusing lens in the final optics assembly is replaced by an off-axis parabolic mirror and a projecting mirror. Therefore, the refitments have marginal effect on the whole drive configuration. Regarding the megajoule facilities such as NIF and Laser Megajoule, the wavelength detunings in a quad can effectively suppress the collective instability modes by adding polychromatic generation modules.

The amplification and efficient frequency conversion of the broadband Nd:glass laser are the major obstacles to obtaining high-power broadband ultraviolet lasers. The conversion efficiency of a fundamental laser to the third-harmonic laser with bandwidth $1.5\% \omega_0$ as reported is approximately 20\% [35], which is only a third of the efficiency of the polychromatic light with a spectrum width $\Delta \omega_0 = 3\% \omega_0$. Moreover, the refitment of the broadband laser driver is extremely complicated and incurs enormous cost owing to the upgrade of the front end, preamplifier, and main amplifier. Therefore, the proposed polychromatic driver is a feasible and effective way to mitigate the LPIs compared with the broadband drivers [65].
