November 3, 2021

Abstract

The role of energetic discrimination is of utmost importance for the reaction network of high specificity when the process rate is arbitrarily low, which is implemented here for improving accuracy through a proofreading network for error-dissipation trade-off regime and beyond. The nonequilibrium steady state(NESS) theory incorporated with a recently developed thermodynamic framework is expounded here to obtain the error basin, dissipation, and energetics of kinetic proofreading with energetic discrimination in binding and unbinding processes. We have demonstrated that the system’s error rate can be set at its lower level over an extended parameter space of the control parameter by utilizing the energy discrimination factor. It is a systematic study of the chemostatic control of the error rate based on the mathematical mapping of the generic two-cycle butterfly model into a single cycle case of a proofreading network through substrate selection. Depending on the concentration of ATP flow in a Chemostat, we can find two different kinetic domains of proofreading based on dissipation-error trade-off where the numerical illustration for an error-correcting scheme is provided for tRNA selection and DNA replication as a typical biological scenario. The dissipation-error trade-off domain minimizes its Gibbs free energy rather than the semigrand Gibbs free energy, whereas the domain with a lack of trade-off minimizes its semigrand Gibbs free energy considerably. The trade-off domain has a one-to-one correspondence with the deeper portion of the error basin, which can be advantageous in maintaining and enhancing the specificity with externally controllable concentration parameters.

1 Introduction

The observation of remarkably high accuracy in biosynthesis processes can be rationalized by the strategy known as kinetic proofreading proposed independently by J. J. Hopfield and J. Ninio\textsuperscript{[1, 2]}. The proofreading scheme asserts that the high fidelity can be adopted by strongly driving the reaction network model of core biological events like DNA replication\textsuperscript{[3, 4]}, RNA transcription\textsuperscript{[5, 6]}, protein translation\textsuperscript{[7]} or recognition of amino-acid out of equilibrium and thus facilitating selection of right substrates from the pool of analogous competing substrates. The kinetic proofreading mechanism of the biosynthesis process can be cast into the cyclic receptor-ligand binding model\textsuperscript{[8, 9]} in a nonequilibrium steady state(NESS), consisting of ligands, ‘Wrong’(‘W’) and ‘Right’(‘R’) to quantify expenditure of available free energy in error reduction. ‘R’ and ‘W’ are two structurally very similar competing substrates, with ‘W’ has less favorable energetics. In NESS, the presence of nonzero driving force and reaction flux generates dissipation\textsuperscript{[10]}, a characteristic property of a system operating out of equilibrium. Dissipation plays a guiding role in sustaining or enhancing performance in kinetic proofreading network\textsuperscript{[11]}. A trade-off between two or more characteristic properties is crucial

\textsuperscript{*}gautam@bose.res.in
in investigating the proofreading network’s performance related to different biological processes. A recent theoretical investigation reveals that a biological system prefers to optimize dissipation to the error[12]. For a model copying system operating within a kinetic discrimination regime corresponding to the difference in activation barrier heights, Bennett demonstrates a diverging nature of dissipation near the lowest error rate[13]. However, the lowest error rate can be achieved for vanishingly small dissipation for the energetic discrimination scenario corresponding to the difference of binding energy of intermediates[1, 2]. Generally, both the kinetic discrimination and energetic discrimination can be present in the proofreading network due to different binding, dissociation, and equilibrium rate constants for ‘R’ and ‘W’ pathways[14]. In Ref. [14], it is demonstrated in detail that how these two regimes can be exploited more effectively in a combined manner. However, in much recent analysis of a general proofreading model[15, 16, 17], only an energetic discrimination regime has been exploited to investigate substantial complex and essential features of the proofreading mechanism within different parametric regimes. Indeed, in an investigation of a more general kinetic proofreading scheme within an energetic discrimination regime, Murugan et al. have introduced a quantity called discriminatory index[15] to locally measure the discrimination ability of different regimes and thus correctly classify them. They have demonstrated different coexisting ‘discriminatory regimes’ due to change in error with the energy discrimination factor. In the study of nonequilibrium sensing for a model of chemotaxis, this discriminatory index of kinetic proofreading is regarded to be analogous to the sensitivity in the nonequilibrium sensing[18].

We want to explore how without changing the simple two-cycle proofreading network structurally, we can access the parameter space corresponding to different error rates and dissipation by merely chemostatic controlling. Furthermore, inspecting various possibilities of expanding, shrinking, or shifting of the parameter space corresponding to a specific error rate through energy discrimination factor in terms of a tool akin to the discriminatory index is one of the main motive of this work. Although the error-dissipation trade-off scenarios of the kinetic proofreading model are well-studied, it is still not well-understood how the energetic entity of the system is assigned to different discriminatory regimes. For this purpose, we would evoke the semigrand Gibbs free energy[19, 20] along with the conventional nonequilibrium Gibbs free energy to quantify the kinetic proofreading network’s energetics properly. Thus, we want to unveil the overall performance of the kinetic proofreading network in terms of error, dissipation, and proper energy of the open system. By measuring the error, dissipation, and proper thermodynamics potential of the proofreading network for the same range of a chemostatted species, we want to establish a connection among these three entities within different discriminatory regimes. Further, by utilizing the dissipation-error trade-off scenario, we seek to find how the overall performance of a simple proofreading network gets modified or optimized for a range of chemostatted species’ concentrations when it is subjected to different magnitudes of the energy discrimination factor.

In this paper, we have theoretically investigated the kinetic proofreading at NESS in terms of concentration derived from standard rate equations instead of the probabilistic master equation[21] approach. We have derived the error of the proofreading scheme at the outset using a deterministic kinetic model, and for this purpose, we have mathematically mapped the two-cycle proofreading model into a single cycle model. The discrimination between ‘R’ and ‘W’ substrates in a living system usually occurs through unbinding rather than binding[22]. Hence, it is comprehensible to consider that all rate constants, except those corresponding to unbinding, are equal for ‘R’ and ‘W’ pathways because of the structural similarity of these two substrates in this investigation. Using a pseudo rate constant as a control parameter, we have illustrated that accumulating more ATP concentration does not necessarily coincide with an increase in accuracy as the error rate moves towards the equilibrium error rate beyond a threshold. We would then exploit a quantity similar to the discriminatory index in our investigation to understand its relevance and capability in capturing discrimination ability under different conditions arising through the variation of rate constants and energy discrimination factor of the two cycles model. Further, we have employed here a recently developed chemical thermodynamic framework[19, 20] to systematically analyze the dissipation and energetics coupled with a series of chemostats. In a driven system like this, it would be more natural to measure proper energy and dissipation through ATP concentration. Manipulating error, dissipation, and energetics by steering the concentrations of certain intermediates can indeed open up various opportunities for synthetic reaction networks and biological systems. Moreover, we have introduced an overall performance measuring quantity at NESS that can give insight about the basis of error-dissipation trade-off[13] or non-trade-off scenario within different energetic discrimination regimes in
the presence of chemostatic controlling.

The layout of the paper is as follows. First, we have described the kinetic network and its stoichiometric formulation of an open chemostatted system in section 2. The error as a function of externally controllable concentrations is discussed in the next section. Then, in section 4, we have investigated the impact of the energy discrimination factor, $\Delta$, on the error. In the next section, we have formulated the semigrand Gibbs free energy and its relation with other thermodynamic quantities at a NESS. Then, detailed numerical exploration of the dissipation-error scenario is depicted in section 6. Finally, the summary and conclusions are provided about this work.

2 Kinetic Network

![Kinetic Network Diagram](image)

Figure 1: kinetic model: Here in fig. 1(a) two distinct cycles correspond to two very similar substrates ‘R’ and ‘W’. Species ‘W’, ‘R’, ‘ATP’, ‘ADP’, ‘R_p’ and ‘W_p’ are assumed to have constant concentrations over the time scale of interest and can be absorbed within rate constants. In fig. 1(b), the hypothetical image of free energy landscape for the kinetic network that has been considered here.
The proofreading mechanism is described here with a nominal synthesis rate. Indeed, in the presence of energetic discrimination only, Hopfield’s model shows minimal error at zero velocity. The kinetic network of the proofreading scheme is illustrated with a schematic diagram in fig. 1(a). One cycle of the double-cycle proofreading model corresponds to the ‘R’ pathway, whereas another cycle belongs to the ‘W’ one. The kinetic network of the proofreading scheme is illustrated with a schematic diagram in fig. 1(a). One cycle of the double-cycle proofreading model corresponds to the ‘R’ pathway, whereas another cycle belongs to the ‘W’ one. The network depicts that a protein E binds with substrate ‘R’ (or ‘W’) to form intermediate complexes ‘ER’, ‘ER*’ (or ‘EW’, ‘EW*’) and then would disassociate into enzyme and product. As argued in the section 1, it is sufficient to assume that difference in affinity due to only rate constants $k_R - 1 \neq k_W - 1$ and $k_R^3 \neq k_W^3$ in fig. 1(a). All other rate constants are equal in both pathways. Furthermore, with correct substrate (‘R’) having more residence time, $k_R - 1$ and $k_R^3$ are connected with the corresponding rates of ‘W’ reaction cycle through the relation $k_R - 1 / k_R^3 = \exp -\Delta = \sigma < 1$. Here, $\Delta$ as shown in fig. 1(b) is the binding energy difference between ‘W’ and ‘R’ intermediate complexes.

Now depending on the concentration dynamics of the species, we can divide all the species of the proofreading network in fig. 1(a) into two different disjoint sets of ‘I’ and ‘C’,

$$\{E, ER, ER^*, EW, EW^*\} 
\bigcup \{R, ATP, ADP, R_p, W, W_p\}$$

where ‘I’ is a set of intermediate species having dynamic concentration, and ‘C’ is a set of chemostatted species with a constant concentration along the entire system within the time scale of interest. Elements of the set ‘I’ form the vertices in the graphical representation of a reaction network, whereas elements of set ‘C’ are associated with the graph’s edge. $R_p$ and $W_p$ instead of more commonly used $R$ and $W$ has been considered in the third step of the kinetic proofreading network to keep the approach more general.

From schematic diagram in fig. 1(a), we can simply write

$$eR^* + eR + eW + eW^* + e = e_0$$

where $e_0$ is the total enzyme concentration and $eR, eR^*, eW, eW^*$ are concentrations of species ‘ER’, ‘ER*’, ‘EW’, ‘EW*’ respectively. We assume that total enzyme concentration $e_0 = e_R^0 + e_W^0$ to simplify the problem considerably and generally $e_R^0 \neq e_W^0$. With the aid of this assumption, we now have $eR^* + eR + eR = e_0^R$ and $eW + eW + eW^* = e_0^W$ where $e = e_R + e_W$. With these considerations,
we can mathematically map this two cycle proofreading model into a single cycle model as shown in fig. 2. Hence kinetics of the cycle involving right substrate ‘R’ can be expressed by following equations

\[
\frac{\partial eR}{\partial t} = k_R^1(e_R^0 - eR^* - eR) - (k_R^1 + k_R^2)(eR) + k_R^B_2(eR^*)
\]

\[
\frac{\partial eR^*}{\partial t} = k_R^3(e_R^0 - eR^* - eR) - (k_R^3 + k_R^2)(eR^*) + k_R^B_2(eR).
\]

Here \( k_1 = k_0^R(R), k_{-3} = k_0^R(R_b), k_{+2} = k_0^{A}\) and \( k_{-2} = k_0^{A}\) are pseudo-first-order rate constants\([8, 9]\) and concentration of ATP, ADP, S, and P are held at constant levels. Solving equations obtained by setting \( \frac{\partial eR}{\partial t} = 0 \) and \( \frac{\partial eR^*}{\partial t} = 0 \) in eq. (1a) and (1b) respectively and then using the equality condition \( eR^* + eR + e^R = e_R^0 \), we acquire following steady state concentrations,

\[
e_{R_{ss}} = \frac{(k_R^1 k_R^3 + k_R^2 k_R^3 + k_R^B_2 k_R^3) e_R^0}{(k_R^1 k_R^2 + k_R^1 k_R^3 + k_R^B_2 k_R^3) + (k_R^1 k_R^2 + k_R^1 k_R^3 + k_R^B_2 k_R^3)}
\]

\[
e_{R_{ss}}^* = \frac{(k_R^1 k_R^3 + k_R^2 k_R^3 + k_R^B_2 k_R^3) e_R^0}{(k_R^1 k_R^2 + k_R^1 k_R^3 + k_R^B_2 k_R^3) + (k_R^1 k_R^2 + k_R^1 k_R^3 + k_R^B_2 k_R^3)}
\]

\[
e_{R}^* = \frac{(k_R^1 k_R^2 + k_R^1 k_R^3 + k_R^B_2 k_R^3) e_R^0}{(k_R^1 k_R^2 + k_R^1 k_R^3 + k_R^B_2 k_R^3) + (k_R^1 k_R^2 + k_R^1 k_R^3 + k_R^B_2 k_R^3)}
\]

Unlike the equilibrium steady state, there will be a clockwise steady state flux for the cyclic reaction network at NESS. Here a single cycle of the network comprises of three elementary reactions and net fluxes of these reactions are following: \( j_1 = k_1(e) - k_{-1}(es); j_2 = k_2(es) - k_{-2}(es^*); j_3 = k_3(es^*) - k_{-3}(e) \). Now by substituting the steady state concentrations of \( e, es \) and \( es^* \) in any of these elementary reaction fluxes, the steady state cycle flux in clock-wise direction for single cycle case can be obtained as

\[
j_{R_{ss}} = \frac{(k_R^1 k_R^3 - k_R^1 k_R^3 - k_R^B_2 k_R^3) e_R^0}{(k_R^1 k_R^2 + k_R^1 k_R^3 + k_R^B_2 k_R^3) + (k_R^1 k_R^2 + k_R^1 k_R^3 + k_R^B_2 k_R^3)}
\]

In the case of wrong substrate pathway, \( eW_{ss}, eW_{ss}^*, eW_{ss}^* \) and \( j_{W_{ss}} \) will have the same expression with all the superscript ‘W’ instead of ‘R’ in each term. One of the main features of the model considered here that all the steps are reversible. From a thermodynamic viewpoint, we cannot take a step completely irreversible no matter how low is the rate constant.

The driving force associated with the NESS cycle flux is the net chemical potential around the single cycle \( \mu_L = \mu_{es} + \mu_{es^*} + \mu_{e^*} = \ln e_{ss} - \ln e_{ss}^* - \ln e_{ss}^* = \ln \gamma \). Both the ‘W’ and ‘R’ cycles are subjected to equal driving force as the rate constants \( k_1, k_{+2}, k_{-3} \) are equal in both pathways and \( k_{-1} \) and \( k_3 \) of ‘W’ and ‘R’ cycles are connected through a common factor \( \exp^{-\Delta} \). We have set Boltzmann’s constant \( k_B = 1 \) and temperature \( T = 1 \) to split our notations throughout this study. Unless otherwise stated, we have considered following rate constants throughout our study following the work of Banerjee et al.\[23\] \( k_R^1 = 5, k_R^3 = 1, k_R^B_2 = 50, k_R^B_3 = k_W^B_2 = 10^{-3} \) and \( k_R^B_3 = k_W^B_1 = 10^{-3} \). Rate constants with equal magnitudes for ‘R’ and ‘W’ cycle will be used without a superscript in future discussion.

\section{3 Error Basin}

In the limit of slow synthesis rate, the error rate of the kinetic proofreading network at NESS can be defined as \[15\]

\[
\eta = \frac{eW_{ss}^*}{eW_{ss}} \frac{eR}{eR_{ss}}
\]

where \( eW_{ss}^* \) and \( eR_{ss}^* \) are steady-state concentrations of ‘EW’ and ‘ER’ respectively and concentration of enzyme corresponding ‘R’ and ‘W’ cycles is given by \( e_{ss}^R \) and \( e_{ss}^W \). With \( \Delta \) being the energetic discrimination, the error rate of kinetic proofreading network would result in \( \eta = \exp^{-\Delta} \) under equilibrium condition. Whereas, under the fulfillment of several other kinetic conditions in the model, an error rate as low as \( \eta = \exp^{-2\Delta} \) can be achieved within a nonequilibrium regime.
Now from eq. (2b) and (2c), the ratio between $eR^*_s$ and $e^R_s$ is simply
\[
\frac{eR^*_s}{e^R_s} = \frac{(k^R_1k^R_3 + k^R_1k^R_3 + k^R_1k^R_3)(k^R_1k^R_3 + k^R_1k^R_3 + k^R_1k^R_3)}{(k^R_1k^R_3 + k^R_1k^R_3 + k^R_1k^R_3)}.
\tag{5}
\]

Similarly, we have
\[
\frac{eW^*_s}{e^W_s} = \frac{(k^W_1k^W_3 + k^W_1k^W_3 + k^W_1k^W_3)(k^W_1k^W_3 + k^W_1k^W_3 + k^W_1k^W_3)}{(k^W_1k^W_3 + k^W_1k^W_3 + k^W_1k^W_3)}.
\tag{6}
\]

Now using eq. (4), we can write the general expression of error rate by substituting $\frac{e^R}{eR^*_s}$ from (5) and $\frac{eW^*}{e^W_s}$ from (6),
\[
\eta = \frac{(k^W_1k^W_3 + k^W_1k^W_3 + k^W_1k^W_3)(k^R_1k^R_3 + k^R_1k^R_3 + k^R_1k^R_3)}{(k^R_1k^R_3 + k^R_1k^R_3 + k^R_1k^R_3)} = \frac{(k^R_1k^R_3 + k^R_1k^R_3 + k^R_1k^R_3)}{(k^R_1k^R_3 + k^R_1k^R_3 + k^R_1k^R_3)}.
\tag{7}
\]

Now it is quite logical to consider that substrate-enzyme complex $eR^*$ or $eW^*$ in fig. 2(a) should be produced through step 2 rather than step 3 and this simply implies $k_1 >> k_3$. Furthermore, step 3 will dominate the formation of ‘R\_p’ (or ‘W\_p’) from $eR^*$ (or $eW^*$) and it suggests $k_3 >> k_2$. Taking very small values of $k_3$ and $k_2$ will ensure that corresponding steps of reaction network are almost irreversible. Now under these assumptions, we would analyze how the relative strength between rate constants $k_1$ and $k_2$ modifies the specificity of proofreading network.

Here we have taken three different conditions according to following relative strength between rate constants $k_1$ and $k_2$:

- **Condition (i):** $k_1 >> k_2$; $\gamma = \frac{k^R_1k^R_3}{k^R_1k^R_3} \approx 1$
- **Condition (ii):** $k_1 \simeq k_2$; $\gamma >> 1$
- **Condition (iii):** $k_1 << k_2$; $\gamma >> 1$.

For the condition (i), $k_1 >> k_2$, the general expression of the error rate in eq. (7) becomes
\[
\eta_1 = \frac{(k^R_1k^R_3)(k^R_1k^R_3) + (k^R_1k^R_3)(k^R_1k^R_3) + (k^R_1k^R_3)(k^R_1k^R_3)}{(k^R_1k^R_3)(k^R_1k^R_3) + (k^R_1k^R_3)(k^R_1k^R_3) + (k^R_1k^R_3)(k^R_1k^R_3)} = \exp^{-\Delta} = \sigma.
\]

Now for the Condition (ii), $k_1 \simeq k_2$ along with $k_1 >> k_3$, $k_3 >> k_2$, error rate in eq. (7) results in
\[
\eta_2 = \frac{(k^R_1k^R_3)(1 + k^R_1k^R_3) + (k^R_1k^R_3)(1 + k^R_1k^R_3) + (k^R_1k^R_3)(1 + k^R_1k^R_3)}{(1 + k^R_1k^R_3)(1 + k^R_1k^R_3)(1 + k^R_1k^R_3)} = \sigma^2.
\]

Finally for the condition (iii), $k_1 << k_2$ along with $k_1 >> k_3$, $k_3 >> k_2$, the error rate equation becomes
\[
\eta_3 = \frac{k^R_1k^R_3}{(1 + k^R_1k^R_3)} = \sigma.
\]

The central observation from this theoretical analysis is that error $\eta$ is not constant under the nonequilibrium condition but strongly depends on the relative strength between rate constants $k_1$ and $k_2$. Therefore we can use either $k_2$ or $k_1$ as a control parameter of this proofreading scheme to access different discriminatory regimes. Most importantly, we have found for the condition $k_1 << k_2$; although $\gamma >> 1$, i.e., the system is far from equilibrium, we do not get any improvement over the error rate near equilibrium. This result reveals the subtle role of the relative strength of rate constants $k_1$ and $k_2$ in the modification of error.
Figure 3: Error basin: In fig. 3(a), basin-like characteristic of error rate has been found by varying only \( k_2 \). Other rate constants of proofreading network are fixed at \( k_1 = 5, k_R^2 = 1, k_{R-1}^R = 50, k_{-2} = 10^{-3} \) and \( k_{-3} = 10^{-3} \). In fig. 3(b), a 3D counterpart of “error basin” is obtained by changing both \( k_{-1} \) and \( k_{+2} \) simultaneously. Other rate constants are fixed at values mentioned earlier. The energetic discrimination factor, \( \Delta = 3 \) in both figures.

Here in fig. 3(a) keeping all other rate constants at a fixed value, we have obtained an error rate profile from the general expression of the error rate in eq. (7) by varying only rate constant \( k_{+2} \) at a fixed value of binding energy difference \( \Delta \). As we proceed from \( k_{-1} \gg k_{+2} \) to \( k_{-1} \approx k_{+2} \) regime by varying \( k_{+2} \), it is evident from fig. 3(a) that there is an abrupt fall in error and eventually the error will reach its minimum value \( \sigma^2 \). The plateau region in fig. 3(a) represents the \( k_{-1} \approx k_{+2} \) regime with the error rate \( \sigma^2 \). Finally, as we move from the \( k_{-1} \approx k_{+2} \) region in parameter space to \( k_{-1} << k_{+2} \), a basin-like characteristics of the error has been emerged due to the error rate approaching toward the equilibrium error rate value \( \sigma \) within nonequilibrium environment. To visualize the characteristics of error rate more lucidly, we have taken the log scale of the \( k_{+2} \) in fig. 3(a). As expected, the graphical representation of the general error rate in fig. 3 depicts the analytical results under three conditions, as discussed earlier in this section. Therefore, the kinetic proofreading network can have two different regimes with distinct discrimination ability depending on the relative strength of rate constants \( k_{-1} \) and \( k_{+2} \) under nonequilibrium conditions. In fig. 3(b), we have obtained a 3D counterpart of “error basin” in fig. 3(a) by varying both \( k_{-1} \) and \( k_{+2} \) simultaneously. This 3D figure illustrates more clearly how the error rate curve changes due to relative strength between \( k_{-1} \) and \( k_{+2} \). This figure will be crucial to ensure maximum accuracy of the proofreading scheme by controlling either \( k_{-1} \) or \( k_2 \) or both rate constants at the same time for a fixed \( \Delta \)(it is 3 here). As in this open chemical reaction network, pseudo-first-order rate constants contain the concentration of chemostatted species; therefore, any changes in these species’ concentrations will also modify the error rate curve.

4 Impact of energy discrimination factor on error

To capture the impact of energy discrimination factor \( \Delta \) on the error rate of the kinetic proofreading network, we have here plotted \( \log(\eta) \) with respect to \( \Delta \) separately for three different regimes depending on relative strength between \( k_{-1} \) and \( k_{+2} \). Then akin to the discriminatory index, we have defined, \( \nu = \frac{\partial \log(\eta)}{\partial \Delta} \), which is the slope of a \( \log(\eta) \) vs \( \Delta \) plot. For example, this definition will result in \( \nu = -1 \) for the equilibrium condition as \( \eta = \exp^{-\Delta} \) in this regime. Now we would analyze the error rate, \( \eta \), and the newly defined quantity, \( \nu \), for three different regimes, mentioned earlier.

For the regime corresponding to \( k_{-1} \gg k_{+2} \) in fig. 4(a), \( \log(\eta) \) follows line corresponding to \( \exp^{-\Delta} \) over the whole range of \( \Delta \) keeping all other parameters fixed. Hence error in this regime is not effected by \( \Delta \). The same is evident from fig. 4(d) as \( \nu = -1 \) over the whole range of \( \Delta \). Then, for the regime of \( k_{-1} \approx k_{+2} \), \( \log(\eta) \) fairly follows the line corresponding to \( \exp^{-2\Delta} \) up to a certain extent \( \Delta \) and after that it deviates from this line as \( \Delta \) is increased further in fig. 4(b). From the fig. 4(e), it is clear that \( \nu \) in this regime switches from \(-2\) to \(-1\) for higher \( \Delta \) value. Hence, accuracy
is obtained in similar way to the fig. 4(e) and fig. 4 respectively. The Corresponding Variation of \( \nu \) over the range of \( \Delta \) for \( k_{-1} >> k_{+2}, k_{-1} \approx k_{+2} \) and \( k_{-1} << k_{+2} \) is depicted in fig. 4(d), fig. 4(e) and fig. 4(f) respectively.

Figure 4: Impact of \( \Delta \) on error, \( \eta \) for three different regimes: \( \log(\eta) \) vs \( \Delta \) is shown here for three regions corresponding to \( k_{-1} >> k_{+2}, k_{-1} \approx k_{+2} \) and \( k_{-1} << k_{+2} \) in fig. 4(a), fig. 4(b) and fig. 4(c) respectively. The Corresponding Variation of \( \nu \) over the range of \( \Delta \) for \( k_{-1} >> k_{+2}, k_{-1} \approx k_{+2} \) and \( k_{-1} << k_{+2} \) is depicted in fig. 4(d), fig. 4(e) and fig. 4(f) respectively.

will be less than the minimum error rate for this relatively higher \( \Delta \) parameter region. The error rate in such case can be generally represented by \( \eta = \exp(-(1 + \beta)\Delta) \) with \( 0 < \beta < 1 \). Finally, for the regime corresponding to \( k_{-1} << k_{+2} \), \( \log(\eta) \) at first follows the line of \( \exp-\Delta \) as expected from the “error basin” in fig. 3(a). However, as the \( \Delta \) is further increased over a certain value, the \( \log(\eta) \) line gradually deviates from the \( \exp-\Delta \) line to the \( \exp-2\Delta \). This deviation for higher values of \( \Delta \) suggests that it is possible to have a much lower error rate and hence relatively more effective proofreading(with respect to lower \( \Delta \) counterpart) even for regime corresponding to \( k_{-1} << k_{+2} \). Now if we keep increasing \( \Delta \) above a certain value, it again moves towards the \( \exp-\Delta \) line. From the fig. 4(f), we can observe the variation of the \( \nu \) between \(-1 \) and \(-2 \). Areas confined within the slope line of \( \log(\eta) \) and \( \nu = -1 \) line in all slope plots quantify the chemical potential driving the network. Thus, one can expand, shrink, or shift the parameter space corresponding to a particular error rate by using \( \Delta \) as a control parameter. Hence the graphical analysis in fig. 4 reveals the crucial role of \( \Delta \) in obtaining desirable error at NESS.

We now seek to extend our investigation regarding the effect of \( \Delta \) in terms of the whole “error basin”. In fig. 5, we have changed \( k_2 \) and \( \Delta \) simultaneously to reveal how the shape of error basin changes as a function of both \( k_2 \) and \( \Delta \). The range of \( k_2 \) in fig. 5(a) and fig. 5(b), only corresponds to \( k_{-1} \approx k_{+2} \) and \( k_{-1} << k_{+2} \) regimes, respectively. For intermediate \( \Delta \) values here it is \( 3 - 8 \), \( \nu \) deviates from \(-2 \) to \(-1 \) for \( k_{-1} \approx k_{+2} \) regime and from \(-1 \) to \(-2 \) for \( k_{-1} << k_{+2} \) regime( see fig. 4(e) and fig. 4(f)). Therefore at the upper end of this intermediate \( \Delta \) range, both of these regimes have \( \nu \) something between \(-1 \) and \(-2 \). This is what exactly depicted by fig. 5(a). Initially there is a considerable difference in error rate for two regimes but as \( \Delta \) increases we have almost equal error rate for both the regime. Now for more higher range of \( \Delta \) i.e. for \( \Delta = 9 - 12 \), we have \( \nu \approx -2 \) for \( k_{-1} << k_{+2} \) regime(fig. 4(f)) and \( \nu \approx -1 \) for \( k_{-1} \approx k_{+2} \)(fig. 4(e)). Therefore, as fig. 5(b) reveals, the error rate in \( k_{-1} << k_{+2} \) regime is less in comparison to the error rate in \( k_{-1} \approx k_{+2} \) regime. Here fig. 5(c) and fig. 5(d) is obtained in similar way to the fig. 3 for \( \Delta = 8 \) and \( \Delta = 12 \), respectively. We can see from fig. 5(c) that unlike the fig. 3, as we increase \( k_2 \), the error profile does not get back to the equilibrium error value due to the fact that \( \nu \) for \( k_{-1} << k_{+2} \) regime deviates from \(-1 \) to \(-2 \) for \( \Delta = 8 \). It is worth mentioning that, having \( \nu \) equal to the equilibrium regime does not necessarily mean that error’s magnitude is the same as the equilibrium error. The same is true for \( \nu = -2 \) i.e.
\( \nu = -2 \) does not guarantee minimum error. From fig. 5(d), it is clear that for \( \Delta = 12 \), although \( \nu \) is equal, \( \nu = -1 \) in both \( k_{-1} \approx k_{+2} \) and \( k_{-1} >> k_{+2} \) regimes, the error rate is much less in the \( k_{-1} \approx k_{+2} \) regime and it is rather close to the error in \( k_{-1} << k_{+2} \) regime with \( \nu = -2 \). Thus, fig. 5 illustrates how the higher \( \Delta \) value sustains error rate of the proofreading mechanism at a much lower level throughout the whole nonequilibrium range of rate constant \( k_2 \). However, for a very high \( \Delta \) values (near \( \Delta = 20 \)), proofreading would be very less effective as \( \nu = -1 \) for the whole range of \( k_2 \). Meanwhile, we can assert that the error under a nonequilibrium environment is always at a much lower level than the equilibrium error magnitude. Hence, \( \Delta \) above a certain level would set the system’s error rate at its lower value over the whole parameter space of \( k_2 \) under a nonequilibrium environment for a fixed \( k_{-1} \). So without changing the proofreading network structurally, we can modify the parameter space corresponding to the lower error by merely changing \( \Delta \). It is important to note that any change in \( \Delta \) can be seen analogous to change in \( k_{-1}^{R} \) and \( k_{+2}^{R} \).

The error rate of the proofreading network also has an absolute thermodynamic lower bound [25, 26] for given energy \( \gamma \) per ATP hydrolysis irrespective of the detailed networking of the model. Assuming no energy loss due to coupling between the reaction network and energy source, this lower bound can be expressed in terms of intrinsic discrimination factor \( \sigma \) and external factor \( \gamma \) as, \( \eta_{lb} = \frac{\gamma}{\sigma} \).

The absolute lower bound corresponding to four different values of \( \Delta \) has been shown by the ‘dotted’ line for a range of \( k_2 \) values in fig. 6. The solid lines represent the error rate obtained from the analytical error expression for the same set of \( \Delta \). In fig. 6, the error curve and absolute lower bound
of error for the same $\Delta$ are well separated, whereas the error curve corresponding to a higher $\Delta$ value approaches the absolute lower bound of error corresponding to a lower $\Delta$ value. Therefore, a graphical representation like fig. 6 could be useful to predict an optimal number of the cycle for a particular $\Delta$ in a general multiple cycle model, which would have the capability to reach the thermodynamic limit of error. In fact, in a biomolecular system functioning for a time, the impact of enhanced discrimination factor proves to be decisive in maintaining the system’s operation close to the thermodynamic uncertainty relation[27] bound or farther from the bound[28].

5 Entropic and energetic response due to chemostatted concentration

In open chemical reaction networks like kinetic proofreading, pseudo reaction rates are connected to chemostatted species’ concentrations. Therefore, any change in chemostatted concentrations can be a source of massive modification in the system’s entropic and energetic response under a nonequilibrium environment[29].
5.1 Conservation laws and emergent Cycles

As there are 6 elementary chemical reactions and 11 species in reaction networks, the proofreading network in fig. 1(a) can be presented as the following 11 × 6 stoichiometric matrix

\[ S^\sigma = \begin{pmatrix} R_1 & R_2 & R_3 & R_4 & R_5 & R_6 \\ E & -1 & 0 & 1 & -1 & 0 & 1 \\ ER & 1 & -1 & 0 & 0 & 0 & 0 \\ ER^* & 0 & 1 & -1 & 0 & 0 & 0 \\ EW & 0 & 0 & 0 & 1 & -1 & 0 \\ EW^* & 0 & 0 & 0 & 0 & 1 & -1 \\ ATP & 0 & -1 & 0 & 0 & -1 & 0 \\ ADP & 0 & 1 & 0 & 0 & 1 & 0 \\ W & 0 & 0 & 0 & -1 & 0 & 0 \\ R_p & 0 & 0 & 1 & 0 & 0 & 0 \\ W_p & 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix}. \] (8)

The left null linear independent vectors corresponding to left null space of the stoichiometric matrix \( S^\sigma \) are known as the conservation laws \[30\] and can be expressed as

\[ \sum_{\sigma} l_\lambda^\sigma S^\sigma = 0 \] (9)

where

\[ \{l_\lambda^\sigma\} \in \mathbb{R}^{(\sigma-w)\times\sigma}, w = \text{rank}(S^\sigma). \]

For the stoichiometric matrix (8) of the kinetic proofreading network, the conservation laws of the closed reaction network are following five vectors,

\[ l_\lambda^1 = \begin{pmatrix} E & ER & ER^* & EW & EW^* & R & ATP & ADP & W & R_p & W_p \\ 1 & 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix} \]

\[ l_\lambda^2 = \begin{pmatrix} E & ER & ER^* & EW & EW^* & R & ATP & ADP & W & R_p & W_p \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 & 0 \end{pmatrix} \]

\[ l_\lambda^3 = \begin{pmatrix} E & ER & ER^* & EW & EW^* & R & ATP & ADP & W & R_p & W_p \\ 0 & 1 & 0 & 1 & 0 & 1 & -1 & 0 & 1 & 0 & 0 \end{pmatrix} \]

\[ l_\lambda^4 = \begin{pmatrix} E & ER & ER^* & EW & EW^* & R & ATP & ADP & W & R_p & W_p \\ 0 & 1 & 1 & 0 & 1 & 0 & 0 & 0 & 1 & 0 & 0 \end{pmatrix} \]

and

\[ l_\lambda^5 = \begin{pmatrix} E & ER & ER^* & EW & EW^* & R & ATP & ADP & W & R_p & W_p \\ -1 & -2 & -1 & -1 & 0 & -1 & 1 & 0 & 0 & 0 & 1 \end{pmatrix}. \]

Components of the system are defined as conserved quantities \[30\] and can be specified in terms of the conservation laws of the reaction network as

\[ L_\lambda = \sum_{\sigma} l_\lambda^\sigma z_\sigma \] (10)

such that \( \frac{d}{dr} \int dr L_\lambda = 0 \). Thus, components corresponding to those five conservation laws are

\[ L_1 = e + eR + eR^* + eW + eW^*; \ L_2 = ATP + ADP; \ L_3 = eR + eW + R - ATP + W; \ L_4 = eR + eR^* + R + R_p \]

and

\[ L_5 = -e - 2eR - eR^* - eW - R + ATP + W_p. \] When a closed system is opened by chemostatting,
the stoichiometric matrix $S^s_\rho$ breaks into two parts: $S^I_\rho$ corresponding to intermediate species and $S^C_\rho$ belonging to chemostatted species. Therefore, conservation laws in an open system are represented by

$$l^\lambda S^I_\rho + l^\lambda S^C_\rho = 0 \begin{cases} l^\lambda S^I_\rho \neq 0 & \text{broken CL}, \\ l^\lambda S^I_\rho = 0 & \text{unbroken CL} \end{cases}$$

with $u$ and $b$ being labels corresponding to unbroken and broken ones, respectively and $\{l^\lambda\} = \{l^\lambda_u\} \cup \{l^\lambda_b\}$. In this reaction network, conservations laws, $l^\lambda_u = 2$, $l^\lambda_b = 3$, $l^\lambda_c = 4$ and $l^\lambda_d = 5$ of the closed system are broken due to chemostating. The set of chemostatted species is divided into two subsets $\{C\} = \{C_b\} \cup \{C_u\}$ depending on whether it breaks a conservation law or not. From eq. (11), it is clear that broken conservation laws are not left null vectors of $S^I_\rho$ for at least one reaction of the network. Hence, components of the open system corresponding to broken conservation laws denoted as $L^\lambda_\sigma$ are no longer a global conserved quantities.

The unbroken conservation law of the open system as obtained from the stoichiometric matrix of intermediate species, $S^I_\rho$ is

$$l^\lambda_{\sigma=1} = \begin{pmatrix} E & ER & ER^* & EW & EW^* \\ 1 & 1 & 1 & 1 & 1 \end{pmatrix}$$

and corresponding component $L^\lambda_\sigma = e + eR + eR^* + eW + eW^*$ refers to the total concentration of the enzyme, a global conserved quantity of the open system. Right null vectors of the stoichiometric matrix, $S^g_\rho$, represent internal cycles which upon completion restore all the species’ concentration to its prior state. This kinetic proofreading network has no internal cycle. However, it has two independent emergent cycles[31]

$$c_1 = \begin{pmatrix} 1 \\ 2 \\ 3 \\ 4 \\ 5 \\ 6 \end{pmatrix} \quad \text{and} \quad c_2 = \begin{pmatrix} 0 \\ 1 \\ 3 \\ 4 \\ 5 \\ 6 \end{pmatrix}$$

which are the right null eigen vector corresponding to null space of $S^I_\rho$. A complete emergent cycle keeps the states of intermediate species unchanged but chemostatted species are exchanged between system and chemostats[19]. The net stoichiometry of the emergent cycle $c_1$ is $R + ATP \rightarrow R_p + ADP$ and it is $W + ATP \rightarrow W_p + ADP$ for the emergent cycle $c_2$. The total number of chemostatted species must be equal to the sum of the number of broken conservation laws and the number of emergent cycles in open chemical reaction network[31, 19].

The steady-state current vectors for the emergent cycle $c_1$ and $c_2$ are

$$\dot{j}_{c_1} = \begin{pmatrix} j_{c_1} \\ 3 \\ 4 \\ 5 \\ 6 \end{pmatrix} \quad \text{and} \quad \dot{j}_{c_2} = \begin{pmatrix} j_{c_2} \end{pmatrix}$$

respectively. Each of this flux can be given by any of the corresponding reactions by inserting steady state concentrations of intermediate species within it

$$j_{c_1} = j_1 = k^R e_{ss} - k^R e_{ss} \quad \text{and} \quad j_{c_2} = j_4 = k^W e_{ss} - k^W e_{ss}$$

Both $j_{c_1}$ and $j_{c_2}$ have expression same as (3) with two different superscript ‘R’ and ‘W’ respectively for rate constants. The overall steady state flux of kinetic proofreading reaction network is then given
by $J_{ss} = j_{c1} + j_{c2}$. Now the chemical force, affinities acting along the cycles obeys following equation in terms of emergent cycle

$$\mu_c = c_c \ln \frac{k_p c_p - S_c^p}{k - \rho}$$

(12)

where $c_c$ and $S_c^p$ are concentrations of chemostatted species and stoichiometric elements corresponding to chemostatted species, respectively. Therefore, the chemical affinities along $c_1$ and $c_2$ are

$$\mu_1 = \ln \frac{k_{\rho}^c k_{\rho}^{b2} k_{\rho}^{b3}}{k_{\rho}^{b1} k_{\rho}^{b2} k_{\rho}^{b3}}$$

and

$$\mu_2 = \ln \frac{k_{\rho}^{b9} k_{\rho}^{b10} k_{\rho}^{b11}}{k_{\rho}^{b12} k_{\rho}^{b13} k_{\rho}^{b14}}.$$ We previously found same expression for chemical affinities of two different reaction cycle corresponding to ‘W’ and ‘R’ substrate.

### 5.2 Dissipation

![Graphs](image)

Figure 7: Error rate and dissipation: In fig. 7(a) and fig. 7(c), error rate and dissipation of kinetic proofreading for the range of ATP concentration $10^{-6} - 10^0$ is shown. As error rate decreases over the ATP concentration, dissipation increases. The error rate and dissipation of kinetic proofreading for the higher range of ATP concentration $10^9 - 10^6$ is illustrated in fig. 7(b) and fig. 7(d). In this range of ATP concentration, dissipation qualitatively reflects the profile of error rate. The rate constants of proofreading network are fixed at $k_1 = 5, k_2 = 1, k_1^{R} = 1, k_2^{R} = 50, k_{-2} = 10^{-3}$ and $k_{-3} = 10^{-3}$.

Dissipation is a fundamental characteristic of a nonequilibrium system. Any non-zero positive values of affinities $\mu_1$ and $\mu_2$ will drive the system out of equilibrium. Our assumptions for reaction rates here make sure that $\mu_1 = \mu_2 = \mu$. Using flux-force relation, we can represent total dissipation\[32] of the reaction network as

$$\dot{\Sigma} = J_{ss} \mu.$$ (13)

Under the second law of thermodynamics, this dissipation would always be positive.
and fig. 7(a) and fig. 7(b). Details about the dynamics of these thermodynamic elements are discussed in main text. For both the cases, \( \Delta = 3 \) has been considered. The rate constants of proofreading network are kept at \( k_1 = 5, k_2 = 1, k_3^R = 1 \), \( k_{-1}^R = 50 \), \( k_{-2} = 10^{-3} \) and \( k_{-3} = 10^{-3} \).

The modulation in dissipation due to a change in ATP concentration from very low to high is illustrated in fig. 7. Changing the ATP concentration, keeping ADP concentration fixed at a certain level, implies that we gradually increase the system’s ATP to ADP concentration ratio. We have plotted two breakdown figures fig. 7(d) and fig. 7(c) to understand the dissipation curve, and corresponding error variations with respect to ATP concentration are shown in fig. 7(a) and fig. 7(b). From fig. 7(a) and fig. 7(c), we can say that, as the error enters the nonequilibrium error regime from near-equilibrium, dissipation becomes nonzero and increases monotonically. This shows the trade-off nature of error and dissipation. Then, in a higher range of ATP concentration, as the error increases and approaches the equilibrium magnitude within the nonequilibrium environment, the dissipation curve qualitatively reflects the same dynamics as the error rate of the proofreading mechanism. This can be observed by comparing fig. 7(d) and fig. 7(b). In this range of ATP concentration, both error and dissipation increase simultaneously. This hints at the lack of trade-off between error and dissipation in this regime under a nonequilibrium environment.

5.3 Semigrand Gibbs free energy

We now need to consider the proper nonequilibrium thermodynamic potential of the open system to analyze the energetics of the kinetic proofreading network at the nonequilibrium regime. We can characterize each chemical species thermodynamically by chemical potential \( \mu \). The expression of the chemical potential is \( \mu = \mu^o + \ln \frac{z}{z_0} \) with solvent concentration \( z_0 \) and standard-state chemical potential \( \mu^o \). The standard-state quantities with notation ‘\( o \)’ are taken at standard pressure \( p = p^o \) and molecular concentration and chemical potential to set a baseline for substances. Moreover, a constant term like \( \ln z_0 \) can also be absorbed within \( \mu^o \) of the chemical potential. The nonequilibrium Gibbs free energy of a chemical reaction network can be written in terms of the chemical potential as\[33\]

\[
G = G_0 + \sum_{\sigma \neq 0} (z_\sigma \mu_\sigma - z_\sigma) \tag{14}
\]

with \( G_0 = z_0 \mu^o_0 \). However, the proper entity to capture the energetics of the open system like the proofreading network is semigrand Gibbs free energy\[20\]. The semigrand Gibbs free energy of an open

![Figure 8: The Variation of error rate, Gibbs free energy, semigrand Gibbs free energy and slope of semigrand Gibbs free energy for lower range of ATP concentration (10^{-6} – 10^0) is plotted in (i), (ii), (iii) and (iv) of fig. 8(a). Whereas the dynamics corresponding to higher range of ATP concentration is shown in (i), (ii), (iii) and (iv) of fig. 8(b). Details about the dynamics of these thermodynamic elements are discussed in main text. For both the cases, \( \Delta = 3 \) has been considered. The rate constants of proofreading network are kept at \( k_1 = 5, k_2 = 1, k_3^R = 1 \), \( k_{-1}^R = 50 \), \( k_{-2} = 10^{-3} \) and \( k_{-3} = 10^{-3} \).](image-url)
system can be obtained from the nonequilibrium Gibbs free energy by a Legendre transformation\[19]\:
\[ \mathcal{G} = G - \sum_{\lambda_b} \mu_{\lambda_b} M_{\lambda_b}. \] (15)

where \( M_{\lambda_b} = \sum_{C_b} \frac{\mu_{\lambda_b}}{C_b} L_{\lambda_b} \) represents moieties exchanged between chemostats and system through the external flow of the chemostatted species.

The fig. 8(a) and fig. 8(b) represent the variation in Gibbs free energy, semigrand Gibbs free energy, and its slope due to change in ATP concentration over two different error regimes. From (ii) and (vi) of fig. 8(a) and fig. 8(b), respectively, we can see Gibbs free energy of the system shows similar qualitative characteristics as the error profile of the system for both the lower and higher range of ATP concentration. For the ATP range corresponding to minimum error, when dissipation starts increasing from zero(fig. 7(c)), the Gibbs free energy lowers accordingly. However, as the error grows after the plateau region of the error basin within a more strongly driven nonequilibrium environment, the dissipation further enhances(fig. 7(d)), and Gibbs free energy rapidly moves towards a very high positive value. The sum of nonequilibrium Gibbs free energy and dissipation of proofreading network would quantify the chemical work performed on the system\[19]. This statement is conceptually analogous to the nonequilibrium Landauer’s principle\[34]. The proofreading network performs optimally for small and finite chemical work, and the chemical work diverges rapidly for the strongly driven nonequilibrium regime with lower accuracy.

The fig. 8(a) suggests that as more ATP accumulates in the system, the semigrand Gibbs free energy, \( \mathcal{G} \), moves towards zero from a negative value while the error goes towards minima. The semigrand Gibbs free energy slope is initially constant and then goes from one to zero, as the error changes from the equilibrium value to the minimum one. For a comparatively higher ATP concentration in fig. 8(b), semigrand Gibbs free energy remains near zero over an extended range of ATP concentration and sustains the system’s minimum error within a nonequilibrium environment. However, as the error curve starts to increase from its minimum value due to further change in ATP concentration, a sharp and vast change towards negative value can be seen in this transformed Gibbs free energy profile. This massive change is also evident from the slope of the semigrand Gibbs free energy in fig. 8(b). The semigrand Gibbs free energy of the proofreading network is proportional to the dissipation of the reaction network in a nonequilibrium environment. The enormous magnitude of Gibbs free energy and semigrand Gibbs free energy in fig. 8(b) suggests the system is far from the equilibrium state. Hence, the system here operates at optimal accuracy and dissipation when semigrand Gibbs free energy has a value near zero.

## 6 Dissipation-Error Curve

Dissipation plays a vital role in an error-prone system by restricting error. A trade-off between error and dissipation will be there if any modification in a parameter cannot simultaneously improve both. However, this trade-off feature can be completely absent in some other parts of the same process. We have investigated the trade-off nature of the dissipation and related error for different discrimination regimes corresponding to a variation of some specific rate constants or the energy discrimination factor \( \Delta \).

Here, fig. 9(a) illustrates a trade-off curve of error and dissipation, in which we have used error as if it is an independent parameter. We have found from the figure that dissipation is infinitesimally small up to a minimum error is reached. From fig. 9(d), we can see how dissipation changes near the equilibrium error, and it is almost infinitesimal in this regime. A sharp and finite increase in the dissipation profile near the system’s minimum error rate can be seen from fig. 9(c). The fast-increasing part asserts that as we further decrease the error rate, the dissipation inevitably increases. In fig. 9(b), the system’s error again approaches the magnitude of equilibrium error (for a fixed lower \( \Delta \)) due to a further increase in external driving force. However, dissipation monotonically increases owe to the external driving force. One can observe that the error value does not exclusively determine the dissipation as the dissipation can be different for the same error value depending on the distance from the equilibrium.

In fig. 10(a), dissipation vs error plot similar to fig. 9(a) is drawn for different \( \Delta \) values. Although the magnitude of the error rate improves for higher \( \Delta \) values, maximum dissipation for the same range of \( k_2 \) decreases as the \( \Delta \) value gets high. However, one can observe the difference between
the dissipation curves corresponding to higher and lower values of $\Delta$ as in the case of higher $\Delta$ values, the error rate of the proofreading scheme for a much wider parameter space of $k_2$ within the nonequilibrium environment is supposed to get stuck at a lower value. In other words, a more rapidly increasing nonzero portion of the dissipation plot for $\Delta = 3$ than the same part of $\Delta = 12$ owes to the $k_{-1} << k_{+2}$ nonequilibrium regime where we have no improvement in error over the equilibrium error for relatively lower $\Delta$ values. It is important to note that the dissipation corresponding to the lowest error for higher $\Delta$ is greater than the one corresponding to the lower $\Delta$. Although we previously observed in section 4, the lowest error corresponding to higher $\Delta$ can be less effective than the lower $\Delta$. As we have considered equal driving forces for different $\Delta$ values, these differences of dissipation curves are solely due to the different fluxes for distinct $\Delta$ values.

Now we want to unveil the reaction network’s overall performance in terms of error and dissipation for the whole range of $k_{+2}$. In other words, we want to quantify how the performance of the kinetic proofreading network in terms of both error and dissipation is modified due to changes in ATP concentration in the presence of different energy discrimination factors. In a recent study[28], the
Figure 10: In fig. 10(a), dissipation with respect to error is shown for four different values of the ∆(= 3, 6, 9 and 12). For all the cases, $k_2$ varies from $10^{-6}$ to $10^4$. All other rate constants are fixed. In fig. 10(b), Q value defined as a product of the average dissipation and the coefficient of variation for the whole range of $k_2$ is shown for ∆(= 3, 6, 9 and 12). Q’s lowest value at ∆ = 9 hints at comparatively good trade-off between error and dissipation for the whole range of $k_2$.

performance of the kinetic proofreading network representing biological operation has been studied with the aid of bound set by the thermodynamic uncertainty relation[27]. However, we have analyzed the kinetic proofreading network at a fixed time with a variation in chemostatic controlling and energetic discrimination.

For the NESS of a deterministic system at a fixed time, we have introduced a performance measuring entity for the variation of ATP concentration. For this purpose, We have set the error, $A_o = \eta$ as the observable of our interest, and it changes with pseudo reaction rate $k_2$ or the concentration of ATP. Now for the NESS at a fixed time, we can denote the mean and standard deviation associated with $A_o$ as $\langle A_o \rangle$ and $\sqrt{\langle (A_o^2) - (\langle A_o \rangle)^2 \rangle}$ respectively. Then, the coefficient of variation across the whole range of rate constant $k_2$ in this case can written as, $\epsilon = \sqrt{\langle (A_o^2) - (\langle A_o \rangle)^2 \rangle} / \langle A_o \rangle$. Exploiting the coefficient of variation will be useful here as we have drastically different means corresponding to distinct ∆ values. We now define the performance measuring factor Q as a product of the average dissipation and the coefficient of variation for a particular ∆ value, $Q = \langle \sigma \rangle \epsilon$. For a specific velocity and a fixed energy budget of the kinetic proofreading network, this Q term aids us in revealing a parameter space of ∆ that has optimal overall performance in terms of error and dissipation. A lower Q value better adjusts error and dissipation to maintain optimal overall performance concerning different operating regimes for the whole $k_2$ range. In fig. 10(b), the factor Q decreases to a minimum value for ∆ = 9 after having almost equal magnitude for ∆ = 3 and ∆ = 6. It is evident from the fig. 10(b) that this factor for Q for ∆ = 12 is even higher than the value corresponding to ∆ = 3. Although the coefficients of variation corresponding to the error rate are lower for ∆ = 3 and ∆ = 6 than the other two higher values of ∆, a lower average dissipation for ∆ = 9 drags the corresponding Q value below values for lower ∆. However, for ∆ = 12, even a much lower average dissipation is not enough to compensate for a higher coefficient of variation, and its’ Q value is well above all other three ∆ values. Therefore, although average dissipation for the whole range of $k_2$ decreases monotonically with ∆, the Q factor shows a non-monotonic behavior with ∆. Therefore, this Q factor can be an effective parameter to measure in different synthetic biochemical networks to fulfill a particular purpose or achieve a certain target with a chemostatic control.

7 Conclusions

We have described the kinetic proofreading through substrate selection network from the standpoint of energetic discrimination and thereby exploited the chemical thermodynamic framework at NESS.
of the system to analyze the network’s performance systematically. The main findings and strengths of our theoretical analysis are about exploring the controlling factors that govern the error and the necessary formal development of semigrand Gibbs free energy and dissipation in a generic proofreading network.

Depending on the relative strength between the rate constants $k_{+2}$ and $k_{-1}$, the proofreading kinetics can have different discrimination regimes under a nonequilibrium environment for a constant binding energy difference between two intermediates. Hence, it is possible to access all different discrimination regimes at will by using either $k_{+2}$ or $k_{-1}$ as a control parameter. Furthermore, the error basin found by changing the relative strength between rate constants experiences a modification depending on the magnitude of binding energy difference, $\Delta$. Therefore, without changing the hardcore network structure, one can shift or modify the error regimes by the magnitude of the binding energy difference. Moreover, depending on the various magnitudes of the binding energy, our study will be vital if there is a family of competing substrates in the biological system. Different discriminatory regimes of the kinetic proofreading can also be seen as von Neumann’s error-correcting scheme\[35\] describing the formation of reliable automata from unreliable components.

We have estimated the NESS thermodynamic quantities to explore the optimal regime of proofreading in terms of error and dissipation. By changing the ATP to ADP concentration ratio, we have found that dissipation has the same qualitative variation as the error curve for a higher concentration ratio. On the other hand, the nonequilibrium Gibbs free energy of the system shows similar qualitative characteristics as the error profile of the system for both the lower and higher range of ATP to ADP concentration ratio. The variation of these two quantities establishes a relation between chemical work on the system and the error of different discrimination regimes. Besides the conventional energy entity, the nonequilibrium Gibbs free energy of the system, we have quantified the energetics of the kinetic proofreading network by calculating the semigrand Gibbs free energy of the network. This semigrand Gibbs free energy represents the proper thermodynamic potential of a system maintained in a nonequilibrium environment. The nature of its variation concerning different ranges of a chemostatted species is well understood by the slope of its curve. We have here noted that optimal accuracy and dissipation of the network is associated with near-zero semigrand Gibbs free energy. This finding in a simple proofreading network can be crucial and advantageous for searching the optimal regime of specificity and dissipation in more complex and general proofreading networks and copying schemes. Moreover, dissipation and semigrand Gibbs free energy characteristics reveal the proportionality among them in an open chemical system.

We have demonstrated how the binding energy difference, $\Delta$ modifies the dissipation-error curve to understand the trade-off scenario between the error and dissipation. However, it is observed that dissipation is not exclusively connected to the error value with the existence of a regime with a lack of trade-off between error and dissipation. We have unveiled the reaction network’s overall performance in terms of error and dissipation for the whole range of $k_{+2}$ by defining a $Q$ parameter in terms of average dissipation and coefficient of variation for a particular $\Delta$ value. The $\Delta$ value that results in lower $Q$ can be recommended for a specific purpose within a particular rate constant range. The regimes of trade-off and non-trade-off within the nonequilibrium environment hold the immense possibility to look into new control parameters and the concept of new mechanisms depending on the structure and energetics of the network, which can be captured through externally controlled chemostatted species.

The error basin fits very well with the summation of two logistic functions; the mathematical structure of such function will be shown elsewhere. By finding the equivalence between the error basin of higher $\Delta$ value and absolute thermodynamic lower bound of the error for lower $\Delta$, it can be possible to manipulate the optimal cycle number of a multiple cycle model. The constraints and purposes of synthetic and biological engineered systems\[36, 37, 38\] are different from their natural counterparts. Controlling error regimes and their entropic and energetic cost through the rate of constant strength, concentrations of certain species, and magnitude of energetic discrimination factor would have crucial implications in designing more efficient synthetic biological architectures at the desired NESS. The investigation reported here can even be relevant for systematic performance analysis of self-assembled synthetic system\[39, 40\].
