(Dated: November 5, 2021)

We provide several general upper bounds on device-independent conference key agreement (DI-CKA) against the quantum adversary. They include bounds by reduced entanglement measures and those based on multipartite secrecy monotones such as reduced cc-squashed entanglement. We compare the latter bound with the known lower bound for the protocol of conference key distillation based on the parity-CHSH game. We also show that the gap between DI-CKA rate and the rate of device-dependent is inherited from the bipartite gap between device-independent and device-dependent key rates, giving examples that exhibit the strict gap.

I. INTRODUCTION

Building the Quantum-secured Internet is one of the most important challenges in the field of Quantum Technologies [1, 2]. It would assure a worldwide, information-theoretically secure communication. The idea of quantum repeaters [3–5] gives the hope that this dream will come true. However, the level of quantum security proposed originally in a seminal article by Ch. Bennett and G. Brassard [6] seems to be not sufficient due to the fact that on the way between an honest manufacturer and an honest user, an active hacker can change with the inner workings of a quantum device making it totally insecure [7]. Indeed, the hardware Trojan-horse attacks on random number generators are known [8], and the active hacking on quantum devices became a standard testing approach since the seminal attack by V. Makarov [9]. The idea of device-independent security overcomes this obstacle [7, 10] (see also [11] and references therein). Although difficult to be done in practice, it has been demonstrated quite recently in several recent experiments [12–14].

In parallel, the study of the limitations of this approach in terms of upper bounds on the distillable key has been put forward [15–18]. However, these approaches focus on point-to-point quantum device-independent secure communication. In this manuscript, we introduce the upper bounds on the performance of the device-independent conference key agreement (DI-CKA) [19, 20]. The task of the conference agreement is to distribute to $N > 2$ honest parties the same secure key for one-time-pad encryption. A protocol achieving this task in a device-independent manner has been shown in Ref. [20]. We set an upper bound on the performance of such protocols in a network setting.

We focus on physical behaviors with $N$ users (for arbitrary $N > 2$), where each user is both sender and receiver to the behavior treated as a “black box”. This situation is a special case of network describable with a multiplex quantum channel where inputs and outputs are classical with quantum phenomena going inside the physical behavior [21]. All the trusted $N$ parties have the role of both sender and receiver to the channel, and their goal is to obtain a secret key in a device-independent way against a quantum adversary. Aiming at upper bounds on the device-independent key, we narrow the consideration to independent and identically distributed (i.i.d.) case. In this scenario, the honest parties share $n$ identical devices. All the $N$ parties set (classical) inputs $x = (x_1, ..., x_N)$ to each of the $n$ shared devices $P(a|x)$ and receive (classical) outputs $a = (a_1, ..., a_N)$ from each of them.

In this work, we provide upper bounds on the device-independent conference key distillation rates for arbitrary multipartite states. As the first main result, we show how to construct multipartite states with a strict gap between the rate of the quantum device-independent conference key rates $K_{DI}$ and quantum device-dependent conference key rates $K_{DD}$. As a proxy, we use a bipartite state that satisfies $K_{DD} > K^+$ where $K^+$ is reduced distillable key introduced in Ref. [16]. This implies that also in a multipartite case for some states $\rho_{A_1, ..., A_N}$ (and any $N > 2$), there is neither a Bell-like inequality that can be used for testing nor a distillation protocol based on local operations and public communication (LOPC), that can achieve $K_{DI}(\rho_{A_1, ..., A_N}) = K_{DD}(\rho_{A_1, ..., A_N})$. See Fig. 1.

We further discuss the issue of genuine non-locality [11] and genuine entanglement in the context of DI-CKA [22]. As the second main result, we provide a non-trivial bound on the device-independent key achievable in a parallel measurements scenario, when all the parties set all values of the inputs $x_i$ in parallel. Furthermore, generalizing reduced bipartite entanglement measures in Ref. [18] to
multpartite entanglement measures, we show that the reduced regularized relative entropy of genuine entanglement [21] upper bounds the DI-CKA rate of multipartite quantum states. We further focus on the performance of protocols using single input for key generation, as using such protocols is standard practice (see, e.g., [23]). As the third main result, we introduce a multipartite generalization of the reduced cc-squashed entanglement provided in Ref. [24] and developed in Ref. [16]. In that, we use the notion of the multipartite squashed entanglement given in Ref. [25], as well as the dual one also studied in Ref. [26]. Our technique is based on the approach of Ref. [27], where the upper bounds on key distillable against quantum adversary via LOCP have been studied.

To achieve this, we have generalized the upper bound via (quantum) intrinsic information to the case in which the adversary’s system can be of infinite dimension. This technical contribution was necessary, as in the case of a device-independent attack, the dimension of the attack-tolerable against quantum adversary via LOPC have been studied.

We finally compare the obtained upper bounds with the lower bound on DI-CKA provided in Ref. [26], see Fig. 2. We obtain the plots by considering simplification of the reduced cc squashed entanglement and its dual measure. Namely, the extension to the adversarial system of the state attacking the honest parties device is classical, i.e., diagonal in the computational basis. In that, the bound which we use is in fact a secrecy monotone called (multipartite) intrinsic information [28], and its dual.

The remainder of this manuscript is organized as follows. Section II is devoted to basic facts and provides a bound on DI conference key via entanglement measures. In Section III we provide examples of multipartite states which exhibit a fundamental gap between the device-dependent and independent secure key rates. Section IV discusses the connection between genuine nonlocality, entanglement and DI-CKA. Then in Section V we develop an upper bound on DI-CKA via (reduced) multipartite cc-squashed entanglement. In Section VI we develop an upper bound via a dual version of multipartite cc-squashed entanglement. In Section VII we provide particular examples for the performance of upper bounds considered in the manuscript. We finally conclude with some future directions in the final section.

II. BOUNDS ON DEVICE-INDEPENDENT KEY DISTILLATION RATE OF STATES

Consider a setup, wherein multiple trusted spatially separated users (allies), have to extract a secret key, i.e., conference key, against quantum adversary. Secret keys distilled against quantum adversaries are also called quantum keys. We assume that in this setup, the devices are untrusted. That is, the users do not trust the quantum states, nor do they trust their measurement devices. The untrusted measurement of the device is given by $M \equiv \{M_{a_1} \otimes M_{a_2} \otimes \cdots \otimes M_{a_N}\}_{a_1}$, where $x := (x_1, x_2, \ldots, x_N)$, $a := (a_1, a_2, \ldots, a_N)$, for some $N \in \mathbb{N}$. For each $i \in [N] \equiv \{1, \ldots, N\}$, the set $\{a_i\}$ denotes the finite set of measurements outcomes for measurements choices $x_i$. The measurement outcomes, i.e., outputs of the device, are secure from adversary and assumed to be in the possession of the receivers (allies). The joint probability distribution is given as

$$p(a|x) = \text{Tr}[M_{x_1}^{a_1} \otimes M_{x_2}^{a_2} \otimes \cdots \otimes M_{x_N}^{a_N} \rho_{A_1A_2\ldots A_N}]$$

for measurement $M$ on $N$-partite state $\rho_{N(A)}$ defined on the separable Hilbert space $H_{A_1} \otimes H_{A_2} \otimes \cdots \otimes H_{A_N}$, and in what follows we will use $N(A) \equiv A_1, \ldots, A_N$ for the ease of notation. The tuple $\{\rho, M\}$, where $M \equiv \{M_{x_1}^{a_1}, M_{x_2}^{a_2}, \ldots, M_{x_N}^{a_N}\}$, is called the quantum strategy of the distribution. The number of inputs $\{x_i\}$ and corresponding possible outputs $\{a_i\}$ of local measurement at $A_i$ are arbitrarily finite in general. We denote the identity superoperator by $\mathbb{I}$ and the identity operator by $\mathbb{I}$.

Let $\omega(\rho, M)$ denotes the violation of the given multipartite Bell-type inequality $B$ by state $\rho$ when the measurement settings are given by $M$. We note that by multipartite Bell-type inequality, we mean any inequality derived using locally-realistic hidden variable (LRHV) theories (e.g., [29-37]) such that any violation of a given inequality by a density operator implies the non-existence of respective LRHV model for the given density operator. There are families of Bell-type inequalities directly based on the joint probability distribution of local measurements that get violated by all pure multipartite (genuinely) entangled states [35, 36]. On the other hand, there are Bell-type inequalities based on correlation functions of local measurements for which some families of pure multipartite (genuinely) entangled states satisfy the inequalities [38].
Let \( P_{\text{err}}(\rho, \mathcal{M}) \) denote the expected qubit error rate (QBER). Both the Bell violation and the QBER are a function of the probability distribution of the behavior. \( \Phi_{\text{GHZ}} \) denotes the \( N \)-partite Greenberger–Horne–Zeilinger (GHZ) state:

\[
\Phi_{\text{GHZ}}^N = \frac{1}{d} \sum_{i=0}^{d-1} |i\rangle_{A_1} \otimes |i\rangle_{A_2} \otimes \cdots \otimes |i\rangle_{A_N}
\]

for \( d = \min_i \dim(H_{A_i}) \). For \( N = 2 \), \( \Phi_{\text{GHZ}}^N \) is a maximally entangled (Bell) state \( \Phi_B \).

If \( \{p(a|x)\}_{a,x} \) obtained from \( (\rho, \mathcal{M}) \) and another pair of state and measurements \( (\sigma, \mathcal{N}) \) are the same, we write \( (\rho, \mathcal{M}) = (\sigma, \mathcal{N}) \). In most DI-CKA protocols, instead of using the statistics of the full correlation, we use the Bell violation and the QBER to test the level of security of the observed statistics. In this way, for practical reasons, the protocols coarse-grain the statistics, and we only use partial information of the full statistics to extract the device-independent key. In this context, the notation \( (\rho, \mathcal{N}) = (\sigma, \mathcal{N}) \) also implies that \( \omega(\sigma, \mathcal{N}) = \omega(\rho, \mathcal{M}) \) and \( P_{\text{err}}(\sigma, \mathcal{N}) = P_{\text{err}}(\rho, \mathcal{M}) \). When conditional probabilities associated with \( (\rho, \mathcal{M}) \) and \( (\sigma, \mathcal{N}) \) are \( \varepsilon \)-close to each other, then we write \( (\rho, \mathcal{M}) \approx_{\varepsilon} (\sigma, \mathcal{N}) \). For our purpose, it suffices to consider the distance

\[
d(p, p') = \sup_x ||p(\cdot|x) - p'(\cdot|x)||_1 \leq \varepsilon.
\]

The device-independent (DI) distillable key rate of a device is informally defined as the supremum over the finite key rates \( \kappa \) achievable by the best protocol on any device compatible with \( (\rho, \mathcal{M}) \), within an appropriate asymptotic blocklength limit and security parameter. Another approach taken is to minimize the key rate over statistics compatible with the Bell parameter and a quantum bit error rate (QBER) (e.g., [24]). For our purpose, we constrain ourselves to the situation when the compatible devices are i.i.d.

An ideal conference key state \( \tau^{(d_K)} \), with \( d_K = \log_2 K \) secret key bits for \( N \) allies, is

\[
\tau^{(d_K)}_{N(A)} := \frac{1}{K} \sum_{k=0}^{K-1} |k\rangle_{A_1} \otimes |k\rangle_{A_2} \otimes \cdots \otimes |k\rangle_{A_N} \otimes \sigma_E,
\]

where \( \sigma_E \) is a state of the only system \( E \) accessible to an adversary, i.e., adversary is uncorrelated with trusted users and gets no information about their secret bits.

Consider the following relations:

\[
(\rho, \mathcal{M}) \approx_{\varepsilon} (\sigma, \mathcal{N}) \quad \text{(5)}
\]

\[
\omega(\rho, \mathcal{M}) \approx_{\varepsilon} \omega(\sigma, \mathcal{N}) \quad \text{(6)}
\]

\[
P_{\text{err}}(\rho, \mathcal{M}) \approx_{\varepsilon} P_{\text{err}}(\sigma, \mathcal{M}), \quad \text{(7)}
\]

where Eq. (5) implies Eqs. (6) and (7).

Formally, the definition of device-independent quantum key distillation rate is given as

**Definition 1** (Cf. [16]). The maximum device-independent quantum key distillation rate of a device \( (\rho, \mathcal{M}) \) with i.i.d. behavior is defined as

\[
K^{\text{id}}_{\text{DI,dev}}(\rho, \mathcal{M}) := \inf_{\varepsilon>0} \lim_{n \to \infty} \sup_{\mathcal{P}} \inf_{\kappa_n} \kappa_n(\hat{P}(\sigma, \mathcal{N})^n),
\]

(8)

where \( \kappa_n \) is the quantum key rate achieved for any security parameter \( \varepsilon \), blocklength or number of copies \( n \), and measurements \( \mathcal{N} \).

Here, \( \mathcal{P} \) is a protocol composed of classical local operations and public (classical) communication (CLOPC) acting on \( n \) identical copies of \( (\sigma, \mathcal{N}) \) which, composed with the measurement, results in a quantum local operations and public (classical) communication (qLOPC) protocol.

The following lemma follows from the definition of \( K^{\text{id}}_{\text{DI}} \) (generalizing statements from bipartite DI-QKD in Refs. [16, 18] to DI-CKA):

**Lemma 1.** The maximum device-independent quantum key distillation rate \( K^{\text{id}}_{\text{DI}} \) of a device \( (\rho, \mathcal{M}) \) is equal to the maximum device-independent quantum key distillation rate of a device \( (\sigma, \mathcal{N}) \) when \( (\rho, \mathcal{M}) = (\sigma, \mathcal{N}) \):

\[
(\rho, \mathcal{M}) = (\sigma, \mathcal{N}) \implies K^{\text{id}}_{\text{DI,dev}}(\rho, \mathcal{M}) = K^{\text{id}}_{\text{DI,dev}}(\sigma, \mathcal{N}).
\]

(9)

**Definition 2.** The maximum device-independent quantum key distillation rate \( K^{\text{id}}_{\text{DI,dev}}(\rho, \mathcal{M}) \) of a bipartite state \( \rho_{AB} \) is given by

\[
K^{\text{id}}_{\text{DI,dev(par)}}(\rho) = \sup_{\mathcal{M}} K^{\text{id}}_{\text{DI,dev(par)}}(\rho, \mathcal{M}).
\]

(10)

**Remark 1** (Cf. [11]). We note that there may exist states \( \rho \) for which \( K^{\text{id}}_{\text{DI}}(\rho) = 0 \) but \( K^{\text{id}}_{\text{DI}}(\rho^\otimes k) > 0 \) for some \( k \in \mathbb{N} \).

As discussed above, a large class of device-independent quantum key distillation protocols relies on the Bell violation and the QBER of the device \( p(a|x) \). For such protocols, we can define the device-independent key distillation protocol as:

**Definition 3** (Cf. [24]). The maximal device-independent quantum key distillation rate of a device \( (\rho, \mathcal{M}) \) with i.i.d. behavior, Bell violation \( \omega(\rho, \mathcal{M}) \) and QBER \( P_{\text{err}}(\rho, \mathcal{M}) \), is defined as

\[
K^{\text{id}}_{\text{DI,par}}(\rho, \mathcal{M})
\]

\[
:= \inf_{\varepsilon>0} \lim_{n \to \infty} \sup_{\mathcal{P}} \inf_{\kappa_n} \kappa_n(\hat{P}(\sigma, \mathcal{N})^n),
\]

(11)

**Remark 2.** As Eq. (5) implies Eqs. (6) and (7), it follows from the definitions of \( K^{\text{id}}_{\text{DI,par}}(\rho, \mathcal{M}) \) and \( K^{\text{id}}_{\text{DI,dev}}(\rho, \mathcal{M}) \) that, \( K^{\text{id}}_{\text{DI,par}}(\rho, \mathcal{M}) \leq K^{\text{id}}_{\text{DI,dev}}(\rho, \mathcal{M}) \).

The maximal DI-CKA rate \( K_{\text{DI,dev}}(\rho, \mathcal{M}) \) for the device \( (\rho, \mathcal{M}) \) is upper bounded by the maximal device-dependent CKA rate \( K_{\text{DD}}(\sigma) \) for all \( (\sigma, \mathcal{N}) \) such that \( (\sigma, \mathcal{N}) = (\rho, \mathcal{M}) \) (cf. [16]), i.e.,

\[
K_{\text{DI,dev}}(\rho, \mathcal{M}) \leq \inf_{(\sigma, \mathcal{N})=(\rho, \mathcal{M})} K_{\text{DD}}(\sigma).
\]

(12)
The device-dependent quantum key distillation rate $K_{DD}(\rho)$ (cf. [27]) is the maximum secret key (against quantum eavesdropper) that can be distilled between allies using local operations and classical communication (LOCC) (e.g., [21]).

$$K_{DD}(\rho) := \inf_{\epsilon > 0} \lim_{n \to \infty} \sup_{\Lambda \in \text{LOPC}} \left\{ \frac{\log d_n}{n} \right\} \Lambda(\rho^\otimes n) \approx_{\epsilon} \tau(d_n) \right\}, \quad (13)$$

where $\rho \approx \sigma \iff \frac{1}{2}\|\rho - \sigma\|_1 \leq \epsilon$.

**Corollary 1.** For entanglement measures $\text{Ent}$ which upper bounds the maximum device-dependent key distillation rate, i.e., $K_{DD}(\rho) \leq \text{Ent}(\rho)$ for a density operator $\rho$, we have,

$$K_{DI,dev}(\rho, M) \leq \inf_{(\sigma, N)\equiv(\rho, M)} K_{DD}(\sigma) \leq \inf_{(\sigma, N)\equiv(\rho, M)} \text{Ent}(\sigma). \quad (14)$$

**Remark 3.** We do not make any assumption on the dimension of the Hilbert space on which the states $\sigma$ (Definitions 1, 2, and 3) is defined as the systems can be finite-dimensional or infinite-dimensional. We only assume that the systems $A_i$ accessible by the allies for key distillation upon measurement are finite-dimensional in an honest setting. The systems $E$ accessible to adversary can be finite-dimensional or infinite-dimensional depending on the cheating strategy (see Lemma 7).

### III. GAP BETWEEN DI-CKA AND DD-CKA

In this section, we provide a bound on the conference key agreement of $N$ parties in terms of the bounds for groupings of these parties into groups of less than $N$ users. We further show that there is a gap between device-independent and device-dependent conference key agreement rates. This gap is inherited from the analogous gap shown for the bipartite case [16].

In what follows, by a (nontrivial) partition $P$ of the set of systems $\{A_1,...,A_N\}$, we mean any grouping of the systems into at least two and no more than $N - 1$ subsets, such that each $A_i$ belongs to exactly one subset, and each of them belongs to some subset.

Let us now generalize the definition of the reduced device-dependent key to the case of conference key agreement and the fact that it bounds the device-independent conference key (i.e., Theorem 6 of Ref. [16]).

**Definition 4.** The reduced device-dependent conference key rate of an $N$-partite state $\rho_{N(A)}$ reads

$$K^i(\rho_{N(A)}) := \sup_{\mathcal{M}} \inf_{(\sigma_{N(A)},\mathcal{L})\equiv(\rho_{N(A)},\mathcal{M})} K_{DD}(\sigma_{N(A)}), \quad (16)$$

A direct analog of Theorem 6 of Ref. [16] (with analogous proof which we omit here) states the following:

**Theorem 1.** For any $N$-partite state $\rho_{N(A)}$ and any $\mathcal{M}$, there is

$$K_{DI}(\rho_{N(A)}, \mathcal{M}) \leq \inf_{(\sigma_{N(A)},\mathcal{L})\equiv(\rho_{N(A)},\mathcal{M})} K_{DD}(\rho_{N(A)}), \quad (17)$$

and in particular,

$$K_{DI}(\rho_{N(A)}) \equiv \sup_{\mathcal{M}} K_{DI}(\rho_{N(A)}, \mathcal{M}) \leq K^i(\rho_{N(A)}). \quad (18)$$

We first observe the following bound:

**Proposition 1.** For any $N$-partite quantum behavior $(\rho_{N(A)}, \mathcal{M})$, there is

$$K^i_{DI,dev}(\rho_{N(A)}, \mathcal{M}) \leq \min_{\mathcal{P}} \left\{ \inf_{(\sigma_{N(A)},\mathcal{L})\equiv(\rho_{P(N(A))},\mathcal{M})} K_{DD}(\sigma_{P(N(A))}) \right\}. \quad (19)$$

where $\mathcal{P}$ is any non-trivial partition of the set of systems $A_1...A_N$.

**Proof.** The proof of the bound by $K^i_{DI,dev}(\rho_{P(N(A))})$ follows from the fact that any protocol of distillation of the DI conference key from the $N$-partite state is a special case of a protocol that distills DI conference key from a non-trivial partition $\mathcal{P}$. This is because the class of LOPC protocols in these two scenarios are in relation $\text{LOPC}(A_1,...,A_N) \subseteq \text{LOPC}(\mathcal{P}(A_1,...,A_N))$. The other bound follows from the fact that for any grouping $\mathcal{P}$, by Theorem 1 above,

$$K^i_{DI,dev}(\rho_{P(N(A))}, \mathcal{M}) \leq \inf_{(\sigma_{P(N(A)),\mathcal{L})\equiv(\rho_{P(M(A)),\mathcal{M})},\mathcal{M})} K_{DD}(\sigma_{P(N(A))}). \quad (20)$$

An analogous fact to the above holds for $K^i_{DI,par}$ as well.

Following Ref. [16] we show now that there is a gap between the amount of conference key and device-independent conference key. We will use the fact that there it has been proven that there are states with $K^i(\rho_{AB}) > K_{DD}(\rho_{AB})$. From such state $\rho_{AB}$ we construct a multipartite state with the property that $K_{DI}(\rho_{N(A)}) < K_{DD}(\rho_{N(A)})$, as it is described in the proof of the following theorem.

**Theorem 2.** Let $\rho_{AB} \in \mathcal{B}(\mathcal{H}_A \otimes \mathcal{B})$, where $\dim(\mathcal{H}_A) = d_A$ and $\dim(\mathcal{H}_B) = d_B$, be a bipartite state which admits a gap $K_{DD}(\rho_{AB}) - K^i(\rho_{AB}) \geq c > 0$ for some constant $c$. Then for any $N$ there is a multipartite state $\rho_{N(A)}$ with local dimensions at most $d_A \times d_B$ with $K_{DD}(\rho_{N(A)}) - K_{DI}(\rho_{N(A)}) \geq c$. 

Proof. Consider a state $\rho_{N(A)}$ constructed as a path made of state $\rho_{AB}$ (as e.g. in a line of a quantum repeater)

$$\tilde{\rho}_{N(A)} \coloneqq \rho_{A_1^1A_2^1} \otimes \rho_{A_1^2A_2^2} \otimes \rho_{A_1^3A_2^3} \otimes ... \otimes \rho_{A_{N-1}^1A_{N-1}^2}. \tag{21}$$

Here $\rho_{A_1^1A_2^1} = \rho_{A_1^2A_2^2} = ... = \rho_{A_{N-1}^1A_{N-1}^2} = \rho_{AB}$, and by the way of notation we have $A_1^1 \equiv A_1, A_2^2 \equiv A_2, ..., A_{N-1}^1 \equiv A_N$. That is, the first party has only system $A_1^1$ and the last only system $A_{N-1}^1$, while the $i$-th party for $1 < i < N$ has systems $A_{i-1}^1, A_i^1$ at hand.

Since the states $\rho_{A_1^1A_2^1}$ form a spanning tree of a graph of $N$ systems (in fact a path), we can follow the lower bound given in the Sec. VI. A. of Ref. [21] and note that

$$K_{DD}(\tilde{\rho}_{N(A)}) \geq \min_{i} K_{DD}(\rho_{A_1^iA_2^i}) = K_{DD}(\rho_{AB}). \tag{22}$$

Indeed, the parties can first distill key at rate $K_{DD}(\rho_{AB})$ along the edges of the path. Denote such distilled keys by $k_{ij}$ between nodes $i$ and $j$. Further $A_1$ can XOR her key $k_{12}$ with a locally generated private random bit string $r$ of length $K_{DD}(\rho_{AB})$ and send $k_{12} \oplus r$ to $A_2$, further $A_2$ can obtain $r = k_{12} \oplus (k_{12} \oplus r)$ and send it to the next party by XORing it with the key $k_{23}$. This process repeated $N - 1$ times leaves all the parties knowing $r$, which remained secret due to one-time pad encryption by the keys $k_{12}, k_{23}, ..., k_{N-1,N}$. It then suffices to note that by Proposition 1

$$K_{DI}(\tilde{\rho}_{N(A)}, M) \leq \min_{(\sigma_{A_1^1A_1^2}, ..., A_N^1)} K_{DD}(\sigma_{A_1^1A_1^2A_2^2A_3^2...A_N^1}M) \tag{23}$$

This is because there is no more conference key than the amount of device-dependent key distilled in cut $A_1^1 : (A_2^2...A_{N-1}^2)$. The latter is also upper bounded by the key distilled between system $A_1^1$ and $A_2^2$. This is due to the fact that any distillation protocol between $A_1^1$ and $(A_2^2...A_N)$ is a particular protocol distilling key between systems $A_1^1$ and $A_2^2$.

Taking supremum over $M$ on both sides of inequality (24), we obtain

$$K_{DI}(\tilde{\rho}_{N(A)}) \equiv \sup_{M} K_{DI}(\tilde{\rho}_{N(A), M}) \leq K^{+}(\rho_{A_1^iA_2^1}) \equiv \sup_{M} \inf_{(\sigma_{A_1^iA_1^2})} K_{DD}(\sigma_{A_1^iA_1^2}) \tag{25}$$

Hence we got $K_{DI}(\tilde{\rho}_{N(A)}) \leq K^{+}(\rho_{AB})$. This fact, by Eq. (22), and the fact that by assumption $K_{DD}(\rho_{AB}) - K^{+}(\rho_{AB}) \geq c > 0$, implies the following chain of inequalities:

$$K_{DD}(\tilde{\rho}_{N(A)}) \geq K_{DD}(\rho_{AB}) > K^{+}(\rho_{AB}) \geq K_{DI}(\tilde{\rho}_{N(A)}). \tag{26}$$

The above implies then the desired gap $K_{DD}(\tilde{\rho}_{N(A)}) - K_{DI}(\tilde{\rho}_{N(A)}) > 0$. Moreover this gap is as large as $c > 0$ due to assumption that $K_{DD}(\rho_{AB}) - K_{DI}(\rho_{AB}) \geq c > 0$.

From Ref. [16] we have then immediate corollary, that there is a gap between DI-CKA and DD-CKA:

**Corollary 2.** For any $N$ there is a state $\tilde{\rho}_{N(A)}$ for which

$$K^{id}_{DI,dev}(\tilde{\rho}_{N(A)}) < K_{DD}(\tilde{\rho}_{N(A)}). \tag{27}$$

**Proof.** In Ref. [16] there is shown an example of a bipartite state $\rho_{AB}$ with the gap $K^{+}(\rho_{AB}) < K_{DD}(\rho_{AB})$. The construction given in Eq. (21) based on this $\rho_{AB}$ proves the thesis via Theorem 2.

We note also that similar bound as in the above corollary holds for $K^{id}_{DI,par}$ and $K_{DI}$ itself due to the fact that $K^{id}_{DI} \geq K_{DI}$ by definition [16]. We can modify the proof technique shown above to see the following general remark.

**Remark 4.** In the above construction one need not to use only the state $\rho_{A_1^iA_2^1}$ having $K^{+}(\rho_{A_1^iA_2^1}) < K_{DD}(\rho_{A_1^iA_2^1})$ In fact the state on systems $A_1^1A_2^2...A_{N-1}^1A_{N-1}^2$ can be arbitrary state having $K_{DD}(\rho_{A_1^iA_2^1A_3^2...A_{N-1}^1A_{N-1}^2}) \geq K_{DD}(\rho_{A_1^iA_2^1})$. It can be even a $\Phi^{GHZ}$ of arbitrary large local dimension. This is with no change in the above proof if only $\rho_{A_1^iA_2^1}$ is on systems $A_1^1A_2^1$ with the gap we have mentioned. See Fig. 1 for the tripartite example.

IV. DI-CKA VERSUS GENUINE NON-LocaLY AND ENTANGLEMENT

We now discuss the topic of genuine non-locality and entanglement in the context of DI-CKA, introducing the notion of quantum locality.

We say that a behavior $P(a|x)$ is local in a cut $(A_i...A_k) : (A_{k+1}...A_N)$ if it can be written as a product of two behaviors on systems $A_i...A_k$ and $A_{k+1}...A_N$ respectively. The behavior $P(a|x)$ is genuinely non-local if and only if it is not a mixture of behaviors that are product in at least one cut.

We show that any behavior from which the parties draw the conference key in a single run must exhibit genuine non-locality. The scenario of a single run was considered in context of a non-signaling adversary [39, 40]. In that, we depart from the traditional definition of DI quantum key distillation rate by considering a single-shot DI quantum key distillation rate obtained by an LOPC post-processing of a distribution obtained from some behavior $P(a|x)$ when all the parties measure all the inputs $x$ in parallel at the same time.
For the purpose of the Theorem below, by a “local” set we will mean the set of behaviors that are convex mixtures of behaviors that are product in some cut, and both the behaviors in the product have quantum realization. We will denote this set by LQ (locally quantum). Any distribution which is not in LQ, can be treated as genuinely non-local, although other definitions are adopted in literature [11]. Exemplary, extreme behavior in this set is a product of the Tsirelson behavior \( P(a_1, a_2|x_1, x_2) = \text{Tr}[(\Phi^+^2)(\Phi^-^2)M_{x_1} \otimes M_{x_2}] \) with \( M_{x_1}^0 = \sigma_x, M_{x_1}^1 = \epsilon_{x_1}, M_{x_2}^0 = \frac{(\sigma_x - \epsilon_{x_1})}{\sqrt{2}}, M_{x_2}^1 = \frac{(\epsilon_{x_1} - \sigma_x)}{\sqrt{2}} \) (\( \sigma_x, \epsilon_{x_1} \) being Pauli-X, Pauli-Z operators), and a local behavior \( P(a_3|x_3): \ P(a_1, a_2|x_1, x_2)P(a_3|x_3) \).

**Theorem 3.** If a behavior \( P(a|x) \) satisfies \( K_{\text{single-shot}}(P(a|x)) > 0 \) then it is not LQ.

**Proof.** The proof goes by contradiction. Suppose the behavior \( P(a|x) \) is not genuinely non-local. That is it can be expressed as a convex combination of behaviors which are product in at least one cut denoted as \( (A^{(i)}_j \ldots A^{(i)}_{j_k}) : (A^{(i)}_{j_k+1} \ldots A^{(i)}_{j_N}) \) for the \( i \)-th behavior in the combination. We express this as follows:

\[
\sum_{i} p_i P_i(a|x)_{(A^{(i)}_j \ldots A^{(i)}_{j_k}) : (A^{(i)}_{j_k+1} \ldots A^{(i)}_{j_N})}, \tag{28}
\]

where \( P_i(a|x) \) are some, quantum behaviors. Consider then a device \( P_i \) as a bipartite one, with parties \( (A^{(i)}_j \ldots A^{(i)}_{j_k}) \) together forming \( A' \) and \( (A^{(i)}_{j_k+1} \ldots A^{(i)}_{j_N}) \) forming \( A'' \). Such a device has zero bipartite DI quantum key, as it is product in cut \( A' \). By the virtue of purification, Eve can have access to the mixture (28), knowing which of the mixing term \( i \) happened. By Theorem 1 we have that for any of such terms, one can not draw a conference key, as Eve has a local hidden variable model for it. Indeed, the RHS of (19) is then 0, as Eve can adopt an attack which, e.g., makes zero reduced cc-squashed entanglement [18]. We thus obtained the desired contradiction. \( \Box \)

Let us now recall the notion of genuine entanglement. We say that a multipartite state \( \rho_{A_1A_2 \ldots A_N} \) is separable in a cut \( (A_1, \ldots, A_{i_k}) : (A_{i_k+1} \ldots A_N) \) if it can be written as convex mixtures of \( A_1, \ldots, A_{i_k} \) and \( A_{i_k+1} \ldots A_N \). If a multipartite state \( \rho_{A_1A_2 \ldots A_N} \) can be written as a mixture of separable states that are product in at least one cut then it is called biseparable. We say that \( \rho_{A_1A_2 \ldots A_N} \) is genuinely entangled if and only if it is not a mixture of separable states that are product in at least one cut. It was shown in Ref. [41] that there exist \( N \)-partite states for all \( N > 2 \) where some genuinely entangled states admit a fully LRHV model, i.e., where all parties are separated.

Let GE(\( N(A) \)), BS(\( N(A) \)), and FS(\( N(A) \)) denote the set of all \( N \)-partite states \( \rho_{A_1, A_2, \ldots, A_N} \) that are genuinely entangled, biseparable, and fully separable, respectively (see Ref. [21]). For \( n \)-copies of \( N \)-partite state, when we consider partition across designated \( N \) parties, we denote local groupings by \( N(A^{\otimes n}) \).

**Remark 5.** It is necessary to consider a single-shot DI key in the Theorem 3 because the set of LQ behaviors is not closed under tensor product. This is for the same reason, for which the set of bi-separable states is not closed under tensor product.

The following theorem follows from the Observation 1 and Proposition 2 of Ref. [21]:

**Theorem 4.** The maximum device-independent conference key agreement rates of a device \((\rho, M)\) are upper bounded by

\[
K_{DI, dev}(\rho(A_1, M)) \leq \inf_{(\sigma_{N(A)}, \mathcal{L})=_{(\rho, M)}} E_{GE}(\sigma), \tag{29}
\]

\[
K_{DI, par}(\rho, M) \leq \inf_{P_{\mathcal{L}}(\rho, \mathcal{L})} E_{GE}(\sigma), \tag{30}
\]

where \( E_{GE}(\sigma) \) is the regularized relative entropy of genuine entanglement [21] of a state \( \zeta_{A_1A_2 \ldots A_N} \), with

\[
E_{GE}(\zeta) = \inf_{\mathcal{V} \in \text{BS}(N(\otimes A)=1)} \lim_{n \rightarrow \infty} \frac{1}{n} D(\zeta^{\otimes n}||\varphi) \tag{31}
\]

where \( D(\rho||\sigma) \) is the relative entropy between two states \( \rho \) and \( \sigma \), \( D(\rho||\sigma) = \text{Tr}[\rho\log\rho - \sigma \log \sigma] \) if \( \sup \rho \leq \sup \sigma \), else it is \( \infty \) [42].

We note here that there is a trivial bound that can be obtained from the Theorem 4 above, which is encapsulated in the corollary below.

**Corollary 3.** For any state \( \rho_{N(A)} \) with \( \min_{i \in \{1 \ldots N\}} d_{A_i} =: d, \) there is:

\[
K_{DI}(\rho_{N(A)}) \equiv \sup_{\mathcal{M}} K_{DI}(\rho, M) \leq \min \{ p \log d : p \in [0,1], \rho = p\rho^{fs} + (1-p)\rho_{fs}, \rho_{fs} \in FS \} \tag{32}
\]

**Proof.** Given any decomposition of a state \( \rho_{N(A)} \) into \( \rho = p\rho^{fs} + (1-p)\rho_{fs} \), where the state \( \rho_{fs} \) is a fully separable state, we have

\[
K_{DI}(\rho) \leq \sup_{\mathcal{M}} K_{DI, dev}(\rho, M) \leq \sup_{(\sigma_{N(A)}, \mathcal{L})=_{(\rho, M)}} E_{GE}(\sigma) \leq \sup_{\mathcal{M}} E_{R}(\rho) \leq pE_{R}(\rho') \leq p \min \log d_{A_i}, \tag{33}
\]

where we have used the Theorem 4 (also see Corollary 6 of [21]) and the fact that \( E_{R}(\rho) = \inf_{\kappa \in FS} D(\rho||\kappa) \) is (i) convex (ii) zero on fully separable states (iii) does not exceed the minimum log of dimensions of the input state, which can be proved by noticing, that \( E_{R}(\rho) \leq D(\rho||\rho_{A_1} \otimes \rho_{A_{\bar{n}}}) = I(A_1 : A_{\bar{n}}) \leq \log d \) where \( A_1 \) has minimal dimension among systems \( A_1 \ldots A_N \). \( \Box \)

In Section VII we present this bound on Fig. 2, and we see, that it is indeed above the upper bounds which we derive in Sections V and VI.
V. MULTIPARTITE REDUCED CC-SQUASHED ENTANGLEMENT BOUND

In this section, we focus on scenario where $N$ parties share $n$ devices $P(a|x)$.

In what follows, we first prove that the cc-version of the multipartite squashed entanglement $E^q_{sq}$ defined in Ref. [25], if properly scaled, upper bounds the conference key secure against the quantum adversary. Let us first recall facts and definitions. The multipartite conditional mutual information of a state $\rho_{A_1...A_N}$ reads [43]:

$$I(A_1:...:A_N|E)_\rho = \sum_{i=1}^{N} H(A_i|E)_\rho - H(A_1,...,A_N|E)_\rho.$$  

(34)

Here $H(A_i|E)_\rho = H(A_iE)_\rho - H(E)_\rho$, with $H(AB) := \text{Tr} [\rho_{AB} \log \rho_{AB}]$ and $H(A) := \text{Tr} [\rho_A \log \rho_A]$ being von Neumann entropies. It will be crucial to note that the following identity holds [25]:

$$I(A_1:...:A_N|E)_\rho = I(A_1:A_2|E)_\rho + I(A_3:A_1A_2|E)_\rho + I(A_4:A_1A_2A_3|E)_\rho + ... + I(A_N:A_1...A_{N-1}|E)_\rho.$$  

(35)

Further the multipartite squashed entanglement of a quantum state $\rho_{A_1...A_N}$ reads (Definition 3 of Ref. [25]):

**Definition 5 ([25]).** For an $N$-partite state $\rho_{A_1...A_N}$

$$E^q_{sq}(\rho_{A_1...A_N}) := \inf_{\sigma} I(A_1:A_2:...:A_N|E)_\sigma,$$

where the infimum is taken over states $\sigma_{A_1...A_N}$ that are extensions of $\rho_{A_1...A_N}$, i.e. $\text{Tr} [\sigma_{A_1...A_N} E] = \rho_{A_1...A_N}$.

We will need to generalize the notion of the cc-squashed entanglement [18, 24] to the multipartite form.

**Definition 6.** A multipartite cc-squashed entanglement of a state $\rho_{A_1...A_N}$ is defined as follows

$$E^{cc}_{sq}(\rho,M) := \inf_{\Lambda_c: \Lambda_c(E)\to E'} I(A_1:...:A_N|E')_{\Lambda_c M_{N(A)} \otimes A\psi^\rho_{N(A)}(E')},$$

(37)

where $M_{N(A)}$ is $N$-tuple of POVMs $M_{A_1}...M_{A_N}$ and state $\psi^\rho_{N(A)}(E')$ is a purification of $\rho_{N(A)}$.

As the first theorem of this section there comes the following fact, which is a multipartite generalization of Theorem 5 from Ref. [18], where $N = 2$:

**Theorem 5.** For an $N$-partite state $\rho_{N(A)}$, its purification $\psi^\rho$ and an $N$-tuple of POVMs $M_{N(A)}$, there is:

$$K_{DD}(M_{N(A)} \otimes \text{id}_E \psi^\rho) \leq \frac{1}{N-1} E^q_{sq}(\rho,M).$$  

(39)

**Proof.** We closely follow the proof of Theorem 3.5 of Ref. [27], however, based not on Theorem 3.1 of Ref. [27], but its generalization to the case where system $E$ need not be finite (see Lemma 7). Namely, any function which satisfies: (i) monotonicity under LOPC operations (ii) Asymptotic continuity (iii) Normalisation (iv) Subadditivity, is after regularization an upper bound on the distillable key secure against the quantum adversary ($K_D$).

We first show the monotonicity. The LOPC operations consist of local operation and public communication. A local operation consists of adding a local ancilla, performing a unitary transformation, and a partial trace. It is easy to see that adding a local ancilla at one system does not alter this quantity. The same holds for the unitary transformation. Partial trace does not increase it as it can be rewritten in terms of the conditional mutual information terms as in Eq. (35). Then the same argument as in the proof of Theorem 3.5 of Ref. [27] (see Eq. (57) there) applies.

Finally, for classical communication, we use the form given in Eq. (35) to verify the inequality stated below for the case when $A_i$ produces locally variable $C_i$ and then broadcasts it to all the parties in the form of $C_j$ for $j \neq i$ and to the adversary in the form of $C_{N+1}$. (note that broadcasting followed by a partial trace, if needed, can simulate any classical communication among $N$ parties).

$$I(A_1:...:A_iC_i:...:A_N|E)_\rho \leq I(A_iC_i:A_2:...:A_{i-1}:A_1:A_{i+1}:...:A_N|E)_\rho$$  

(40)

$$= I(A_iC_i:A_2|E)_\rho + I(A_3:A_1A_2|E)_\rho + I(A_4:A_1A_2A_3|E)_\rho + ... + I(A_N:A_1...A_{N-1}|E)_\rho.$$  

(41)

$$\geq I(A_1C_i:A_2|EC_{N+1})_{\rho} + I(A_3:A_1A_2|EC_{N+1})_{\rho} + I(A_4:A_1A_2A_3|EC_{N+1})_{\rho} + ... + I(A_NC_{N}:A_1...A_{N-1}|EC_{N+1})_{\rho}.$$  

(42)

We in Eq. (41) [(I)] we transposed the labels $i$ and $1$ (see Remark 6), and step (III) [Inequality (43)] follows (term-wise) from the monotonicity of the (three-partite) mutual information function proved in Ref. [27] (see proof of the Theorem 3.5 therein).

Regarding asymptotic continuity we consider two states $\rho_{N(A)}$ and $\sigma_{N(A)}$ such that $\|\rho_{N(A)} - \sigma_{N(A)}\|_1 \leq \epsilon$. Then, as in the proof of Theorem 3.5 of Ref. [27], for any map $\Lambda : E \to E'$ there is $\|\rho_{N(A)}(\Lambda) - \sigma_{N(A)}(\Lambda)\|_1 \leq \epsilon$ where
\[ \rho_{N(A)} := \text{id}_{N(A)} \otimes \Lambda_{N(A)} \text{ and } \sigma'_{N(A)} := \text{id}_{N(A)} \otimes \Lambda_{N(A)}. \]

Then by the expansion Eq. (35) we obtain:

\[ |I(A_1 : \ldots : A_{N-1}|E')_\rho - I(A_1 : \ldots : A_{N-1}|E')_\sigma| \leq 2 \varepsilon \log d_{A_1} + 2g(\varepsilon) \]  

\[ (N-1)|2\varepsilon \max_{i \in \{1, \ldots, N\}} \log d_{A_i} + 2g(\varepsilon)| \]  

(45)

For a finite, natural \( N \), the RHS of the above approaches 0, with \( \varepsilon \to 0 \).

The subadditivity follows again from the fact, that we can split the term \( I(A_1 : \ldots : A_N|E) \) into \( N-1 \) terms of the form \( I(A_i : A_{i+1}|E) \). Further treating \( A_1 \ldots A_{N-1} \) together as \( B_i \) (equivalent of \( B \) in the proof of Theorem 3.5 in Ref. [27]), we can prove the additivity of the form

\[ I(A_1 : A'_1 : B_iE'|E') = I(A_1 : B_i|E) + I(A'_1 : E'|E'), \]  

(47)

for each term, and notice the subadditivity from the fact that in the infimum in definition of \( E_{sq}^{cc}(\rho, M) \) there are product channels, hence in general the formula can be lower than the above.

Finally we consider normalization. It is straightforward to see, that assuming \( d_{A_i} = d_A \) for each \( i \in \{1, \ldots, N\} \), on the state representing ideal key \( \tau_{N(A)|E} = \frac{1}{d_A} \sum_{i=0}^{d_{A}-1} |ii\ldots i\rangle \langle ii\ldots i| \otimes \rho_E \) (there is \( E^{cc}(\tau, M) = (N-1) \log d_A \), by noticing that on product state \( I(A_1 : A_{i+1}|E) = I(A_1 : A_{i+1}) = \log d_A \), and there are \( (N-1) \) of such terms in definition of \( E_{sq}^{cc} \). We assume here also that the measurement \( M \) is generating the key in computational basis.

We have further analogue of the Observation 4 of Ref. [18]. Its proof goes along similar lines, as it does not depend on they type of the objective function that is minimized, hence we omit it.

**Observation 1.** For an \( N \)-partite state \( \rho_{N(A)} \) and a POVM \( M_{N(A)} = M_{A_1} \ldots M_{A_N} \) there is

\[ E_{sq}^{cc}(\rho, M) = \inf_{\rho_{N(A)|E} = E_{st}(\rho_{N(A)})} I(A_1 : \ldots : A_N|E)_{M_{N(A)} \otimes \text{id}_{\rho_{N(A)}|E}}. \]  

(48)

Owing to the above Observation, we can obtain the analogue of Lemma 6 of Ref. [18], which states that \( E_{sq}^{cc} \) is convex.

**Lemma 2.** For a tuple of POMVs \( M_{N(A)} \), and two states \( \rho^{(1)}_{N(A)}, \rho^{(2)}_{N(A)} \) and \( 0 < p < 1 \), there is

\[ E_{sq}^{cc}(\rho^{(p)}_{N(A)}) \leq p E_{sq}^{cc}(\rho^{(1)}_{N(A)}) + (1-p) E_{sq}^{cc}(\rho^{(2)}_{N(A)}), \]  

(49)

where \( \tilde{\rho}_{N(A)} = p \rho^{(1)}_{N(A)} + (1-p) \rho^{(2)}_{N(A)}. \)

**Proof.** The proof is thanks to the fact that the function \( E_{sq}^{cc}(\rho_{N(A)}) \) is upper bounded by \( I(A_1 : \ldots : A_N|E) \) evaluate on a state \( \rho_{ABEF} = M_{N(A)} \otimes \text{id}_{E}(p \rho^{(1)} \otimes |0\rangle \langle 0|_F + (1-p) \rho^{(2)} \otimes |1\rangle \langle 1|_F \). Further by Eq. (35), there is

\[ I(A_1 : \ldots : A_N|E)_\rho = p I(A_1 : \ldots : A_N|E)_{M_{N(A)} \otimes \text{id}_{E}} + (1-p) I(A_1 : \ldots : A_N|E)_{M_{N(A)} \otimes \text{id}_{E}} \]  

(50)

Since the states \( \rho^{(1)} \) and \( \rho^{(2)} \) were arbitrary we get the thesis. \( \square \)

We further note that, switching from a bipartite key distillation task, to the conference key distillation does not alter neither formulation nor the proof of the Lemma 7 of Ref. [18]. We state it below for the sake of the completeness of the further proofs.

**Lemma 3.** The i.i.d. quantum device independent key achieved by protocols using (for generating key) single tuple of measurements \( (\hat{x}_1, \ldots, \hat{x}_N) \equiv \hat{x} \) applied to \( M \) of a device \( (\rho_{N(A)}, \mathcal{M}) \), is upper bounded as follows:

\[ K_{\text{id,dec}}^{\hat{x}}(\rho_{N(A)}, \mathcal{M}) := \inf_{\varepsilon > 0} \sup_{n \in \mathcal{LOPC}} \inf_{(\sigma_{N(A)}, \mathcal{L}) \in \mathcal{LOPC}, (\sigma_{N(A)}, \mathcal{L})} \frac{1}{n} \sum_{i=0}^{n-1} K_{\text{DD}}(\mathcal{L}(\hat{x}) \otimes \text{id}_E \psi^\varepsilon), \]  

(51)

where \( \mathcal{L} \equiv \mathcal{L}(\hat{x}) \) is a single pair of measurements induced by inputs \( (\hat{x}) \) on \( \mathcal{L} \) and where \( e_n(\hat{x}) \) is the rate of achieved \( \varepsilon \)-perfect conference key and classical labels from local classical operations in \( \mathcal{P} \in \mathcal{LOPC} \) are possessed by the allies holding systems \( A_i \) for \( i \in \{1, \ldots, N\} \).

Combining Theorem 5 with the above lemma, we obtain the main result of this section. This is a bound by the reduced multipartite cc-squashed entanglement.

**Theorem 6.** The i.i.d. quantum device independent conference key achieved by protocols using single tuple of measurements \( (\hat{x}_1, \ldots, \hat{x}_N) \equiv \hat{x} \) applied to \( M \) of a device \( (\rho_{N(A)}, \mathcal{M}) \), is upper bounded as follows:

\[ K_{\text{id,dec}}^{\hat{x}}(\rho_{N(A)}, \mathcal{M}) \leq \frac{1}{N-1} \inf_{(\sigma_{N(A)}, \mathcal{L}) \in \mathcal{LOPC}, (\sigma_{N(A)}, \mathcal{L})} E_{sq}^{cc}(\sigma_{N(A)}, \mathcal{L}(\hat{x})), \]  

(52)

\[ =: E_{sq}^{cc}(\rho_{N(A)}, \mathcal{M}(\hat{x})). \]  

(53)
We have an analogous result for a key which is a function only of the tested parameters - that of Bell inequality violation and the quantum bit error rate.

**Theorem 7.** The i.i.d. quantum device independent key achieved by protocols using (for generating the key) a single tuple of measurements \( \hat{x} \) applied to a device \((\rho_{N(A)}, M)\), is upper bounded as follows:

\[
K^\text{id,}^{\hat{x}}_{DI,par}(\rho_{N(A)}, M) := \inf_{\lambda \geq 0} \sup_{\nu \in \mathbf{LOPC}} \frac{1}{N-1} \sum_{x} \lambda(E_{\nu}(A_x | L_{\hat{x}}))
\]

\[
\sup_{\nu \in \mathbf{LOPC}(\rho_{N(A)}, M)} E^\text{cc}_{sq,par}(\sigma_{N(A)} | L_{\hat{x}})
\]

where \( L = L(\hat{x}) \) is a single tuple of measurements induced by inputs \( \hat{x} \) on \( L \).

For \( N = 2 \), the above bound recovers the result of Ref. [18].

In definition of the \( E^\text{cc}_{sq,par}(\nu) \) one can take the infimum only over the classical extensions to Eve [25]. In that case, for a single input \( \hat{x} \) this bound reads \( \frac{1}{N-1} I(N(A) \downarrow E) \) as given in Ref. [25] (see Ref. [27] for bipartite case). We have the following immediate corollary:

**Corollary 4.** The i.i.d. quantum device independent key achieved by protocols using tuple of measurements \( \hat{x} \) applied to a device \((\rho_{N(A)}, M)\) is upper bounded as follows:

\[
K^\text{id,}^{\hat{x}}_{DI,dev}(\rho_{N(A)}, M) := \inf_{(\sigma_{N(A)}, L) = (\rho_{N(A)}, M)} \frac{1}{N-1} I(N(A) \downarrow E) P(A_1 : ... : A_N | E)
\]

\[
= \inf_{(\sigma_{N(A)}, L) = (\rho_{N(A)}, M)} \inf_{L \rightarrow F} \frac{1}{N-1} I(N(A) \downarrow E) P(A_1 : ... : A_N | L(E))
\]

where \( P(A_1 : ... : A_N | E) \) is a distribution coming from measurement \( L(\hat{x}) \) on purification of \( \sigma_{N(A)} \) to system \( E \), and the infimum is taken over classical channels transforming random variable \( E \) to a random variable \( F \).

Analogous corollary holds for the case of \( K^\text{id,}^{\hat{x}}_{DI,par} \).

We finally note, that the \( E^\text{cc}_{sq,par} \) is convex also, in multipartite case. This may prove important when one finds upper bounds, as any convexification of two plots obtained from optimization of \( E^\text{cc}_{sq,par} \) are then an upper bound on \( K^\text{id,}^{\hat{x}}_{DI,par} \), as it was used in Ref. [18]. We state it below following Lemma 8 of Ref. [18]:

**Proposition 2.** The \( E^\text{cc}_{sq,par}(\nu) \) is convex, i.e., for every device \((\bar{\rho}, M)\) and an input tuple \( \bar{x} \) there is

\[
E^\text{cc}_{sq,par}(\bar{\rho}, M(\bar{x})) \leq p_1 E^\text{cc}_{sq,par}(\nu_1, M(\bar{x})) + p_2 E^\text{cc}_{sq,par}(\nu_2, M(\bar{x}))
\]

where \( \bar{\rho} = p_1 \rho_1 + p_2 \rho_2 \) and \( p_1 + p_2 = 1 \) with \( 0 \leq p_1 \leq 1 \).

**Proof.** The proof goes the same way as that for bipartite case of Lemma 8 in Ref. [18], with the only change that we base on convexity of its multipartite version, \( E^\text{cc}_{sq} \) i.e. Lemma 2 here, and the fact that

\[
I(A_1 : ... : A_N | E)[\rho_{A_1 : ... : A_N} \otimes |i...i\rangle \langle i...i| A_{N+1} : ... : A_{N+r}]
\]

\[
= I(A_1 : ... : A_N | E)[\rho_{A_1 : ... : A_N}]
\]

where \( i \in \{0,1\} \), \( \rho_{A_1 : ... : A_N} \) is arbitrary state of systems \( A_1 : ... : A_N \), and we denote \( I(A_1 : ... : A_N | E)[\rho] = I(A_1 : ... : A_N | E)[\rho] \). This is by the fact that a pure product state alter neither the entropy of marginals nor the global entropy of the state.

We note that the multipartite function \( E^\text{cc}_{sq} \) can be defined for multiple measurements as in Ref. [18] and the analogous results (e.g., Corollary 6 of Ref. [18]) to the bipartite case would hold for the multipartite case.

**Definition 7.** The multipartite cc-squashed entanglement of the collection of measurements \( M \) with probability distribution \( p(x) \) of the input reads:

\[
E^\text{cc}_{sq}(\rho_{N(A)}, M, p(x)) := \sum_{x} p(x) E^\text{cc}_{sq}(\rho_{N(A)}, M_x).
\]

Usually, the parties broadcast their inputs used to generate the key during the protocol. One can therefore consider a version of the distillable device independent key achieved by such protocols which do this broadcasting. We then consider the following quantum device-independent key rate:

\[
K^\text{id, \text{broad}}(\rho, M, p(x)) := \inf_{\lambda \geq 0} \sup_{\nu \in \mathbf{LOPC}(\sigma, N, M)} \frac{1}{N-1} I(N(A) \downarrow E) P(A_1 : ... : A_N | L_{\hat{x}})
\]

where by \( \text{broad} \) we mean that \( x := (x_1, \ldots, x_N) \) are broadcasted, and made explicit by adding systems \( E_x := E_{x_1} \otimes \cdots \otimes E_{x_N} \) to Eve. We have then a generalization of Theorem of 6 to the case of more measurements, that are revealed during protocol of key distillation.

**Proposition 3.** The i.i.d. quantum device-independent key achieved by protocols using measurements of a device \((\rho_{N(A)}, M)\), with probability \( p(x) \) is upper bounded
as follows:

\[
K^\text{id,broad}_{\mathcal{D}1}(\rho, \mathcal{M}, p(x)) = \inf_{\varepsilon > 0} \limsup_n \sup_{\varepsilon \in \text{LREP}(\sigma, \mathcal{N})} \inf_{(\rho, \mathcal{M})} \kappa_{\sigma}(\hat{P}(\sum_x p(x)N_x \otimes \text{id}_E(|\psi_x\rangle\langle\psi_x| \otimes |x\rangle\langle x|_{E_x})^\otimes n)) \leq \frac{1}{N-1} \inf_{(\sigma, \mathcal{N})=(\rho, \mathcal{M})} E^{cc}_{sq}(\sigma, \mathcal{N}, p(x)) =: E^{cc}_{sq,dem}(\rho, \mathcal{M}, p(x)),
\]

where \(N_x\) are measurements induced by \(x\) on \(\mathcal{N}\) respectively.

**Proof.** The proof follows straightforwardly from generalization of Lemma 10 and Theorem 10 from Ref. [18] for the case of \(E^{cc}_{sq}\) taking as argument the measurements as in Eq. (60), composed with a broadcast map which for the choice of inputs \(x\) creates systems \(E_x\) in state \(|x\rangle\langle x|\).

\[\square\]

**VI. DUAL BOUND**

In this section we develop analogous bound to given in Theorems 6 and 7, however based on a different multipartite squashed entanglement, denoted in Ref. [26] as \(\tilde{E}_{sq}\). It originates from a quantifier of correlations denoted as \(S_N\) in Ref. [25]. Let us first recall the latter quantity:

\[
S_N(\rho_{A_1\ldots A_N}) := I(A_1 : A_2\ldots A_N|E)_{\rho_{(A_1)E}} + I(A_2 : A_3\ldots A_N|A_1E)_{\rho_{(A_1)E}} + \ldots + I(A_{N-1} : A_N|A_1\ldots A_{N-2}E)_{\rho_{(A_1)E}}
\]

Based on this quantity one defines an entanglement measure which in Ref. [26] (see also [25]) reads:

**Definition 8.** For an \(N\)-partite state \(\rho_{A_1\ldots A_N}\)

\[
\tilde{E}_{sq}(\rho_{(A_1)}) := \inf S_N(\sigma_{(A_1)})E,
\]

where the infimum is taken over states \(\sigma_{(A_1)}E\) that are extensions of \(\rho_{(A_1)}\), i.e. \(\text{tr}_E \sigma = \rho\).

We will refer to it as to dual squashed entanglement due to the fact noted in [25] that for any \(N\)-partite state \(\rho\) the two squashed entanglement functions are dual:

\[
S_N(\rho) + I(A_1 : \ldots : A_N)_{\rho} = \sum_{i=1}^N I(A_i : A_{i-1}A_{i+1}\ldots A_N)_{\rho}.
\]

Based on \(\tilde{E}_{sq}\), we define its reduced version, called dual cc-squashed entanglement.

**Definition 9.** A dual cc-squashed entanglement of a state \(\rho_{A_1\ldots A_N}\) is defined as follows

\[
\tilde{E}^{cc}_{sq}(\rho, \mathcal{M}) := \inf_{\mathcal{E}} S(N(A)|E')_{M_{N(A)} \otimes \rho_{(N(A))E}},
\]

where \(M_{N(A)}\) is \(N\)-tuple of POVMs \(M_{A_1}\ldots M_{A_N}\) and state \(|\psi^\rho_{N(A)}E\rangle\) is a purification of \(\rho_{(A)}\). Here, \(S(N(A)|E')\) is the conditional Shannon entropy as before.

Based on the Theorem 5 we can have analogous fact, claimed in Refs. [25, 26]. We state the sketch of the proof for the sake of completeness of the presentation.

**Theorem 8.** For an \(N\)-partite state \(\rho_{N(A)}\), its purification \(\psi^\rho\) and an \(N\)-tuple of POVMs \(M_{N(A)}\), there is:

\[
K_{DD}(M_{N(A)} \otimes \text{id}_E \psi^\rho) \leq \tilde{E}^{cc}_{sq}(\rho, \mathcal{M}).
\]

**Proof.** In this proof we follow the argument made for \(E^{cc}_{sq}\). We will prove several properties of \(\tilde{E}^{cc}_{sq}\), which assure the upper bound for the key due to multipartite version of Theorem 3.1 of Ref. [27] (see Lemma 7 in the Appendix).

To see monotonicity of the \(\tilde{E}^{cc}_{sq}\) under LOCC operations we first note the fact that this quantity does not increase under local operations (see Proposition 2 of Ref. [25]).

Regarding public communication we note, as in the proof of Theorem 5 that first when \(A_N\) is broadcasting information \(C_N\) to all the parties \(A_{i\neq N}\) and \(E\), there is

\[
I(A_1 : A_2\ldots A_N|C_N|E) + I(A_2 : A_3\ldots A_N|A_1E) + \ldots + I(A_{N-1} : A_N|A_1\ldots A_{N-2}E) \geq I(A_1C_1 : A_2C_2\ldots A_{N-1}C_{N-1}|C_{N+1}) + \ldots + I(A_{N-1}C_{N-1} : A_N|C_1C_2\ldots C_{N-2}C_{N+1})
\]

term-wise: \(I(A_1 : A_{i-1}\ldots A_N|A_1\ldots A_{i-2}E) \geq I(A_1C_1 : A_{i-1}C_{i-1}\ldots A_N|A_1C_1\ldots A_{i-2}C_{i-2}C_{N+1})\). Indeed this inequality coincides with the one proved in Ref. [27] (see the proof of the theorem 3.5 there), where we identify \(A_i\) with \(B\), \(A_{i-1}\ldots A_N\) with \(A\) and \(E\) with \(E'\). For the case when other party \(i\neq N\) is broadcasting, we swap (by symmetry of the formula of \(S_N\)) the \(A_i\) with \(A_N\) and follow the same argument as explained above.

Asymptotic continuity of the \(\tilde{E}^{cc}_{sq}\) follows from the fact that it consists of conditional information terms, each of which is asymptotically continuous due to Lemma 5 (note that we allow system \(E\) to be infinite-dimensional).

The argument for the subadditivity of this function follows from the fact that \(S_N\) is a product on tensor-products (see Ref. [25] for the case of \(N=3\)).

Regarding normalization, for the state containing ideal key \(\tau_{(A_1)E}\) (4) there is \(\tilde{E}_{sq}(\tau, \mathcal{M}) = \log d_A\) where we assume \(\log d_i = \log d_A\) for all \(i \in \{1, \ldots, N\}\). Indeed, as it is argued in Ref. [25], the first term in (65) equals \(\log d_A\) while the remaining ones are equal to 0. \[\square\]
Combining Lemma 3 and the above Theorem, we obtain analogue of Theorem 6.

**Theorem 9.** The i.i.d. quantum device-independent conference key achieved by protocols using single tuple of measurements \((x_1, \ldots, x_N) \equiv \hat{x}\) applied to \(\mathcal{M}\) of a device \((\rho_{N(A)}, \mathcal{M})\), is upper bounded as follows:

\[
\begin{align*}
K_{\text{DI,dev}}^{\text{iid, } \hat{x}}(\rho_{N(A)}, \mathcal{M}) & \leq \inf_{(\sigma_{N(A)}, \mathcal{L}) = (\rho_{N(A)}, \mathcal{M})} \bar{E}_{\text{sq}}(\sigma_{N(A)}, \mathcal{L}(\hat{x})) \\
& =: \bar{E}_{\text{sq, dev}}^{\text{cc}}(\rho_{N(A)}, \mathcal{M}(\hat{x})).
\end{align*}
\] (71) (72)

We also note, that analogous bound to the above holds for \(K_{\text{DI,par}}^{\text{iid, } \hat{x}}\). Thanks to the above theorem, we get an analog of the Corollary 4:

**Corollary 5.** The i.i.d. quantum device-independent key achieved by protocols using tuple of measurements \(\hat{x}\) applied to a device \((\rho_{N(A)}, \mathcal{M})\) is upper bounded as follows:

\[
\begin{align*}
K_{\text{DI,dev}}^{\text{iid, } \hat{x}}(\rho_{N(A)}, \mathcal{M}) & \leq \inf_{(\sigma_{N(A)}, \mathcal{L}) = (\rho_{N(A)}, \mathcal{M})} S_N(N(A) | E) P(A_1; \ldots; A_N | E) \\
& \equiv \inf_{(\sigma_{N(A)}, \mathcal{L}) = (\rho_{N(A)}, \mathcal{M})} \inf_{\Lambda_{E \rightarrow F}} S_N(N(A) | E) P(A_1; \ldots; A_N | \Lambda(E)),
\end{align*}
\] (73) (74)

where \(P(A_1; \ldots; A_N | E)\) is a distribution coming from measurement \(\mathcal{L}(\hat{x})\) on purification of \(\sigma_{N(A)}\) to system \(E\), and the infimum is taken over classical channels transforming random variable \(E\) to a random variable \(F\).

**VII. BOUND ON THE RATE OF A PARITY-CHSH BASED PROTOCOL BY THE REDUCED MULTIPARTITE CC-SQUASHED ENTANGLEMENT**

Below we exemplify the use of the bound by the reduced multipartite \(E_{\text{sq}}^{\text{cc}}\) in the case with classical Eve. That is, when infimum in its definition runs over the extensions of the form \(\sum_i p_i \rho_{A(N)}^i \otimes |i\rangle \langle i|_E\). We exemplify the bound given in the Corollary 4 by means of \(I(N(A) \downarrow E)\). It then boils down to checking the value of multipartite intrinsic information measure of a distribution which is the output of key-generating measurement on the attacking state. We also provide the dual upper bound originating from the Corollary 5.

For the honest implementation, we focus on the GHZ state, on which depolarizing noise acts locally on three qubits [20]. Having this state, and playing a tripartite game on it, called the Parity-CHSH game, one can obtain (in the low noise regime) a secure conference key. More precisely, we have:

**Definition 10 (Parity-CHSH game [20]).** The Parity-CHSH inequality extends the CHSH inequality to \(N\) parties as follows. Let Alice, Bob_1, ..., Bob_{N-1} be the \(N\) players of the following game (the Parity-CHSH game). Alice and Bob_1 are asked uniformly random binary questions \(x \in \{0, 1\}\) and \(y \in \{0, 1\}\) respectively. The other Bobs are each asked a fixed question, e.g. always equal to 1. Alice will answer bit \(a\), and \(\forall_i \in \{1, \ldots, N-1\}\), Bob_\(i\) answers bit \(b\). We denote by \(\hat{b} = \bigotimes_{2 \leq i \leq N-1} b_i\), the parity of all the answers of Bob_2, ..., Bob_{N-1}. The players win if and only if

\[a + b_1 = x(y + \hat{b}) \text{ mod2}.\]

As for the CHSH inequality, classical strategies for the Parity-CHSH game must satisfy,

\[
P_{\text{win}}^{\text{Parity-CHSH}} \leq \frac{3}{4}.
\] (75)

The above inequality can be violated with \(\Phi^N_{\text{GHZ}}\) state, with the maximal (quantum) value of \(\frac{1}{2} + \frac{1}{2\sqrt{2}}\).

We adopt the same model of noise as in the Ref. [20], which is represented by qubit depolarising channels acting the same way on each qubit of the GHZ state.

\[
D_{\nu}(\rho) = (1 - \nu)\rho + \nu \frac{1}{2}.
\] (76)

Below we explain the result of applying of this global channel to the GHZ state \(|\Phi^N_{\text{GHZ}}\rangle \langle \Phi^N_{\text{GHZ}}|\) in the case of \(N = 3\).

**Observation 2.** The GHZ state after action of depolar-
izing noise on each qubit reads
\[
D_\nu \otimes \mathbb{1}_{B_1B_2} \left( |\Phi_3^{\text{GHZ}}\rangle \langle \Phi_3^{\text{GHZ}}| \right)_{AB_1B_2} \\
= (1 - \nu)|1\rangle\langle 1|_{AB_1B_2} + \nu \frac{1}{2} \kappa_{B_1B_2},
\]
where \( \kappa_{B_1B_2} = \frac{1}{2} (|00⟩⟨00| + |11⟩⟨11|) \) state is biseparable.

**Remark 7.** The biseparable state originating from a depolarizing channel (single party), i.e., \( \frac{1}{2} \mathbb{1}_{B_1B_2} \), where \( \chi \) is biseparable state which reads
\[
\chi_\nu := \frac{1}{1 - (1 - \nu)^3} \left[ (1 - \nu^2)\nu \kappa_{AB_1} \otimes \frac{1}{2} B_2 + (1 - \nu^2)\nu \kappa_{AB_2} \otimes \frac{1}{2} B_1 + (1 - \nu^2)\nu \kappa_{B_1B_2} \otimes \frac{1}{2} A + (3 - 2\nu)\nu^2 \frac{1}{2} |AB_1B_2⟩⟨AB_1B_2| \right].
\]

(79)

In Ref. [20] the expected winning probability for parity-CHSH game (with respect to depolarizing noise parameter) is calculated.

\[
p_{\text{exp}} := \left[ \frac{1}{2} + \frac{(1 - \nu)^N}{2\sqrt{2}} + \frac{(1 - \nu)^2(1 - (1 - \nu)^{N-2})}{8\sqrt{2}} \right].
\]

(80)

From the above equality for \( N = 3 \), the state in equation (78) violates the classical bound of \( \frac{3}{4} \) for \( 0 \leq \nu < \nu_{\text{crit.}} \), where \( \nu_{\text{crit.}} \approx 0.1189 \).

In this place, we start the construction of the eavesdropper strategy. According to the DI-CAK protocol in Ref. [20] the ranges of inputs and outputs are: \( x \in \{0, 1\} \), \( y_1 \in \{0, 1, 2\} \), \( y_2 \in \{0, 1\} \), \( a, b_1, b_2 \in \{0, 1\} \). The setting \( (x, y_1, y_2) = (0, 2, 0) \) associated with measurements of \( \sigma_z \) observable is the key generating round.

\[
P_\nu(a, b_1, b_2|x, y_1, y_2) = \text{tr} M_{a|x} \otimes M_{b_1|y_1} \otimes M_{b_2|y_2} D_\nu \left( |\Phi_3^{\text{GHZ}}\rangle \langle \Phi_3^{\text{GHZ}}| \right)_{AB_1B_2} \\
= (1 - \nu)^3 \text{tr} M_{a|x} \otimes M_{b_1|y_1} \otimes M_{b_2|y_2} |\Phi_3^{\text{GHZ}}\rangle \langle \Phi_3^{\text{GHZ}}|_{AB_1B_2} \\
+ (1 - \nu)^3 \text{tr} M_{a|x} \otimes M_{b_1|y_1} \otimes M_{b_2|y_2} \chi_\nu \\
= (1 - \nu)^3 P_{\text{GHZ}}(a, b_1, b_2|x, y_1, y_2) \\
+ (1 - \nu)^3 P_{\nu}(a, b_1, b_2|x, y_1, y_2).
\]

(81-83)

Here, behavior \( P_{\text{GHZ}} \) arises from measurements of the GHZ state (that allows to violate the classical bound maximally). The local behavior \( P_{\nu} \) arises from the same measurements (\( \sigma_z \) observable) for biseparable state and therefore can be expressed as a convex combination of deterministic behaviors.

Eve prepares convex combination (CC) attack [45, 46]:

\[
P_{\text{exp}}^\text{CC}(a, b_1, b_2, c|x, y_1, y_2) = (1 - \nu)^3 P_{\text{GHZ}}(a, b_1, b_2|x, y_1, y_2) \delta_{c,?} \\
+ (1 - \nu)^3 P_{\nu}(a, b_1, b_2|x, y_1, y_2) \delta_{c,(a, b_1, b_2)}. 
\]

(84)

This attack might not be optimal as it uses a particular decomposition of \( P_{\nu} \). In order to optimize the attack, Eve should find a decomposition with a maximal weight of local behavior \( (1 - \nu)^3 \) here.

We now consider a particular strategy of post-processing the data which is in Eve’s possession, represented by a channel \( E \rightarrow F \) in Corollary 4. Following Ref. [17], we consider only the distribution coming from a key-generating measurement which according to protocol of Ref. [20] is \( X = 0 \) for Alice, \( B_1 = 2 \) and \( B_2 = 0 \) for Bobs in case of \( N = 3 \).

\[
P_{\text{ATTACK}}(a, b_1, b_2, f|020) = \Lambda_{E \rightarrow F} P_{\text{exp}}^\text{CC}(a, b_1, b_2, c|020) \\
= (1 - \nu)^3 P_{\text{GHZ}}(a, b_1, b_2|x, y_1, y_2) \delta_{c,?} \\
+ (1 - \nu)^3 P_{\nu}(a, b_1, b_2|x, y_1, y_2) \delta_{c,(a, b_1, b_2)} \\
\times [\delta_{a, b, c} \delta_{f, a} + (1 - \delta_{a, b, c}) \delta_{f, ?}],
\]

(85)

where \( \delta_{a, b, c} \) is 1 if all three indices have the same value and 0 otherwise. The above attack strategy is therefore a direct three-partite generalisation of strategy proposed in Ref. [17]. The eavesdropper aims to be correlated only with the events \( (a, b_1, b_2) = (0, 0, 0) \) or \( (a, b_1, b_2) = (1, 1, 1) \), that mimic outputs of the honest strategy of GHZ state. By applying the above attack strategy we are ready to plot an upper bound on the upper bound in the Corollary 4.

**VIII. DISCUSSION**

We have demonstrated a number of upper bounds on the quantum secure conference key, generalizing (i) results of Ref. [18] regarding relative entropy based bound and (ii) results of Ref. [17] regarding the multiparty reduced cc-squashed entanglement. More precisely, we base on two secrecy monotones which generalize intrinsic information to the multipartite case, following Ref. [25]. Although, as shown in Ref. [26] the quantities \( I(A_1 : \ldots : A_2) \) and \( S_{\nu}(A_1 : \ldots : A_N) \) coincide for pure states, they are not comparable for mixed states, and \( E_{CC}^{\text{exp}} \) based on \( I(A_1 : \ldots : A_N) \) performs better as an upper bound. It is, however, an open problem if one can establish an inequality between the two reduced multipartite squashed entanglements.
Interestingly, the approach of Ref. [17] does not result in zero key in any noise regimes for the parity-CHSH game of Ref. [20]. It would be important to see if this can be improved by changing Eve’s strategy or the bound needs to be changed.

We have also shown that the fundamental gap between device-independent and device-dependent keys also holds in the multipartite case. We have given an exemplary device-independent and device-dependent keys also holds in the multipartite scenario.

Finally, our results hold for the static case of quantum states. The next step would be to generalize results of [18] for the dynamic case of quantum channels to the multipartite scenario.

Note added.—The topic of upper bounds on the DI-CKA is also studied in the parallel work by Aby Philip, Eneet Kaur, Peter Bierhorst, and Mark M. Wilde titled “Intrinsic Non-Locality and Device-Independent Conference Key Agreement” [47].

Appendix A: Continuity statements

Lemma 4 (AFW continuity bounds [48]). For states \( \rho_{AB} \) and \( \sigma_{AB} \), if \( \frac{1}{2} \| \rho - \sigma \|_1 \leq \varepsilon \leq 1 \), then
\[
|H(A|B)_\rho - H(A|B)_\sigma| \leq 2 \varepsilon \log d + g(\varepsilon),
\]
where \( d = \dim(H_A) < \infty \) and \( g(\varepsilon) := (1 + \varepsilon) \log(1 + \varepsilon) - \varepsilon \log \varepsilon \).

Lemma 5 ([44]). If \( d = \min\{\dim(H_A), \dim(H_B)\} < +\infty \) then
\[
|I(A; B|C)_\rho - I(A; B|C)_\sigma| \leq 2 \varepsilon \log d + 2g(\varepsilon)
\]
for any states \( \rho_{ABC} \) and \( \sigma_{ABC} \), where \( \varepsilon = \frac{1}{2} \| \rho - \sigma \|_1 \).

Appendix B: Secrecy monotones

In this section, we revisit Theorem 3.1 of Ref. [27] and generalize the result by relaxing the constraints on the Hilbert spaces in the following way. Firstly, we prove an analogy to Lemma A.1 of Ref. [27].

Lemma 6 (Cf. [27]). The maximization in the definition of \( K_{DD} \) (13) can be restricted to protocols that use communication at most linear in the number of copies of \( \rho_{ABE} \). The eavesdropper system is not necessarily restricted to a finite dimension.

Proof. The proof of the above Lemma goes along the lines of the proof of Lemma A.1 in Ref. [27]. The change that is necessary to allow the eavesdropper to hold the system of infinite dimension is the use of asymptotic continuity of the conditional mutual information of Ref. [44] (see Lemma 5 here) instead of the Alicki–Fannes inequality. This results in:
\[
I(A : B)_\sigma - I(A : E)_\sigma \geq l_{n_0}(1 - 4\varepsilon) - 4g(\varepsilon), \quad (B1)
\]
where \( l_{n_0} \) is the length of the output of a distillation protocol using \( n_0 \) copies of the input state. The state \( \sigma \) is the output of the latter protocol. The overall key rate of the modified protocol which has linear communication, admits then a lower bound:
\[
\tilde{R} \geq (1 - 4\varepsilon)(R - \varepsilon) - \frac{4g(\varepsilon)}{n_0}. \quad (B2)
\]
The other parts of the proof are not altered. \( \square \)

Lemma 7 (Cf. [27]). Let \( E(\rho) \) be a function mapping tripartite quantum state \( \rho_{ABE} \) into the positive numbers such that the following holds:

1. Monotonicity: \( E(A(\rho)) \leq E(\rho) \) for any LOPC operation \( A \).

2. Asymptotic continuity: for any states \( \rho^n, \sigma^n \) on \( H_A \otimes H_B \otimes H_E \), the condition \( \| \rho^n - \sigma^n \|_1 \to 0 \) implies \( \frac{1}{\log n} |E(\rho^n) - E(\sigma^n)| \to 0 \) where \( r_n = \dim(H^n_A) \).

3. Normalisation: \( E(\tau^{(l)}) = l \).

Then the regularisation of the function \( E \) given by \( E^\infty(\rho) = \limsup_{n \to \infty} \frac{E(\rho^\otimes n)}{n} \) is an upper bound on the device-dependent key distillation rate \( K_{DD} \), i.e., \( E^\infty(\rho_{ABE}) \geq K_{DD}(\rho_{ABE}) \) for all \( \rho_{ABE} \) with \( \dim A < \infty \). If in addition \( E \) satisfies

4. Subadditivity on tensor products: \( E(\rho^\otimes n) \leq nE(\rho) \), then \( E \) is an upper bound on \( K_{DD} \).

Proof. Proof arguments are same as those stated in Ref. [27] with relaxation on the Hilbert space of \( E \). We observe that the proof arguments hold even when there is no restriction on the \( \dim(H_E) \), i.e., \( E \) can be finite-dimensional or infinite-dimensional. It suffices to have \( \dim(H_A) \) to be finite-dimensional. \( \square \)
