The controllable generation of spin polarization is essential for spintronics, for which 3D topological insulators (TIs) are ideal candidate materials because of the fascinating spin-momentum locking of their topological surface states (TSSs). Here, we propose a band tilt-induced nonlinear Nernst effect (NLNE) in 3D TIs in the absence of magnetic field. It’s found that the presence of finite band tilt can induce the imbalance of two spin carriers and give rise to spin-polarized NLNE current. Remarkably, we show that, the realized carrier spin polarization exhibits highly flexible tuning regimes i.e. rapid and smooth tuning regimes, and near-unity spin polarization can be generated within a wide range of tunable parameters. The spin-polarized NLNE proposed here is also robust against temperature, thus providing an alternative mechanism to realize room-temperature high-degree spin polarization.

Introduction.—Topological spintronics, focusing on the interplay between topological states and the spin degree of freedom of carriers, has attracted growing attention in the past years [1–4]. The realization of high degree of spin polarization with long lifetime at room temperature remains a vital issue in spintronics [5–10]. Electrical generation is one of the most general approaches to generate spin polarization, which has been widely studied in various materials including non-magnetic materials [11–13], ferromagnets [14–17] and non-collinear antiferromagnets [18–22]. Owing to the fascinating spin-momentum locking of their topological surface states (TSSs), 3D Topological insulators (TIs) are excellent platforms for generating and detecting spin-polarized current [23–31]. Unlike many other intriguing effects which have already been studied in the nonlinear regime, the spin-polarized current has been investigated only in the linear regime so far.

Recently, several novel nonlinear transport effects, namely the bilinear magnetoelectric resistance [32], nonlinear planar Hall effect (PHE) [33], and the nonlinear planar Nernst effect (NPNE) [34], have been revealed in 3D TIs Bi$_2$Se$_3$. These nonlinear effects can be attributed to the joint results of spin-momentum locking, hexagonal warping effect and in-plane magnetic field. More recently, thermoelectric effect has been utilized to control the generation of spin-polarized current in ZrTe$_5$ nanowires within the linear response regime [35], demonstrating the potential role of the transport effects (e.g., electrical and thermoelectric effects) in the spintronics applications. Motivated by these works, here, we investigate the thermally driven NLNE in 3D TIs in the presence of the hexagonal warping effect without magnetic field, in which the response current is quadratically proportional to the temperature gradient, and more importantly, carriers tunable spin polarization.

The NLNE investigated in this work has a quantum origin from the finite band tilt effect that effectively generates the transverse nonlinear spin and charge currents coplanar with the thermal gradient. Therefore, it is fundamentally different from the previously reported NLNEs, which can originate from Berry curvature dipole [36–39], chiral anomaly [39, 40], or the combined effect of Berry curvature with an in-built electric field [41]. The proposed NLNE also differs from the aforementioned nonlinear planar effects [33, 34] that requires an in-plane magnetic field to convert the nonlinear spin current into nonlinear charge current. More interestingly, because of the spin-momentum locking in 3D TIs, the band tilt-induced distortion of the Fermi surface results in an imbalance of the

FIG. 1. Schematic experimental setup for measuring the spin-polarized nonlinear Nernst effect (NLNE) in 3D topological insulators. A transverse charge current can be probed from the two leads (in grey) along y-direction as a second-order response to the longitudinal heat current flowing on the top surface. The left Dirac cone is non-tilted while the right one is slightly tilted along $k_y$-direction. The spin-up and spin-down components are increased differently due to the finite tilt, rendering not only an enhanced NLSNE but also a finite NLNE. The warped contour plots of a given Fermi surface (yellow plane) for these two Dirac surface states are also presented, where the red arrows and dashed lines represent for the spin textures and the Fermi surfaces with particle-hole asymmetry, respectively.

* ygyao@bit.edu.cn
spin-up and spin-down carriers (thereby parameter-dependent spin polarization), as schematically shown in Fig. 1. Such mechanism to generate the spin polarization is totally different from spin alignment operated by the magnetic field or magnetization. Hence our work here provides a practical way to generate NLNE with controllable spin polarization without a magnetic field, which can be directly probed in experiment (see Fig. 1). In what follows, we present the semiclassical formalism of the spin-polarized NLNE in 3D TIs and discuss it along with its spin polarization tunability in detail.

**Semiclassical Boltzmann transport formalization.**—The nonequilibrium distribution of carriers in response to external fields can be phenomenally depicted by the Boltzmann transport theory. Within the relaxation time approximation, the Boltzmann transport equation in steady state is

\[ \dot{\mathbf{f}} + \hat{k} \partial_{k} f = -\frac{f - f_{0}}{\tau}, \]  

where \( f_{0} \) is equilibrium Fermi-Dirac distribution function and \( f \) indicates the perturbed one. Here, \( \tau \) denotes the relaxation time dependent on the detailed scattering processes. For simplicity, we treat it as a constant in the following discussions. Let’s consider a configuration in which only the thermal gradient is present, i.e., \( \mathbf{E}, \mathbf{B} = 0, \nabla T \neq 0 \). Thus, Eq. (1) can be written as \( \tau \partial_{k} f = \sum_{n} g_{k}^{(n)} \) where \( g_{k}^{(n)} \) implies the correction of \( n \) th order \( (n \geq 1) \) of \( \nabla T \) to \( f_{0} \), i.e., \( f = f_{0} + \sum_{n} g_{k}^{(n)} \).

The corrections \( g_{k}^{(n)} \) are generally obtained via the iterative substitutions in Boltzmann equation [42], through which we have

\[ g_{k}^{(1)} = \frac{\tau}{\hbar} (\varepsilon_{k} - \mu) \frac{\partial f_{0}}{\partial k_{x}} \nabla_{x} T, \]
\[ g_{k}^{(2)} = \tau^{2} \left[ 2 v_{F} \frac{\partial f_{0}}{\partial k_{x}} + (\varepsilon_{k} - \mu) \frac{\partial f_{0}^{2}}{\partial k_{x}^{2}} \right] \frac{\varepsilon_{k} - \mu}{\hbar^{2} k_{x}^{2}} (\nabla_{x} T)^{2}. \]  

Without loss of generality, a thermal gradient applied along \( x \)-direction is considered above. Recently, it is pointed out that the temperature-gradient induced lower-order corrections considered here [i.e., \( g^{(1),(2)}(k) \)] are surprisingly consistent in these two methods, whereas the inconsistency will occur for the higher-order thermal corrections or in the presence of electric field.

Analogous to the charge and energy current [45, 46], the spin current operator can be defined for the spin current as \( j_{\mu}^{\sigma} = -\frac{\hbar}{2} \mathcal{H}_{\mathbf{k}}^{\sigma} \). where velocity operator \( \mathcal{H}_{\mathbf{k}}^{\sigma} = \partial \mathcal{H}_{\mathbf{k}} / \hbar \partial k_{\mu} \), and \( s_{\mu}^{\sigma} \) indicates the \( \mu \)-spin component with Pauli matrix \( \sigma_{\mu} \). In the absence of electric and magnetic field, the semiclassical equations of motion of Bloch electrons are simplified as \( \dot{\mathbf{k}} = 0, \dot{\mathbf{r}} = \langle \mathbf{v} \rangle_{n} = \partial \mathbf{v}_{n,k} / \hbar \partial k_{\mu} \) [45, 47]. Consequently, the charge current and the spin current are respectively given as,

\[ j_{\mu} = \sum_{n} \int \langle \mathbf{k} \rangle f_{n,k} \langle -e \mathbf{v}_{\mu} \rangle_{n}, \]
\[ j_{\mu}^{\sigma} = \sum_{n} \int \langle \mathbf{k} \rangle f_{n,k} \langle \tilde{q}_{\mu}^{\sigma} \rangle_{n}, \]  

where \( \langle \ldots \rangle_{n} \) represents the thermal average value with respect to \( n_{th} \) eigen band, and \( f_{n,k} \) is the distribution function of the \( n_{th} \) energy band \( \varepsilon_{n,k} \). Note that, \( j_{\mu}^{\sigma} \) implies the spin current along \( \mu \)-direction with spin pointing in direction \( \sigma \).

In this work, we focus on the nonlinear responses to temperature gradient stemming from the second-order correction \( g^{(2)} \) in Eq. (2). It is important to note that, the second-order nonlinear spin current requires broken IS, whereas both the breaking of IS and TRS are required to guarantee a finite second-order nonlinear charge current.

**Surface states in 3D TIs.**—The effective Hamiltonian for the surface state of topological insulator is

\[ H = Dk^{2} + \left[ v_{F} \hbar k \times \hat{z} + \lambda k \times \hat{g} (k_{y}^{2} - 3k_{x}^{2}) \right] \sigma + v_{i} k_{i} \sigma_{0}, \]  

where the first term refers to particle-hole asymmetry, \( v_{F} \) is the Dirac velocity, \( \lambda \) denotes the hexagonal warping strength promised by the \( C_{3v} \), rotational invariance of \( \text{Bi}_{2} \text{Te}_{3} \) (a rhombohedral crystal structure) and regarded as a counterpart of cubic Dreselhau spin-orbit coupling [49]. Additionally, a band tilt term along \( t \)-direction (\( t = x, y \)) for the Dirac cone, namely the forth term in Eq. (4), is also considered in this work. The tilt of Dirac cone can be realized in various materials [50–54], and also manifests fascinating effects on the low-energy behaviors of Dirac fermions [55–58]. Such a lifting effect, as we will show follows, is crucial to induce the NLSNE and NLNE.

The surface band dispersion based on Eq. (4) is

\[ E_{\pm,k} = Dk^{2} + v_{i} \hbar k_{i} \pm \sqrt{(v_{F} \hbar)^{2} k^{2} + \lambda^{2} k^{6} \cos^{2} 3\phi}, \]  

where \( \phi \) is the azimuth angle of momentum \( k \) with respect to \( k_{z} \)-axis, and “\( \pm \)” denotes the conduction (upper) and valence (lower) band, respectively, and the corresponding eigenstates are defined as \( \{ \pm, k \} \). Interestingly, the warping term coupled to \( \sigma_{z} \) in Eq. (4) explicitly introduces an out-of-plane spin polarization along \( s_{z} \) direction. However, in this work, we are interested in the in-plane spin polarization \( \langle \sigma_{||} \rangle \), which can be obtained as

\[ \langle \pm, k | \sigma_{||} | \pm, k \rangle = \langle \langle \sigma_{x}, \sigma_{y} \rangle \rangle = \pm \frac{v_{F} \hbar}{E_{0}} \left( k_{y}, -k_{x} \right), \]  

with \( E_{0} = |E_{\pm,k}| \Big|_{\phi=0,\sigma_{z}=0} \). Eq. (6) explicitly reveals that the spin polarization is perpendicularly locked to the momentum, independent of the presence or absence of the warping and/or band tilting effect, as shown in Fig. 1. Such helical spin textures have been experimentally observed in the TSSs of \( \text{Bi}_{2} \text{Se}_{3} \) [59–61].

The asymmetry between the conduction and valence bands has been applied to investigate the spin current generation
Spin direction of the NLSNE. The other parameters used here are the upper branch of the surface state (denoted as \( E^\alpha \)).

\[ (2e/h) j_y^\alpha / (\nabla_x T)^2 \]

where \( \lambda_0 = 250 \, eV \lambda^3 \) is fixed. (c) NLSNE versus \( v_{\parallel}/v_{\parallel} f \) for different Fermi energy. The inset illustrates the zoomed view around the black dashed line with zero magnitude.

(d) Texture of the spin current \( |j_y^\alpha| \) in the polar coordinate plane. The solid and dashed blue lines represent \( |j_y^\alpha| \) at \( E_f = 0.8 \) and \( 0.5 \, eV \), respectively, and the red arrows indicate the spin direction of the NLSNE. The other parameters used here are \( v_{\parallel} f = 2.25 \, eV \, A \, D = 0, T = 50K \).

[33, 34], band tilt-induced PHE [55], and super-resonant transport [58]. It has also been mentioned to be an additional contribution to the nonlinear PHE in previous work [33]. In effect, the presence of such a parabolic term will suppress the warping effect, as shown by the contour plots in black dashed lines in Fig. 1. This in turn will inevitably weaken the warping-effect–dependent nonlinear responses. To better analyze the band tilting effect on generating NLSNE and NLNE, we here consider the particle-hole symmetric case \( (D = 0) \) for TSSs of 3D TIs in the following discussions.

**Band tilt-enhanced NLSNE.—** Based on Eqs. (3), (6), the second-order nonlinear spin current transverse to thermal gradient is found to be

\[
j_y^\alpha = \frac{\tau^2}{2} \int [dk] \frac{v_{\parallel} f h k_y}{E_0} v_y \left[ 2h v_x \frac{\partial f_0}{\partial k_x} + (E_k - \mu) \frac{\partial^2 f_0}{\partial k_x^2} \right] (E_k - \mu) \frac{\partial^2 f_0}{\partial k_x^2} (\nabla_x T)^2, \tag{7}\]

where the upper branch of the surface state (denoted as \( E_k \)) is considered. Note that, the integral in Eq. (7) \( (\propto k_f^2 k_y^2) \) is even in momentum \( k \) without considering the band warping or band tilting effect, hence \( j_y^\alpha \) is finite even without the breaking of additional symmetry. Such a feature is implied by the non-zero intersections at \( \lambda = 0 \) in Fig. 2(a). In addition to the hexagonal warping-induced enhancement [34], we find that a finite band tilt (e.g., \( v_t/v_{\parallel} f h = 0.2 \)) can further enhance the NLSNE by about \( \sim 10 \) times on its order of magnitude [Fig. 2(a)]. Such an evident enhancement is not revealed in previously reported nonlinear PHE and NLNPNE, in which the nonlinear spin current remains basically unchanged with an increasing magnetic field [33, 34].

To further manifest the tilting effect, we plot in Fig. 2(b) the NLSNE as a function of parameters \( v_t \) and \( E_f \), where the upper branch of the surface state (denoted as \( E^\alpha \)).

\[ (2e/h) j_y^\alpha / (\nabla_x T)^2 \]

(\( \propto \)), the presence of such a parabolic term \( (\propto Dk^2) \) will further enhance the NLSNE magnitudes, and the black lines indicate isolines at \( 0, 0.3, 1.0 \), respectively. As indicated by the dark red color, NLSNE displays much more larger magnitudes relatively in the presence of a finite band tilt. A linecut plot with different chemical potentials \( E_f \) is also given in Fig. 2(c).

Is it obviously observed, that even a moderate tilting strength \( (v_t/v_{\parallel} f h \sim 0.4) \) can easily increase the NLSNE by hundreds of times on its order of magnitude compared to the non-tilted case at \( v_t = 0 \), especially at higher chemical potentials.

Through parity analysis (see details in SM [63]), one finds that, when applying temperature gradient \( \partial T \) along direction \( c = x \) or \( v_x \), a transverse nonlinear spin current \( j_y^\alpha \) with spin along direction \( c \) and a longitudinal nonlinear spin current \( j_y^\alpha \) with spin pointing in direction \( c_\perp \) (orthogonal to \( c \)) can be generated. In this work, however, we are only interested in the transverse ones. Particularly, both transverse components \( j_y^\alpha \) \( \propto (\nabla_x T)^2 \) and \( j_y^\alpha \) \( \propto (\nabla_y T)^2 \) will be simultaneously generated, given the presence of misalignment between the externally applied temperature gradient and the principal axes. In such cases, a real-space texture of the generated spin current can be determined as \( |j_y^\alpha| = \sqrt{(j_x^\alpha \sin \theta)^2 + (j_y^\alpha \cos \theta)^2} \), where \( \theta \) stands for the polar angle in the rotational coordinate system commonly applied in realistic measurement [37, 62, 64]. The numerically calculated spin current textures \( |j_y^\alpha| \) with \( E_f = 0.8 \) (solid) and \( E_f = 0.5 \, eV \) (dashed) are plotted in Fig. 2(d), where an anisotropic magnitude is observed with the red arrows representing the spin texture. Interestingly, the texture of spin-momentum locking is still preserved for the NLSNE, irrespective of the magnitude anisotropy. More discussions regarding the angular dependency of different components of nonlinear spin current are given in SM [63].

**NLNE and the spin polarization.—** Based on Eq. (3) and Eq. (6), the second-order NLNE is obtained as

\[
j_y = -e v^2 \int [dk] v_y \left[ 2h v_x \frac{\partial f_0}{\partial k_x} + (E_k - \mu) \frac{\partial^2 f_0}{\partial k_x^2} \right] (E_k - \mu) \frac{\partial^2 f_0}{\partial k_x^2} (\nabla_x T)^2, \tag{8}\]

which differs from the NLSNE in Eq. (7) only by the factor \( -\frac{h}{2e} \langle \sigma_z \rangle \) inside the integral. In contrast to the thermally driven nonlinear spin current which are generated in both
transverse and longitude directions, the nonlinear charge current can only flow along the direction of the band tilt, e.g. $y$-direction perpendicular to the temperature gradient $\nabla_x T$ in the current configuration. This is because the intergrand for $j_y$ in Eq. (8) is odd in momentum, which vanishes unless $v_y$ contains the momentum-independent part from the finite band tilt, i.e., $v_y \rightarrow v_t/\hbar \pm 1$. When the applied temperature gradient is colinear with the band tilt, all the nonlinear currents will flow longitudinally, namely there is no NLNE current generated. On the other hand, when the applied temperature gradient is perfectly perpendicular to the band tilt, the NLNE signal reaches its maximum [63].

Fig. 3 shows the variation of NLNE on different parameters. Unlike the symmetric dependence of NLSNE $j_y^{s \rightarrow}$ with respect to $v_t$ [Fig. 2(b)], the NLNE $j_y$ manifests itself as an asymmetric dependence on the tilting strength $v_t$ and undergoes a sign change when modulating $v_f$ into $-v_f$ [Fig. 3(a)]. In the absence of band tilt $(v_t = 0)$, no finite NLNE current survives [i.e. $j_y = 0$, see Fig. 3], as restricted by TRS. On the other hand, nonzero NLNE current that highly depends on the tilting strength emerges when band tilt is finite. A larger NLNE can be obtained by enhancing the warping effect and/or band tilting effect. It’s interesting to point out that NLNE rapidly increases when increasing the Fermi energy, which can be explained by the enhanced warping effect at higher Fermi energy.

To investigate the spin polarization of the generated NLNE, we extract the currents with the spin-up and spin-down components, which are respectively given as, $j_y^{s \rightarrow} = \frac{1}{2}(j_y \pm \frac{\eta}{\hbar} j_y^{s \rightarrow})$. Here, coefficient $2e/\hbar$ is incorporated to match the dimension. Owing to the band-tilt dependency of both NLSNE $j_y$ and NLNE $j_y^{s \rightarrow}$, the above spin-up $j_y^{s \rightarrow}$ and spin-down $j_y^{s \rightarrow}$ component of NLNE current are individually tunable by tilting strength, which fundamentally differs from previous works [33, 34]. To illustrate such tunability, we plot the spin-up and spin-down NLNE at $E_f = 0.6$ eV as a function of the tilt parameter $v_t$ in Fig. 4(a). Apparently, $j_y^{s \rightarrow}$ increases rapidly when tilting the band in $y$-direction $(v_t > 0)$, while $j_y^{s \rightarrow}$ gets strongly enhanced when the band is tilted in the negative $y$-direction $(v_t < 0)$. This significant anisotropy in band-tilt dependency explicitly result in the spin polarized NLNE current. It’s observed that the spin-down component $j_y^{s \rightarrow}$ is larger than the spin-up component $j_y^{s \rightarrow} (j_y^{s \rightarrow} > j_y^{s \rightarrow})$, when fixing Fermi energy at 0.15 eV and varying tilting strength $v_t/\hbar$ in the range of $[-0.5, 0.5]$ [inset of Fig. 4(a)], which leads to a negative NLSSE consistent with Fig. 2(c). Interestingly, in the case of $j_y^{s \rightarrow} = -j_y^{s \rightarrow}$, a pure nonlinear spin current is generated as a second-order response to the temperature gradient.

With the knowledge of $j_y^{s \rightarrow}$ in Fig. 2 and $j_y$ in Fig. 3, we can obtain the spin polarization in parameter plane $(E_f, v_t)$ for the tilted Dirac surface state described by Eq. (4). Generally, the spin polarization $\eta$ is defined as the ratio of the subtraction and the addition of $j_y^{s \rightarrow}$ and $j_y^{s \rightarrow}$, namely $\eta = 2e j_y^{s \rightarrow}/\hbar j_y$ in our case. As shown in Fig. 4(b), the white region with $|2e j_y^{s \rightarrow}/\hbar | > |j_y|$, where NLSNE is dominant over NLNE with the spin polarization $\eta$ being ill-defined, shall be considered as the spin current regime (SCR). The previously proposed
nonlinear planar effects engendering from spin-to-charge conversion with conversion rate less than 100% [33, 34], exactly belong to such SCR.

For the sake of practical applications, the charge current regime (CCR) with $|j_y| > |2\alpha j_{x}^{\uparrow \downarrow} / \hbar|$ that corresponds to the colorful regions in Fig. 4(b), is more interesting to us. Note that, the CCR condition also implies $j_{y}^{x_{\uparrow}, \downarrow} = j_{y}^{x_{\downarrow}, \uparrow} > 0$, namely the spin-up and spin-down components of NLNE flow in the same direction. Such condition defines a series of threshold strengths of the band tilt [63].Remarkably, the spin polarization exhibit considerably high tunability in terms of the band tilt and Fermi energy. It undergoes a sign change near the spin balance region (SBR) that satisfies $j_{y}^{x_{\uparrow}, \downarrow} = j_{y}^{x_{\downarrow}, \uparrow} = 0$ or $\eta = 0$, when varying band tilting strength $v_t$ with fixed Fermi energy or modulating the Fermi energy with selective $v_t$ [Fig. 4(b)]. This interesting feature may promise the realization of switchable spin polarization. Moreover, the spin polarization varies rapidly before SBR while gradually tends to be a constant after going through SBR [Fig. 4(c), (d)], exhibiting rapid and smooth tuning regime respectively. Such tunability (sensitiveness) difference is especially evident for the case of a fixed tilt but varying chemical potential [Fig. 4(c)]. More importantly, it is shown that NLNE current with near unity ($\sim 100\%$) spin polarization can be generated in a wide range of Fermi energy and band tilting strength (see the dark blue and dark red colors in Fig. 4(b)). The impact of varying temperature on our proposed spin-polarized NLNE is found to be negligible (see SM [63]), consistent with NPNE in Ref. [34], thus our work can achieve robust room temperature spin polarization. Note that, the spin components involved in the nonzero NLNE always remain orthogonal to the charge and spin flows [see Eqs. (7, 8)], enabling the generation of perfect transverse spin polarization.

Discussion and conclusion— The proposed spin-polarized NLNE in this work can be ascribed to the joint effect of spin-momentum locking, hexagonal warping and band tilting effect, where the former two ingredients are quite generic in realistic materials. The finite band tilt is symmetry-allowed when TRS is broken for TSSs, e.g., through in-plane magnetization doping or proximity effect of ferromagnetic insulators [65, 66]. Additionally, the magnetic topological semimetals that hold tilted Dirac cones can also support nonzero spin-polarized NLNE in principle, provided the inversion symmetry is further broken. It should be mentioned that the introduced mechanism to generate spin polarization by our work can be generalized to other transport effects (e.g., the nonlinear Hall effect and thermal Hall effect) in other potential materials (e.g., the trigonally warped graphene and bilayer graphene [67–69], etc). Besides, to better reveal the tilt-induced spin-polarized NLNE, a more detailed analysis of the scattering processes that especially incorporate magnetic disorders will be necessarily important. These interesting topics beyond the scope of the current work are all left for future studies.

In conclusion, we successfully demonstrate the band tilt-induced spin-polarized NLNE in the complete absence of the magnetic field and Berry curvature-involved effects. Such a novel transport effect can remarkably realize high-degree (near-unity) spin polarization with flexible tunabilities and robustness against temperature, which thereby hints significant advance and possible applications in spintronics.
