ABSTRACT

We describe an optimal procedure, as well as its efficient software implementation, for exact and approximate synthesis of two-qubit unitary operations into any prescribed discrete family of XX–type interactions and local gates. This arises from the analysis and manipulation of certain polyhedral subsets of the space of canonical gates. Using this, we analyze which small sets of XX–type interactions cause the greatest improvement in expected infidelity under experimentally-motivated error models. For the exact circuit synthesis of Haar-randomly selected two-qubit operations, we find an improvement in estimated infidelity by ≈32% when including CX1/2 and CX1/3 alongside the standard gate CX, near to the optimal limit of ≈34% obtained by including all fractional applications CXα, α ∈ [0, 1].

1 INTRODUCTION

In this paper, we describe an optimal synthesis routine for two-qubit unitary operations which targets a discrete family of XX–type interactions (e.g., a finite set of controlled unitaries). Such two-qubit unitary operations are common on contemporary platforms: the gate CX is such an example, and synthesis routines for it have long been known to give rise to algorithmic schemes for universal quantum computation, making it an attractive target for device engineers. The physical processes which give rise to the operation CX can typically be truncated to produce "fractional applications" CXα for 0 ≤ α ≤ 1, each of which is also of XX–type, giving rise to an infinite family of further examples. Though not required for universal computation, the availability of these "overcomplete" basis gates has the potential to yield more efficient synthesized circuits, particularly if the error magnitude of CXα correlates with α: while the universally programmable CX circuit invokes CX three times, the universally programmable fractional CX circuit invokes CXα, CXβ, and CXγ with (α + β + γ) = 3/2.1

In practice, however, these parametric families are difficult to operate. The relationship between the degree of truncation and the value α is often nonlinear and prone to imperfect measurement, and constraints in the steering electronics (e.g., waveform sample rate) can make truncations unavailable below some threshold. Hence, when extreme precision is required (as is typical), wholesale use of these families may be prohibited. Still, precision can be guaranteed for any particular value of α, which gives rise to the following question:

Question. Given a fixed "calibration budget" which permits the tuning of n fractional operations, which set of values α1,..., αn maximizes (average-case) device performance? How does one efficiently find expressions for generic two-qubit unitaries in terms of these operations? How does one simultaneously guarantee the optimality of such expressions, as measured against device performance?

We answer this question fully. Our fundamental results are an efficient test for when a two-qubit unitary operation admits expression as a circuit using any particular sequence of XX–interaction strengths (α1,..., αn) with local gates interleaved, an efficient synthesis routine for manufacturing such circuits, and an efficient routine for producing the best approximation (in average gate fidelity) within the set of such circuits.2 These tools combine to give an optimal synthesis scheme for reasonably behaved cost functions (e.g., average gate infidelity), now implemented in Qiskit’s quantum_info subpackage as the class XXDecomposer [6]. We leverage these results to explore the design space of gate set extensions where we constrain α1,..., αn to be drawn from some small, fixed set of pretuned angles. For experimentally realistic error models, our main findings are that including first CX1/3 and then CX1/3 give significant improvement over CX alone at several common tasks (e.g., synthesis of random unitaries, as reported in Figure 18; and synthesis of certain structured operators like QFT, as reported in Figure 2), and that these two gates capture almost all of the benefit of allowing α1,..., αn to be drawn without constraint (cf. Figure 15).

Related literature

We give a non-exhaustive survey of existing ideas.

16 Shende, Markov, and Bullock showed how to synthesize optimal-depth circuits for CX–based gate sets.

[19, 21, 22] Zhang, Vala, Sastry, and Whaley (see also Zhang, Ye, and Guo) gave a synthesis method for gate sets based on controlled unitary operations. Our method constructs circuits out of the same building blocks, but our method for how to arrange those blocks is different. This difference in synthesis strategy gives us optimal circuits, which they miss by a constant offset.

[15] Peterson et al. showed how to detect when a two-qubit unitary operation admits expression using a given circuit type with sufficiently many freely ranging local operations. This gives rise to a method for analyzing the optimality of a synthesis strategy, but it does not show how to perform the actual synthesis.

[7] Earnest, Tornow, and Egger have shown how to produce the entire family of XX–type interactions from a particular pulse-level implementation of CX, which then permits the use of a straightforward synthesis method. Their method

1 See [4] for numerical justification.

2 To our knowledge, this is the first optimal synthesis algorithm which targets a discrete "heterogeneous" set of multiqubit interactions.
with a small affine offset. In the limit of a 

\[ \mathcal{S} \]

family of qubits supporting either 

\[ \{ \text{CX} \} \in \mathcal{S} \]

gates. Below, we refer to the infidelity of this circuit as the "baseline". (2) An exact, optimal synthesis into a triple of \( \text{XX} \) gates. (3) An exact, optimal synthesis into four \( \text{XX} \) gates. (4) An exact, optimal synthesis into a mixed set of gates. Finally, we include the relative infidelity costs of these syntheses in an error model where \( \text{XX} \) gate infidelity is linearly related to the parameter with a small affine offset.

Figure 1: Four syntheses of a two-qubit operator \( U \in SU(4) \) with canonical coordinate \((0.968, 0.273, 0.038)\). (1) An exact, optimal synthesis into a triple of \( \text{CX} \) gates. Below, we refer to the infidelity of this circuit as the "baseline". (2) An exact, optimal synthesis into a triple of \( \text{XX} \) gates. (3) An exact, optimal synthesis into four \( \text{XX} \) gates. (4) An exact, optimal synthesis into a mixed set of gates. Finally, we include the relative infidelity costs of these syntheses in an error model where \( \text{XX} \) gate infidelity is linearly related to the parameter with a small affine offset.

Figure 2: Qiskit syntheses of QFT circuits, targeting a family of qubits supporting either \( \mathcal{S} = \{ \text{CX} \} \) or \( \mathcal{S} = \{ \text{XX}, \text{XX}, \text{XX}, \text{XX} \} \) and with all-to-all connectivity. At right, we include the expected reduction in circuit infidelity under the assumption that \( \text{XX} \) gate infidelity is linearly related to the parameter with a small affine offset. In the limit of a large qubit count, the expected infidelity of a QFT circuit synthesized to the fractional gate set drops by two-thirds that of the standard \( \text{CX} \)-based gate set.

does not extend to other hardware implementations of \( \text{CX} \), including the implementation used by the IBM group to achieve quantum volume 64 [9], which does not lend itself to non-calibrated scaling.

[8] Huang et al. have recently shown how to synthesize (optimal) circuits for a gate set containing \( \sqrt{\text{SWAP}} \), a particular “fractional ISWAP”. While similar on the surface, our results differ substantially: \( \sqrt{\text{SWAP}} \) is not of \( \text{XX} \)-type; they work with the fixed gate \( \sqrt{\text{SWAP}} \) as opposed to an unknown family of fractional applications; and they consider only circuits of depth at most 3.

[11] Lao et al. have used brute-force numerical search to uncover which fractional interactions might be valuable to include in a native gate set put to different purposes. This has substantial overlap with our discussion of gate set optimization, but it does not solve the synthesis problem: numerical search is both non-optimal and two orders of magnitude slower than our direct synthesis.

The case of one qubit

To give a sense of our methods and results, let us analyze the analogous problem for one-qubit unitaries: decomposition into a fixed set of fractional \( X \)-rotations and unconstrained \( Z \)-rotations. The fixed \( X \)-rotation most typically available is \( X_\frac{\pi}{8} \), and an \( X_\frac{\pi}{8} \)-based circuit can be synthesized for a unitary \( U \) through “Euler ZYZ decomposition”. Namely, there are angle values \( \theta, \phi, \) and \( \lambda \) which satisfy

\[
U = Z_\phi \cdot Y_\theta \cdot Z_\lambda = Z_{\theta+\pi} \cdot X_\frac{\pi}{8} \cdot Z_{\theta+\pi} \cdot X_\frac{\pi}{8} \cdot Z_\lambda.
\]

easily calculable by diagonalizing \( UU^T \). Since \( U \) can freely range, the right-hand side of this equation gives a universally programmable quantum circuit. A downside to this circuit is that the operational cost of \( U \) is always that of a pair of \( X_\frac{\pi}{8} \) gates, even if \( U \) itself is a “small” rotation of the Bloch sphere. \(^3\)

For circuits based on other choices of choices of \( X \)-rotation angles, such as

\[
Z_{\phi'} \cdot X_{\phi'} \cdot Z_{\phi'} = Z_{\phi'} \cdot Y_\theta \cdot Z_{\phi'}
\]

easy to solve, and the equation

\[
X_{\psi'} \cdot Z_\theta \cdot X_{\psi'} = Z_{\phi'} \cdot Y_\theta \cdot Z_{\phi'}
\]

can be seen to admit a solution precisely when \( \theta \) satisfies

\[
|\psi - \psi'| \leq \theta \leq \pi - |\psi - \psi'|.
\]

Let us refer to this interval as \( I_{\phi,\psi'} \). In the same manner, a longer sequence of interactions \( X_{\phi_1}, \ldots, X_{\phi_n} \) interleaved with \( Z \)-rotations gives rise to a corresponding interval \( I_{\phi_1,\ldots,\phi_n} \) of achievable values of \( \theta \). Additionally, for any particular value of \( \theta \in I_{\phi,\psi'} \), one can synthesize a circuit which models \( U_{\theta} \) by taking a z as in

\[
\cos \theta = \cos \psi \cdot \cos \psi' - \cos \phi \cdot \sin \psi \cdot \sin \psi';
\]

and \( \phi, \phi' \) can be explicitly determined by inspecting the complex phases of a pair of matrix entries.

\(^3\)One can set aside special cases when \( \theta = 0 \) or \( \frac{\pi}{2} \), but these are probability-zero events in common measures.
Now suppose that any given gate $X_\psi$, with $\psi \in [0, \pi]$, can be made available in an experimental setting with infidelity

$$m \cdot \left( \frac{\pi}{2} \right)^{-1} \cdot \psi + b$$

for some error model parameters $m$ and $b$, and at a fixed calibration cost per gate. We seek a small set of gates $\{X_\psi, \ldots, X_\psi\}$ so that the intervals constructed above cover the possible values of $\theta$ so as to minimize the expected infidelity cost of a given operation. For instance, Figure 3 shows the relevant intervals for the gate set $\{X_\pi, X_\pi\}$. Several aspects of this goal can also be understood with additional nuance:

"Expected": The distribution of operations $U$ to be synthesized will affect the relative importance of the various choices of $\psi$. A safe assumption is that $U$ is drawn according to the Haar distribution, in which case the distribution of angle values $\theta$ is given by $p(\theta) = \frac{1}{\pi} \sin(\theta)$.

"Cost": In addition to the operational cost of a synthesized circuit (i.e., the cost from gate applications), one can also incorporate a cost stemming from synthesizing some $\theta'$ rather than the requested $\theta$. There are then some circumstances where it is profitable to *deliberately* mis-synthesize $Y_\theta$ as $Y_{\theta'}$, provided the difference between $\theta$ and $\theta'$ is small and the difference in operational cost between the two circuits is large. Average gate infidelity gives a popular embodiment of this idea, where the fidelity of two one-qubit operations is given by the formula

$$F_{\text{avg}}(Y_{\theta}, Y_{\theta'}) = \frac{2 + \cos(\theta - \theta')}{3}.$$ 

Against this yardstick, the $\theta' \in I_{\phi, \psi'}$ which gives the best approximation to $\theta \notin I_{\phi, \psi'}$ occurs at one of the interval endpoints.

"Given operation": Rather than synthesizing the operation $U$ requested, the compiler can choose to inject a reversible logic operation $R$ and its inverse $R^{-1}$ into the program, synthesizing the composite $U \cdot R$ and either commuting $R^{-1}$ forward through the circuit or absorbing its effect into software. This option can be used to further shape the expected distribution of inputs. For single-qubit operations, a typical choice of $R$ is the classical logic gate $X_{\pi}$, which has the effect of trading $X_\theta$ for $X_{\pi - \theta}$. \footnote{For two-qubit operations, a common choice of $R$ is the classical logic gate SWAP.}

Considering only exact synthesis for now, we compute the following expected (i.e., Haar-averaged) average gate infidelities for various gate sets:

- $X_\pi$: $2m + 2b$, the standard decomposition, used as a baseline.
- $X_\pi$: $\frac{3}{4}m + \frac{9}{4}b$, an improvement of $\approx 25\%$ over the baseline, provided $b \ll m$.
- $(X_\pi, X_\pi)$: $\frac{19\sqrt{3}}{12}m + 2b$, an improvement of $\approx 28\%$ over the baseline, provided $b \ll m$.
- $(X_{\pi\pi})$: In the continuous limit with all gates $X_\theta$ available, the cost becomes $m + b$, an improvement of $50\%$ over the baseline.

These values can be further improved by considering approximate and mirrored synthesis, either separately or in tandem.

**Outline**

Our analysis of the two-qubit case follows along roughly the same lines as above, and in the same order.

- **Section 2**: Generalizing Euler decomposition, we give a lightning review of KAK decomposition as specialized to two-qubit unitary operations.
- **Section 3**: We describe a more detailed plan of attack on the two-qubit problem, outlining the steps in the proofs to come.
- **Section 4**: Generalizing the interval $I_{\phi, \psi'}$, we give a compact description of which two-qubit gates are accessible to a circuit built out of a fixed sequence of $XX$-type interactions with one-qubit operations interleaved (Theorem 4.1). This leverages previous work of Peterson et al. [15]: it detects when a two-qubit operation admits synthesis as a circuit of a certain type, but it does not indicate how to produce the circuit.
- **Section 5**: Generalizing the formula relating $\cos \theta$ and $\cos s$, we single out a method for choosing local circuit parameters which are simple to analyze (Theorem 5.3). We then compare with Section 4 and prove that each of these restricted circuits nonetheless exhaust the space of possibilities (Theorem 5.5).
- **Section 6**: Generalizing the discussion around cost, we provide an efficient method to find the best approximation within a given circuit family (Theorem 6.10), and we couple it to the preceding results to produce the promised efficient synthesis method (Procedure 6.1, Procedure 6.8).
- **Section 7**: Generalizing the calculations of expected cost for various gate sets, we use experimental data to justify the use of a particular error model as a cost function (Definition 7.3), study the effect of choice of gate set (Example 7.6), and describe what is left to gain in the large limit of fractional gate count (Remark 7.8).

We give a small example of the effectiveness of these techniques as applied to a random operator in Figure 1 and to a family of structured operators in Figure 2, reserving further analysis for Section 7.

**Conventions**

We use the following abbreviations throughout:

$$c_\theta = \cos(\theta), \quad s_\theta = \sin(\theta), \quad x_+ = \sum_j x_j.$$
2 RÉSUMÉ ON TWO-QUBIT UNITARIES AND THE MONODROMY MAP

We briefly recall the theory of Cartan decompositions as it applies to two-qubit unitary operations and its role in circuit synthesis.

Lemma 2.1 ([10], [12], [20], [15]). Let CAN denote the following two-qubit gate:

\[ \text{CAN}(a_1, a_2, a_3) = \exp(-i(a_1 XX + a_2 YY + a_3 ZZ)) = \begin{pmatrix} e^{ia_1} c_{a_1 - a_2} & 0 & 0 & -ie^{ia_1} s_{a_1 - a_2} \\ 0 & e^{ia_2} c_{a_2 + a_3} & -ie^{ia_2} s_{a_2 + a_3} & 0 \\ 0 & -ie^{ia_3} s_{a_3 + a_2} & e^{ia_3} c_{a_3 + a_2} & 0 \\ -ie^{ia_1} s_{a_1 - a_2} & 0 & 0 & e^{ia_1} c_{a_1 - a_2} \end{pmatrix}. \]

Any two-qubit unitary operation \( U \in \text{PU}(4) \) can be written as

\[ U = L \cdot \text{CAN}(a_1, a_2, a_3) \cdot L', \]

where \( L, L' \in \text{PU}(2)^{\otimes 2} \) are local gates and \( a_1, a_2, a_3 \) are (underdetermined) real parameters.

Definition 2.2 ("Canonical decomposition", cf. [15]). In Lemma 2.1, there is a unique triple \((a_1, a_2, a_3)\) satisfying \( a_1 \geq a_2 \geq a_3 \geq 0 \), \( \frac{\pi}{4} \geq a_1 + a_2 \), and one of either \( a_3 > 0 \) or \( a_1 \leq \frac{\pi}{4} \). Such a triple is called a positive canonical coordinate, and we denote the space of such \( \mathbb{C}_2 \). This unicity determines a function \( \Pi: \text{PU}(4) \to \mathbb{C}_2 \), called the monodromy map. Away from the plane \( a_3 = 0 \), this function is continuous.3

Example 2.3. Here are the positive canonical triples for some familiar gates:

\[ \Pi(I) = (0, 0, 0), \quad \Pi(\text{SWAP}) = \left( \frac{\pi}{4}, \frac{\pi}{4}, \frac{\pi}{4} \right), \quad \Pi(\text{CX}) = \left( \frac{\pi}{4}, 0, 0 \right). \]

Generalizing the last example, the positive canonical triple for any controlled unitary gate has the form \((a_1, a_2, 0)\); we say that such an operation is of \( XX\)-type. Specifically, the fractional gate \( \text{CX}^a \) is of \( XX\)-type, with coordinate \( \Pi(\text{CX}^a) = (a \cdot \frac{\pi}{4}, 0, 0) \). From this perspective, the final coordinate measures interaction duration, so that smaller values give rise to less entanglement.

For us this apparatus has two main uses, captured in the following pair of results:

Lemma 2.4. A pair of two-qubit operations \( U \) and \( V \) are said to be locally equivalent when there exist local gates \( L, L' \in \text{PU}(2)^{\otimes 2} \) with \( U = L \cdot V \cdot L' \). This condition holds if and only if \( \Pi(U) = \Pi(V) \).

Theorem 2.5 ([15]). Let \( S, S' \subseteq \text{PU}(4) \) be two sets of two-qubit operations whose images \( \Pi(S), \Pi(S') \subseteq \mathbb{C}_2 \) through \( \Pi \) are polytopes (e.g., a set of isolated points). Then the image of the set

\[ S \cdot \text{PU}(2)^{\otimes 2} \cdot S' = \left\{ S \cdot (L \otimes L') \cdot S', \quad S \in S, S' \in S', \quad L, L' \in \text{PU}(2) \right\} \]

through \( \Pi \) is also a polytope. Given explicit descriptions of the input polytopes as families of linear inequalities, the output polytope can also be so described.4

Our work will lead us directly into considering families of two-qubit gates and their parametrizations, so we introduce some attendant language.

Definition 2.6. A gate set is any collection of two-qubit unitaries; typically we will consider gate sets which are made up of finitely many controlled unitaries. For a gate set \( S \), an \( S \)-circuit is a finite sequence of members of \( S \) and local gates. The operation which it encodes is given by the product of the sequence elements. A circuit shape5 is a circuit-valued function

\[ C: \emptyset \mapsto (L_0, L_1, \ldots, L_{n-1}, S_n, L_n), \]

where each \( L_j \) is a parametrized local operator and each \( S_j \in S \) is fixed.

It can be convenient to place further restrictions on the \( L_j \) (e.g., that they consist only of \( Z \)-rotations), but absent explicit mention we take each \( L_j \) to surject onto \( \text{PU}(2)^{\otimes 2} \). In this surjective case, the sequence \((S_1, \ldots, S_n)\) determines the image of \( C \), and it follows from Theorem 2.5 that the image of \( \Pi \circ C \) in \( \mathbb{C}_2 \) is a polytope, called the circuit polytope of \( C \) (or of \((S_1, \ldots, S_n)\)). In the case that \( S \) consists of \( XX\)-type, locally surjective circuits can be further identified with the underlying sequence of interaction strengths \((a_1, \ldots, a_n)\) with \( S_j = \text{XX}^{a_j} \).

Remark 2.7. The coordinate system given in Definition 2.2 is not unique: a similar theorem holds for any choice of "Weyl alcove" in \( \mathfrak{pi}_4 \). When \( g \) is the Lie algebra of a simply connected Lie group (e.g., \( \mathfrak{su}_4 \)), each Weyl alcove is related to every other by a discrete set of linear transformations including reflections and shears. Without the simply-connected hypothesis (e.g., \( \mathfrak{pi}_4 \)), they are related by linear transformations and "scissors congruence". Our choice of coordinate system differs from that used in previous work of Petroner et al. [15] by a nontrivial scissors congruence, effectively replacing the condition stated there,

\[ (\text{LogSpec} U)_3 > \frac{1}{2} \quad \text{by the alternative} \quad (\text{LogSpec} U)_2 + (\text{LogSpec} U)_3 > 0. \]

Remark 2.8 (cf. Remark 4.5). Later, it will be convenient for us to consider a variant of positive canonical triples which are not required to be sorted. Unsorted triples \((a_1, a_2, a_3)\) which become positive canonical triples upon sorting are those which satisfy \( 0 \leq a_j + a_k \leq \frac{\pi}{4} \) for all choices of \( j \) and \( k \). The set of such triples still gives a convex polytope.

3 XX-BASED CIRCUIT SYNTHESIS: STRATEGY

Let us turn to the task of synthesizing for any two-qubit unitary operator \( U \) and gate set \( S \) consisting of \( XX \) interactions an \( S \)-circuit \( C \) modeling \( U \). To set the stage for our strategy, suppose instead that \( C \) is given. We can produce from it a sequence of truncations \( C_j \) that retain steps 1 through \( j \). Each \( C_j \) is also a circuit modeling some other unitary operator \( U_j \), and if \( C \) is optimal for circuits modeling \( U \) against some well-behaved cost function (say, operation count), then each \( C_j \) will be so optimal for \( U_j \). The images \( p_j = \Pi(U_j) \in \mathbb{C}_2 \) of these intermediate operators then describe a path through the Weyl alcove, where the \( j \)th step in the path belongs to the region \( P_j \) of operations whose optimal circuits take the form of \( C_j \).

Near the plane \( a_3 = 0 \), the function \( \Pi \) becomes continuous after imposing the identification \((a_1, a_2, 0) \sim (\frac{\pi}{4} - a_1, a_2, 0)\).

Also commonly called a (circuit) template.
Since our goal is to construct $C$, we might instead begin by constructing the path $(p_j)$, subject to the two constraints:

1. $p_j$ lies in $P_j$.
2. The hop from $p_j$ to $p_{j+1}$ is given by some nice circuit.

In order to understand the first constraint, we give a compact description of $P_j$ by way of describing the circuit polytope associated to an arbitrary sequence of $XX$–type interactions. We call this the global theorem (Theorem 4.1) since it describes the large-scale structure of the problem and does not reference the individual point $p_j$.

Though our main tool here is Theorem 2.5, for a generic sequence families as the strength, slant, and frustrum bounds.

families of linear inequalities is satisfied:

$$L \text{ CAN}(n_1, n_2, n_3) \equiv \text{CAN}(n_1, n_2, n_3)$$

where $L_j$ are local operators, if and only if either of the following two families of linear inequalities is satisfied:

$$\begin{align*}
\alpha_x & \geq a_1 + a_2 + a_3, \quad \text{(strength)} \\
\min_k \alpha_x - 2a_k & \geq -a_1 + a_2 + a_3, \quad \text{(slant)} \\
\min_k a_x - a_k - a_l & \geq a_3; & \text{(frustrum)} \\
-\frac{\pi}{2} + a_x & \geq -a_1 + a_2 + a_3, \quad \text{(strength)} \\
\frac{\pi}{2} + \min_k a_x - 2a_k & \geq a_1 + a_2 + a_3, \quad \text{(slant)} \\
\min_k a_x - a_k - a_l & \geq a_3. & \text{(frustrum)}
\end{align*}$$

We respectively refer to the first, second, and third inequalities in these families as the strength, slant, and frustrum bounds.

Important Remark. From a physical perspective, the circuit polytope ought to be invariant under injecting extra zero-strength interactions into the defining sequence of interaction strengths. Accordingly, we always treat expressions like $\min_k a_x - a_k - a_l$ as if the sequence were padded by arbitrarily many zero entries.

Proof of Theorem 4.1. For the base case, note that the empty list of interaction strengths yields the polytope $a_1 = a_2 = a_3 = 0$,

which agrees with the set of circuits locally equivalent to the identity interaction.

Suppose then that we have established the claim for a sequence of interaction strengths $(a_1, \ldots, a_n)$ and would like to establish the claim for $(a_1, \ldots, a_n, \beta)$ for some new interaction strength $\beta$. By allowing the $(n+1)$ different strengths to range, we note the region in the claim is naturally expressed as a polytope in $(n+1) + 3$ dimensions. In fact, we can reduce it to a certain 6–dimensional polytope as follows: writing $a'$ and $a''$ respectively for the largest and second-largest elements in the hypothesized sequence of interaction strengths, we may rewrite the inequality families above as

$$\begin{align*}
\alpha_x & \geq a_1 + a_2 + a_3, \quad \text{(strength)} \\
a_x - 2a' & \geq -a_1 + a_2 + a_3, \quad \text{(slant)} \\
a_x - a' - a'' & \geq a_3; & \text{(frustrum)} \\
-\frac{\pi}{2} + a_x & \geq -a_1 + a_2 + a_3, \quad \text{(strength)} \\
\frac{\pi}{2} + a_x - 2a' & \geq a_1 + a_2 + a_3, \quad \text{(slant)} \\
a_x - a' - a'' & \geq a_3. & \text{(frustrum)}
\end{align*}$$

with the additional constraints

$$n \cdot \frac{\pi}{4} \geq \alpha_x, \quad a_x \geq a' + a'', \quad \frac{\pi}{4} \geq a' \geq a'' \geq 0.$$

Altogether, these statements over $a_1, a_2, a_3, a_x, a', a''$ describe a pair of convex polytopes in 6–dimensional space.

Theorem 2.5 gives an explicit, finite family of linear inequalities (the "monodromy polytope") so that $a_1, a_2, a_3, a_x, a', a''$ satisfy the constraints if and only if there is a local gate $L$ and a local equivalence

$$\text{CAN}(a_1, a_2, a_3) \cdot L \cdot \text{CAN}(a'_1, a'_2, a'_3) \equiv \text{CAN}(b_1, b_2, b_3).$$

We combine this with the polytope from the inductive hypothesis so that its coordinates are shared with $(a_1, a_2, a_3)$ and the coordinates $(a'_1, a'_2, a'_3)$ are set to $(\beta, 0, 0)$. This produces a union of convex polytopes in 10–dimensional space, a point of which simultaneously captures:

$(\alpha_x, a', a'')$: Values extracted from the prefix of interaction strengths.

$(a_1, a_2, a_3)$: A positive canonical coordinate which admits expression as an $XX$–circuit as in the inductive hypothesis.

$\beta$: A new interaction strength.

$(b_1, b_2, b_3)$: A canonical coordinate which admits expression as a concatenation of the aforementioned circuit, a local gate, and $XX\beta$.

Our goal is to describe a certain projection of this polytope. Projection has the effect of introducing an existential quantifier into the above description: a point belongs to the projection of a polytope
We note that we have won these pleasing formulas by losing convexity—where we have collected the inequalities which give communal lrs ware package non-convex union of these convex polytopes.

In our case, we seek to project away the coordinates \((a_1, a_2, a_3)\), which leaves only constraints on \((b_1, b_2, b_3)\), given in terms of \((a_+, a', a'', \beta)\), ensuring that a prefix circuit of the indicated type exists, without actually naming it.

To compute this projection, we apply Fourier–Motzkin elimination to project away the remaining coordinates and eliminate redundancies in the resulting inequality set (using, e.g., the software package 1rs \([2, 3]\)). These reduced inequality sets have the following form:

\[
\begin{align*}
\min \left\{ \begin{array}{l}
\alpha_+ + \beta \\
\alpha_+ + \beta - 2\alpha'
\end{array} \right\} & \geq b_1 + b_2 + b_3, \quad \text{(strength)} \\
\min \left\{ \begin{array}{l}
\alpha_+ + \beta - \alpha' - \alpha'' \\
\alpha_+ + \beta - \alpha' - \alpha''
\end{array} \right\} & \geq b_3, \quad \text{(frustrum)}
\end{align*}
\]

where we have collected the inequalities which give communal upper bounds into single expressions using “\(\min\)”. Notationally absorbing \(\beta\) into the sequence of interaction strengths completes the proof.

\[\square\]

Example 4.2. We include a visualization of an example XX–circuit polytope in Figure 4.

Remark 4.3. The two convex bodies in the statement of Theorem 4.1 are related by the linear transformation

\[(a_1, a_2, a_3) \mapsto \left(\frac{\pi}{2} - a_1, a_2, a_3\right).
\]

Remark 4.4. Theorem 4.1 is manifestly invariant under permutation of the interaction strengths.

Remark 4.5. By dropping the assumption that the entries of positive canonical triples are ordered descending (as in Remark 2.8), we can rewrite the above inequality families in a manner that is more pleasingly symmetric. For example, the first\(^7\) family is rewritten as:

\[
\begin{align*}
\alpha_+ & \geq a_+ , \quad \text{(strength)} \\
\min_k \alpha_+ - 2a_k & \geq \min_k a_+ - 2a_k, \quad \text{(slant)} \\
\min_{k \neq \ell} \alpha_+ - a_k - a_{\ell} & \geq \min_{k \neq \ell} a_+ - a_k - a_{\ell}. \quad \text{(frustrum)}
\end{align*}
\]

We note that we have won these pleasing formulas by losing convexity: the “\(\min\)’s” appearing in the lower bounds encode disjunctions of linear sentences rather than conjunctions, so we see merely a non-convex union of these convex polytopes.

\[\text{Example 4.2.}\]

Remark 4.6 ([21]). In the case of a uniform interaction strength \(\alpha\), we compute the quantities appearing in the upper bounds of Theorem 4.1 to be

\[
\begin{align*}
\alpha_+ & = n\alpha, \\
\min_k a_+ - 2a_k & = (n - 2)\alpha, \\
\min_k a_+ - a_k - a_{\ell} & = (n - 2)\alpha.
\end{align*}
\]

This causes the slant and frustrum inequalities to degenerate, which recovers a theorem of Zhang et al. as a special case.

\[\text{Figure 4: Two perspectives on the XX–circuit polytope for the interaction strength sequence } (\frac{\pi}{2}, \frac{\pi}{3}, \frac{\pi}{4})\text{. From the perspective where SWAP is near the eyepoint, the strength faces are the pair facing inwards, the slant faces are the pair facing outwards, and the frustrum face is colored tan.}\]
5 THE LOCAL THEOREM

In this section, we study the problem of appending a single new XX interaction strength $\beta$ to a specific circuit formed from a sequence of strengths $(a_1, \ldots, a_n)$. Note that Theorem 4.1 gives us an understanding of the “global” effect of appending XX$_\beta$, where the interaction strengths are fixed but the circuit is allowed to range. Note also that if we are able to achieve such a local understanding, we would then look to use it in reverse: given a point $p_{n+1}$ which Theorem 4.1 guarantees to be modelable using a circuit with square-norms of the matrix entries in Lemma 5.1. The system with input the phases of the top half of the left-hand matrix.

Excepting the caveat about constructive, algorithmic identification, this can be accomplished directly using nothing more than the methods of the monodromy polytope. However, because we are interested in circuit construction, we restrict what sorts of circuits we are willing to append to those of the particularly simple form given in Lemma 5.1. In trade, the method of the monodromy polytope no longer directly applies.

We show in Theorem 5.3 the “forward” direction of the strategy described above, then in Theorem 5.5 the “reverse” direction, culminating in the recursive step in a synthesis procedure whose full description we defer to Section 6. First, however, we introduce the simplified circuit which we will consider.

Lemma 5.1. For any choice of $a_1$, $a_2$, $\beta$, $d$, and $e$ in

$$U := \text{CAN}(a_1, a_2, 0) \cdot (Z_d \otimes Z_e) \cdot (XX_{\beta})$$

there exist values $r$, $s$, $t$, $u$, $b_1$, and $b_2$ so that the operator $U$ may be equivalently expressed as

$$(Z_r \otimes Z_s) \cdot \text{CAN}(b_1, b_2, 0) \cdot (Z_t \otimes Z_u)$$

Proof. The vector subspace $g = \text{span}\{XX, YY, XY, YX, ZI, IZ\}$ forms a Lie subalgebra of $pu_4$. The subspaces

$$a = \text{span}\{XX, YY\}, \quad t = \text{span}\{IZ, IZ\}$$

give rise to a KAK decomposition yielding the desired result.

Next, we note that this choice of simple local gates gives rise to the desired explicit expressions for the gate parameters.

Lemma 5.2. Except for the outer parameters $r$, $s$, $t$, and $u$, the parameters in Lemma 5.1 are related by the equations

$$\frac{c_a^2 - a c_b^2 + a^2 - a^2 - b^2}{2 a c_a c_b a^2 - c_b^2} = c_2(d+e),$$

$$\frac{c_a^2 + a c_b^2 + a^2 + a^2 - b^2}{2 a c_a c_b a^2 + c_b^2} = c_2(d-e).$$

The outer parameters $r$, $s$, $t$, and $u$ can then be deduced from a linear system with input the phases of the top half of the left-hand matrix.

Proof. The trigonometric equalities follow by equating the square-norms of the matrix entries in Lemma 5.1. The (1, 1) and (3, 3) entries respectively yield

$$|c_{b_1-b_2}|^2 = |c_\beta c_{a_1-a_2} - e^{2i(d+e)} s_{a_1-a_2}|^2,$$

$$|c_{b_1+b_2}|^2 = |c_\beta c_{a_1+a_2} - e^{-2i(d-e)} s_{a_1+a_2}|^2,$$

where we have used the absolute values to suppress some of the phases. We then apply the identity

$$|x + r e^{i\beta}|^2 = x^2 + r^2 + 2x r \cos \theta$$

and isolate $d$ and $e$ to deduce the statement.

The linear system then arises by inspecting the phases of any nondegenerate quadruple of entries. For example, the nonzero entries in the top half, read left-to-right, have respective phases

$$e^{-i(r+s+t+u)}, e^{-i(r-s-t+u)}, e^{-i(r+s-t-u)}.$$  

This collection of linear combinations is of full rank.

We can interpret the constraints imposed by these expressions on the positive canonical triples in terms of $\beta$.

Theorem 5.3 ("Interference inequalities"). For positive canonical triples $(a_1, a_2, 0)$ and $(b_1, b_2, 0)$ and for $\beta$ an interaction strength, there exist parameters $d$ and $e$ satisfying

$$\text{CAN}(a_1, a_2, 0) \cdot (Z_d \otimes Z_e) \cdot XX_{\beta} \equiv \text{CAN}(b_1, b_2, 0)$$

if and only if the following inequalities hold:

$$a_1 + a_2 - \beta \leq b_1 + b_2 \leq \frac{\pi}{2} - \frac{\pi}{2} - (a_1 + a_2 + \beta),$$

$$|a_1 - a_2 - \beta| \leq b_1 - b_2 \leq a_1 - a_2 + \beta.$$  

Moreover, the local gates witnessing the equivalence can be taken to be $Z$-rotations.

Proof. Starting from Lemma 5.2, there exist solutions to $d$ and $e$ exactly when the following inequalities are met:

$$|c_{a_1-a_2} c_{a_1-a_2} + s_{a_1-a_2} s_{a_1-a_2} - c_{b_1-b_2}| \leq |2 c_{a_1-a_2} c_{a_1-a_2} s_{a_1-a_2}|,$$

$$|c_{a_1+a_2} c_{a_1+a_2} + s_{a_1+a_2} s_{a_1+a_2} - c_{b_1+b_2}| \leq |2 c_{a_1+a_2} c_{a_1+a_2} s_{a_1+a_2}|.$$  

Using the inequalities $a_1 + a_2 \leq \frac{\pi}{2}$, $a_1 \geq a_2$, and $0 \leq \beta \leq \frac{\pi}{4}$, we see that both the right-hand quantities are always positive, hence the right-hand absolute value can be suppressed. The left-hand absolute value can be equivalently expressed as a pair of inequalities, giving

$$-2 c_{a_1-a_2} c_{a_1-a_2} s_{a_1-a_2} \leq c_{a_1-a_2} c_{a_1-a_2} + s_{a_1-a_2} s_{a_1-a_2} - c_{b_1-b_2},$$

$$c_{a_1-a_2} c_{a_1-a_2} + s_{a_1-a_2} s_{a_1-a_2} - c_{b_1-b_2} \leq 2 c_{a_1-a_2} c_{a_1-a_2} s_{a_1-a_2}.$$  

Rewriting the binomials as cosines of differences / sums and then converting square cosines to double-angle cosines yields

$$c_2(a_1-a_2) \leq 2 c(b_1-b_2) \leq c_2(a_1-a_2),$$

$$c_2(a_1+a_2) \leq 2 c(b_1+b_2) \leq c_2(a_1+a_2).$$

It is extremely unusual that image under II of a circuit with constrained local gates is again a polytope. This is, perhaps, the most important ingredient in our approach.
Linear rearrangement yields the claimed inequality family.

minpolytope for a sequence of interaction strengths accessible via Theorem 5.3.

Finally, we use the piecewise monotonicity and reflection invariance of cosine, as well as the bounds on the inputs, to deduce inequalities on the angles:

$$2(a_1 - a_2 + \beta) \geq 2(b_1 - b_2) \geq \max(2(a_1 - a_2 - \beta), -2(a_1 - a_2 - \beta)),$$

$$\min(2(a_1 + a_2 + \beta), 2\pi - 2(a_1 + a_2 + \beta)) \geq 2(b_1 + b_2) \geq 2(a_1 + b_2 - \beta).$$

Linear rearrangement yields the claimed inequality family. □

Example 5.4. In Figure 5, we give a visualization of the regions accessible via Theorem 5.3.

Figure 5: Two perspectives on the configuration of polytopes in Theorem 5.3. The solid, inner polytope is the XX–circuit polytope for a sequence of interaction strengths \((a_1, \ldots, a_n)\), and the translucent outer polytope is the XX–circuit polytope for the sequence \((a_1, \ldots, a_n, \beta)\). We have chosen a particular point on the edge of the inner figure and drawn the regions accessible from it by applying Theorem 5.3 for the interaction strength \(\beta\) to any pair of coordinates (red: XX and YY; green: YY and ZZ; blue: XX and ZZ). These appear as a triple of flat polygons. Theorem 5.5 states that when the point on the inner body is permitted to range, the union of the corresponding translates of the red, green, and blue polygons sweeps out the entirety of the outer body.

Figure 6: The circuit emitted by a typical simple step of Procedure 6.1 (i.e., by Theorem 5.5), modeling \(CAN(b_1, b_2, b_3)\) in terms of \(CAN(a_1, a_2, a_3)\), XX\(\beta\), and local gates. The gates \(W, W', W''\) are quarter-turns which realize the action of Weyl group elements on \(a, b \in \mathbb{C}_2\).

Theorem 5.5 (cf. Figure 6). Given a positive canonical triple \((b_1, b_2, b_3)\) satisfying the conditions of Theorem 4.1 for a sequence of interaction strengths \((a_1, \ldots, a_n)\), there always exists a positive canonical triple \((a_1, a_2, a_3)\) satisfying the conditions of Theorem 4.1 for the sequence \((a_1, \ldots, a_n)\) and for which there are Weyl reflections \(w, w'\) so that the following is solvable:

\[CAN(a_1, a_2, a_3)^w \cdot (Z(d) \otimes Z(e)) \cdot CAN(\beta) \equiv CAN(b_1, b_2, b_3)^{w'}.\]

The outer gates witnessing the local equivalence can be taken to be Z–rotations.

Proof. Any canonical gate \(CAN(b_1, b_2, b_3)\) can be written as

\[CAN(b_1, b_2, b_3) = CAN(0, 0, b_3) \cdot CAN(b_1, b_2, 0).\]

Applying Theorem 5.3 to the right factor gives

\[CAN(b_1, b_2, b_3) = CAN(0, 0, b_3) \cdot (Z_{\tau} \otimes Z_{-\tau}) \cdot CAN(a_1, a_2, 0) \cdot (Z_{\tau} \otimes Z_{-\tau}) \cdot CAN(\beta) \cdot (Z_{-\tau} \otimes Z_{-\tau}),\]

under certain conditions on \(a_1, a_2, b_1, b_2, \) and \(\beta\). Since local Z–rotations commute with canonical gates of the form \(CAN(0, 0, b_3)\), we may abbreviate this to

\[CAN(b_1, b_2, b_3) = (Z_{\tau} \otimes Z_{-\tau}) \cdot CAN(a_1, a_2, b_3) \cdot (Z_{\tau} \otimes Z_{-\tau}) \cdot CAN(\beta) \cdot (Z_{-\tau} \otimes Z_{-\tau}).\]

Additionally, our choice to factor out \(b_3\) is immaterial: there are Weyl reflections which permute the coordinates within a canonical triple, so by conjugating \(CAN(b_1, b_2, b_3)\) we can place any of the three values in the final slot. In short, we may appeal to Theorem 5.3, provided we fix one coordinate and potentially disorder the positive canonical triples.

From here, our proof strategy is similar to that of Theorem 4.1. Theorem 4.1 itself furnishes us with linear constraints on the spaces of triples \((b_1, b_2, b_3)\) so that a triple satisfies the constraints if and only if it can be realized as the positive canonical coordinate of an XX–circuit with interaction strengths \((a_1, \ldots, a_n, \beta)\). Rather than working with ordered triples \((a_1, a_2, a_3)\), we instead consider unordered triples \((a_h, a_t, a_f)\) to be referred to as the “high”, “low”, and “fixed” coordinates—as in Remark 4.5. Then, we interrelate the \(a\)– and \(b\)–coordinates:

- We select one coordinate \(b_f\) from \((b_1, b_2, b_3)\) to serve as the “fixed” coordinate (and take the union over such choices), and we set \(a_f = b_f\).
On \( a_b \) and \( a_l \), we impose the constraint \( a_b \geq a_l \). Similarly, of the remaining coordinates in \((b_1, b_2, b_3)\), we pick \( b_2 \) to be the larger and \( b_3 \) to be the smaller.

- We impose the constraints from Theorem 5.3 on \((a_b, a_l, 0), (b_2, b_3, 0)\), and \( \beta \).

Let us call the resulting (nonconvex) polytope \( P \). Points in \( P \) capture the following interrelated pieces of data:

- A canonical coordinate \((b_1, b_2, b_3)\) which admits expression as an XX–circuit with interaction strengths \((a_1, \ldots, a_n, \beta)\).
- A canonical coordinate \((a_1, a_2, a_3)\) which admits expression as an XX–circuit with interaction strengths \((a_1, \ldots, a_n)\).
- A choice of value to share among the \( a \)– and \( b \)–coordinates.
- The condition that, among the unshared coordinates, there exists a circuit of the form in Lemma 5.1 relating them. (As in the first two bullets, the polytope does not record the literal data of such a circuit, only the predicate that one exists.)

By projecting away \((a_b, a_l, a_f)\) from \( P \), we produce the polytope of positive canonical triples \((b_1, b_2, b_3)\) which can be expressed as XX–circuits with the specified interaction strengths, together with the predicate constraint that the last step in the circuit decomposition can be written in the form of the Theorem statement. This is a subpolytope of that of Theorem 4.1, which merely tracks positive canonical triples which can be expressed as XX–circuits with the specified interaction strengths, without the constraint on the final local operator. Appealing again to a computer algebra system (e.g., 1rs [2, 3]), we find that these two polytopes are equal. \( \square \)

**Remark 5.6.** Naively specified, the polytope \( P \) in the proof of Theorem 5.5 has many convex components: the two convex regions of \( a \)– and \( b \)–coordinates each contribute factors of 2, the choice of which coordinate to fix contributes a factor of 3, and the choice of which slant and frustrum bounds apply to the disordered \( a \)–coordinates contribute factors of 2 and 3. However, the projection of \( P \) onto the \( b \)–coordinates, which we used to conclude the theorem, can be shown to have only four regions:

- The choice of convex region of \( b \)–coordinates is free, but one then uses the same choice for \( a \)–coordinates.
- The fixed coordinate \( a_f \) is taken to be either \( b_1 \) or \( b_3 \).
- For the unreflected (resp., reflected) convex region of \( b \)–coordinates, the slant (resp., strength) inequality is imposed either on \( a_f \) or \( a_k \) depending on whether \( a_f = b_1 \) or \( a_f = b_3 \).
- The frustrum bound is always imposed on \( a_f \).

The inequalities describing these regions are given in Figure 20.

**Remark 5.7.** It is possible for the technophobe reader to rearrange the proofs of Theorem 4.1 and Theorem 5.5 so as to avoid computer algebra systems. First, break Theorem 4.1 into a forward implication, that the positive canonical triple associated to an XX–circuit satisfies the indicated inequality set, and the reverse implication. The forward implication can be checked by hand, using a judiciously chosen subset of inequalities from the monodromy polytope; the reverse implication is much harder from this point of view, so we set it aside for a moment.

Now we turn to Theorem 5.5. Its proof also relies on a computer algebra system, but we may severely limit the amount of work by inspecting only the convex summands described in Remark 5.6, which is then small enough to accomplish manually. With only the forward implication of Theorem 4.1 established, the proof of Theorem 5.5 instead shows that if the \( b \)–coordinate belongs to the polytope named by Theorem 4.1 for \((a_1, \ldots, a_n, \beta)\), then there exists an \( a \)–coordinate in the polytope named by Theorem 4.1 for \((a_1, \ldots, a_n)\) which is related to the \( b \)–coordinate by a particular single-step XX–circuit. Following the induction described in Procedure 6.1 then yields the missing reverse implication of Theorem 4.1, which in turn yields the full strength of Theorem 5.5.

## 6 OPTIMAL SYNTHESIS

We now put the pieces together to form an optimal synthesis routine. The actual synthesis process is now straightforward, given in Procedure 6.1, but it is trickier to pin down exactly what is meant by “optimal”. For instance, the notion of optimality considered by Zhang et al. [21] is to minimize two-qubit operation count—but in a larger gateset, where different gates may have uneven performance impact, optimizing count alone may not optimize performance. Relatedly, if performance is the true goal and the performance penalty incurred for using gates is high, it may be preferable to synthesize a circuit modeling some canonical triple \( a' \neq a \) which requires fewer gates, trading the performance hit due to the mismatch for performance gain of dropping some of the gates.

Let us begin with the synthesis procedure itself:

**Procedure 6.1** (cf. Figure 6). The existence claim of Theorem 5.5 can be promoted into an algorithmically effective synthesis routine. Given a sequence of interaction strengths \((a_1, \ldots, a_n, \beta)\) and a positive canonical triple \((b_1, b_2, b_3)\) which belongs to the associated circuit polytope, the polytope \( P \) from the proof of Theorem 5.5 can then be specialized so that only \( a_b \) and \( a_l \) are free variables. (We report these inequality sets in Figure 21.) The content of Theorem 5.5 is that this specialization is always nonempty, so we may find a point \((a_b, a_l, a_f)\) in it (e.g., by calculating line-line intersections until we produce a vertex). This pair of points can then be fed to Lemma 5.2, which produces the angle values for the \( Z \)–rotations. This proceeds recursively until the sequence of interaction strengths is exhausted.

**Example 6.2.** In Figure 7, we include a visualization of the intermediate steps produced when using Procedure 6.1 to synthesize an XX–circuit for a certain canonical point against a particular sequence of interaction strengths.

To progress, we need a quantitative definition of optimality.

**Definition 6.3.** Given a target unitary \( U \), a gate set \( \mathcal{S} \), and a cost function \( \mathcal{E}_\mathcal{S} \) which consumes \( U \) and an \( \mathcal{S} \)–circuit \( C \), the approximate synthesis task is to produce an \( \mathcal{S} \)–circuit \( C \) maximizing \( \mathcal{E}_\mathcal{S}(U, C) \). Cost functions can enjoy a variety of pleasant properties:

- **Separable:** For a circuit template \( C(\theta) \), \( \mathcal{E}_\mathcal{S}(U, C) \) can be written as a sum \( \mathcal{E}'(U, C(\theta)) + \mathcal{E}''(C, \theta) \) where \( \mathcal{E}' \) depends only on the unitary which the circuit models and \( \mathcal{E}'' \) depends only on the circuit and parameters—but not its relationship to \( U \).

- **Locally invariant:** \( \mathcal{E}''(C, \theta) = \mathcal{E}''(C, \theta) \) is invariant under choice of parameters \( \theta \) for local gates in the circuit \( C \).

- **Monotonic:** Suppose that \( \mathcal{E} \) is a separable cost function. If \( C \) is contained as a subcircuit in \( D \), then \( \mathcal{E}''(C, \theta) \leq \mathcal{E}''(D, (\theta, \phi)) \).
We record these properties below.

we define a separable, locally invariant, monotonic cost function by

For \( \mathcal{A} \) ’s generic optimizer explore the space of circuits

Their average gate infidelity is given by

\[
20 \cdot I(U, V) = 16 - 16 \left( \prod_j \cos^2 \frac{\delta_j}{2} + \prod_j \sin^2 \frac{\delta_j}{2} \right).
\]

\( \square \)

\[\mathcal{C}'(U, V) \begin{cases} 0 & \text{when } U = V, \\ \infty & \text{otherwise} \end{cases}\]

These features are chosen both because they feed into an efficient algorithm for optimal synthesis and because they are satisfied in the following guiding example:

**Example 6.4.** The average infidelity of two gates \( U \) and \( V \) is

\[I(U, V) = 1 - \int_{\psi \in \mathcal{P}(C)} \langle \psi | U^\dagger V | \psi \rangle^2 = \frac{16 - |\text{tr } U^\dagger V|^2}{4 \cdot 5} \in [0, 4/5].\]

For \( \delta \) a finite collection of XX–interactions with costs \( c: \delta \to \mathbb{R} \), we define a separable, locally invariant, monotonic cost function by

\[\mathcal{C}_\delta(U, C) = I(U, C) + \sum_{s \in \delta} c(s)\]

Average gate infidelity satisfies a few pleasant generic properties, but it is also tightly connected to the theory of KAK decompositions. We record these properties below.

**Remark 6.5.** Average infidelity detects gate equivalence, in the sense that \( I(U, V) = 0 \) if and only if \( U = V \). It is also symmetric: \( I(U, V) = I(V, U) \). However, it fails to satisfy the triangle inequality, even when \( U \) and \( V \) belong to the canonical family, hence does not give a metric. It satisfies compositionality only to first order:

\[16 - 20 \cdot I(UU', (U + \varepsilon E)(V + \varepsilon F)) = |\text{tr } V^\dagger U(1 + \varepsilon E)(V + \varepsilon F)|^2 = |1 + \varepsilon \text{tr } U^\dagger E + \varepsilon \text{tr } V^\dagger F + \varepsilon^2 \text{tr } V^\dagger U^\dagger EF|^2.\]

**Lemma 6.6 ([5]).** Let \( U = \text{CAN}(a_1, a_2, a_3) \) and \( V = \text{CAN}(b_1, b_2, b_3) \) be two canonical gates with parameter differences \( \delta_j = (a_j - b_j) \). Their average gate infidelity is given by

\[20 \cdot I(U, V) = 16 - 16 \left( \prod_j \cos^2 \frac{\delta_j}{2} + \prod_j \sin^2 \frac{\delta_j}{2} \right). \]

\( \square \)

**Lemma 6.7 ([18]).** Suppose that \( C_1, C_2 \) are fixed canonical gates and that \( L_1, L'_1 \) are fixed local gates. Letting \( L_2 \) and \( L'_2 \) range over all local gates, the value \( I(L_1C_1L'_1, L_2C_2L'_2) \) is minimized when \( L_2 = L_1 \) and \( L'_2 = L'_1 \).

\( \square \)

We now describe an optimal synthesis procedure for a nice cost function:

**Procedure 6.8.** Let \( \mathcal{C} \) be a separable, locally invariant, and monotonic cost function. Let \( \delta \) be a finite gate set of XX–type interactions, and consider the set of circuit templates given by interleaving unconstrained local gates into the words formed from \( \delta \). Traverse these available circuit templates (i.e., the words in \( \mathcal{S} \)) for each such circuit template \( C \), use Theorem 4.1 to calculate the circuit polytope \( \Pi(C) \). Calculate the point \( p \in \Pi(C) \) which optimizes \( \mathcal{C}(U, \text{CAN}(p)) \). If the total cost \( \mathcal{C}_\delta \) is the best seen so far, retain \( C \) and \( p \). Continue to traverse circuit templates until \( \Pi(U) \in \Pi(C) \), at which point \( \mathcal{C}_\delta \) vanishes and the ordering of circuit templates guarantees that all future circuit templates will yield a worse cost.\(^{10}\) Finally, apply Procedure 6.1 to synthesize a \( C \)–circuit for \( \text{CAN}(p) \), then apply Lemma 6.7 to produce \( U \) itself.

**Remark 6.9.** In Figure 8, we study the execution characteristics of Procedure 6.8 compared to those of blind numerical search. The implementation of our method is available in Qiskit’s quantum_info subpackage as the class XXDecomposer [6]. Given a Haar-randomly chosen two-qubit unitary operator \( U \), our numerical search procedure is to let numpy’s generic optimizer explore the space of circuits of a particular depth, with the objective of minimizing the infidelity with \( U \). If the optimizer cannot find a circuit with infidelity below some threshold, we retry with a circuit of the next larger depth. Altogether, this is similar to what is implemented in NuOp [11], among other compilation suites. The histograms reported in Figure 8 are the result of sampling over many such \( U \), targeting either the gate set \( \delta = \{XX, \} \) or \( \delta = \{XX, T_1, \} \).\(^{11}\)

\(^{7}\)Using a priority queue, one can perform this traversal without enumerating all possible words beforehand.

\(^{10}\)Theorem 4.1 guarantees that this termination condition will eventually be met provided \( \delta \) contains any interaction XX\(_\beta\) with \( \beta \in (0, \pi) \).

\(^{11}\)Neither our implementation of Procedure 6.8 nor our invocation of numpy is particularly clever. We expect that both distributions can be shifted left with further optimization of the implementations, but that the multiplicative difference will be at least as large between “optimal” implementations of each synthesis method.
This result means that we can repurpose the standard procedure
into fixed $XX$ interactions separately, as numerical search is
solving a least-squares problem, retain those projections which
belong to the polytope, and from that finite set select the point of
minimum (infidelity) distance.

Remark 6.11. This is extremely unusual behavior for these two opti-
mization problems and relies on the specific form of the polytopes
appearing in Theorem 4.1. For contrast, consider the line passing
through the origin with slope $(\frac{\pi}{4}, \frac{4\pi}{3}, \frac{2\pi}{3})$ and the off-body point
$(\frac{2\pi}{3}, \frac{8\pi}{4}, \frac{3\pi}{3})$. The fidelity-nearest point appears after traveling
for one unit of time, but the Euclidean-nearest point appears after
traveling for $\approx 95\%$ of a unit of time.

Remark 6.12. Numerical experiment indicates that the nearest point
under infidelity distance exactly agrees with the nearest point under
Euclidean distance—i.e., that the same critical point achieves the
minimum value in both of these searches. However, this conjecture
yields no algorithmic speedup when producing these minimizers,
so we are not motivated to pursue it here.

7 GATSET OPTIMIZATION AND
NUMERICAL EXPERIMENT

In this section, we bring the theory of Section 6 to bear on deciding
which native gates are worth bestowing on a device. Even if a device
is physically capable of enacting some quantum operation, there is
calibration overhead to making that operation available as a reliable
user-facing gate. At the same time, the more high-fidelity native
interactions are available, the more clever and adaptable a synthesis
method (including ours) can be. Accordingly, we would like to find a
small set of $XX$ operations that optimizes certain objective functions
which measure synthesis performance. The primary objective with
which we will concern ourselves is expected cost:

Definition 7.1. For a two-qubit unitary $U \in PU(4)$ and a native
gate set $\mathcal{S}$, let $\mathcal{E}_{\mathcal{S}}(U) := \min_{C} \mathcal{E}_{\mathcal{S}}(U, C)$ be a cost function as in
Definition 6.3 (e.g., Example 6.4 or its non-approximating variant).
The expected cost is defined as

$$\mathcal{E}_{\mathcal{S}} = \int_{U \in PU(4)} \mathcal{E}_{\mathcal{S}}(U) \, d\mu_{\text{Haar}}.$$ 

For $XX$-based gate sets $\mathcal{S}$ and for favorable cost functions, we
now show how to compute this value exactly. Starting with the
definition

$$\mathcal{E}_{\mathcal{S}} = \int_{U \in PU(4)} \min_{C} \mathcal{E}_{\mathcal{S}}(U, C) \, d\mu_{\text{Haar}},$$

we use separability and non-approximation to reduce to the case
where $U$ admits an exact model by $C$:

$$\mathcal{E}_{\mathcal{S}} = \int_{U \in PU(4)} \min_{C \in \mathcal{C}} \mathcal{E}_{\mathcal{S}}(U, C) \, d\mu_{\text{Haar}}.$$ 

By assuming $\mathcal{S}$ finite and $\mathcal{E}_{\mathcal{S}}$ locally invariant, we learn that the
integrand $\min_{U \in C} \mathcal{E}_{\mathcal{S}}(U)$ takes on finitely many values, supported
by finitely many choices of $C$. By sorting the $C$ compatibly with
$\mathcal{E}_{\mathcal{S}}(C)$, we may further reduce to

$$\mathcal{E}_{\mathcal{S}} = \sum_{C} \int_{U \in \text{image}(C)} \mathcal{E}_{\mathcal{S}}(U) \, d\mu_{\text{Haar}}.$$
Since $\mathcal{E}_\delta''(C)$ is constant on each region, each summand is given by the reweighted Haar volume of the corresponding region. Since constant functions pull back from constant functions, we can also push these integrals forward along $\Pi$ and compute them in $\mathcal{R}_C$:

$$(\mathcal{E}_\delta) = \sum_C \mathcal{E}_\delta''(C) \left( \Pi_* \mu_{\text{Haar}} \left( \Pi(C) \setminus \bigcup_{C' < C} \Pi(C') \right) \right).$$

Altogether, this reduces the problem to calculating the Haar volume of the polytopes which appear in Theorem 4.1. A formula for $\Pi_* \mu_{\text{Haar}}$ which enables this was previously reported by Watts et al.:

**Lemma 7.2** ([17], [14], [13]). The pushforward of the Haar measure is given by

$$\Pi_* \mu_{\text{Haar}} = \frac{384}{\pi} \prod_{1 \leq j < k \leq 5} \sin(2cj + 2ck) \sin(2cj - 2ck).$$

Such trigonometric integrals over tetrahedra can be performed exactly. Altogether, this gives us quantitative means by which to study the effect of tuning the inputs to a parametric gate set, e.g., $\delta(x) = \{XX_x, XX_{x'}\}$. A parametric choice of gate set requires a parametric cost function, and our parametric cost function of interest is as follows:

**Definition 7.3.** In our setting, we find it experimentally justified to assume an affine error model: we take $XX_x$ to have fidelity cost $mx + b$ for some experimentally determined values of $m$ and $b$. From this, we build a separable, locally invariant, additive cost component by

$$\mathcal{E}_\delta'''(C) = \sum_{XX_x \in C} (mx + b).$$

12The extra factor of 2 appearing in this formula comes from a different scaling of our coordinate systems.

13This density function has a unique local maximum at $(\frac{\pi}{4}, \frac{\pi}{4}, 0)$.

14In one experiment, we measured $\frac{\pi}{4} \cdot m = 5.76 \times 10^{-3}$ and $\frac{\pi}{4} \cdot b = 1.609 \times 10^{-3}$. This reported offset $b$ incorporates the average infidelity cost of local post-rotations, so as to better model the total circuit execution cost while maintaining local invariance.

**Remark 7.4.** The reader who would like to account, in the above framework, for the worst case cost of the interleaved single-qubit operations can absorb that extra amount into the $b$ parameter.

**Example 7.5.** Consider the gate set $\delta = \{XX_x, XX_{x'}\}$ with cost given by the additive affine error model with parameters $b \approx 1.909 \times 10^{-3}$ and $\frac{\pi}{4} \cdot m = 5.76 \times 10^{-3}$. In Figure 9, we display how the expected infidelity of synthesizing an $\delta$–circuit for a Haar-randomly chosen unitary varies with the gate set parameter $x$. The ends of this curve degenerate to the case of the smaller gate set.
The expected infidelity of a Haar-random operator decomposed exactly into $\delta_{x,y} = \{XX_x, XX_x, XX_y\}$. Uses an additive affine error model with offset $b \approx 1.909 \times 10^{-3}$ and slope $\frac{\pi}{4} \cdot m \approx 5.76 \times 10^{-3}$.

Example 7.6. Consider next the gate set $\delta = \{XX_{\frac{\pi}{2}}, XX, XX_y\}$ with the same cost function. In Figure 11, we display the expected infidelity of synthesizing an $\delta$–circuit for a Haar-randomly chosen unitary against both parameters $x$ and $y$. The edges of this triangular figure degenerate to the case discussed in Example 7.5 along the lines $x = \frac{\pi}{4}$, $y = 0$, and $x = y$. As before, the precise location of the optimum in the middle depends on the ratio $m/b$, but for experimentally realistic error models like the one depicted here, it is located near $(x, y) = (\frac{\pi}{8}, \frac{\pi}{12})$, this time achieving an expected infidelity of $1.51 \times 10^{-2}$. Again, the basin is fairly wide and the minimum fairly independent of the value of $m/b$, so that $(\frac{\pi}{8}, \frac{\pi}{12})$ are good choices for inclusion in a native gate set even if the observed error model exhibits mild variation over time or across a device. Finally, in Figure 10 we depict the optimal synthesis regions within the Weyl alcove for the gate set $\{XX_{\frac{\pi}{2}}, XX, XX_y\}$.

Example 7.7. Taking these results for exact synthesis as inspiration, we can also explore effects introduced by approximate synthesis. Our results here cannot be so clean, because we lose access to our method for analytic calculation, but we can still perform Monte Carlo experiments to analyze the relationship between $\delta_{x} = \{CX, XX_x\}$ and the expected infidelity. The plot in Figure 13 shares many of the same qualitative features as Figure 9 (e.g., the approximate position of the global minimum, and the non-concave kink near $x = \frac{\pi}{4} \cdot 1/3$), with an overall vertical shift coming from the approximation savings. The global optimum for approximate synthesis into $\delta_{x,y} = \{CX, XX_x, XX_y\}$ is again near to the global optimum for exact synthesis, so we re-use the user-friendly value of $(x, y) = (\frac{\pi}{8}, \frac{\pi}{12})$ and depict in Figure 14 the relative frequencies that these regions are made use of by approximate synthesis of Haar-random operations.
Remark 7.8. In the limit where \( \delta \) contains all XX interactions, the most efficient circuit for \( \text{CAN}(a_1, a_2, a_3) \) is given by a product
\[
\text{CAN}(a_1, a_2, a_3) = \text{CAN}(a_1) \cdot \text{CAN}(0, a_2) \cdot \text{CAN}(0, 0, a_3),
\]
where each factor in the product is a Weyl reflection of a single XX gate of the same parameter, and where factors are dropped when the relevant parameter vanishes. Under the assumption of an additive affine error model, this establishes a lower bound for how efficient we can expect our circuits to possibly be, as they are assembled from a more restrictive gate set.

Comparing Example 7.5 and Example 7.6, we observe that there are rapidly diminishing returns to enlarging the native gate set. Specialized to the same error model as in the Examples, the performance lower bound argued above is \((3/2 \cdot \frac{\pi}{4}) \cdot m + 3b\), resulting in the table in Figure 15.

Remark 7.9. For a two-qubit unitary \( U \), its mirror is \( U \cdot \text{SWAP} \). The mirror of a canonical gate is again canonical, given by the formula
\[
\text{CAN}(a_1, a_2, a_3) = \begin{cases} 
\text{CAN} \left( \frac{2}{7} + a_3, \frac{4}{7} - a_2, \frac{2}{7} - a_1 \right) & \text{when } a_1 \leq \frac{4}{7}, \\
\text{CAN} \left( \frac{2}{7} - a_3, \frac{4}{7} - a_2, a_1 - \frac{4}{7} \right) & \text{otherwise}.
\end{cases}
\]

This formula shows that mirroring interchanges the regions of \( \mathbb{R}^2 \) with the most and least infidelity cost, suggesting that our technique may be particularly fruitful at reducing the cost of mirrorable gates. We summarize the numerical results in Figure 17, and we depict in Figure 16 the relative frequency of different circuit templates when synthesizing up to mirroring.

Example 7.10. We summarize the statistics on exact, approximate, and mirrored synthesis for the gate sets \{XX, XX\}, \{XX, XX, XX\}, and \{XX, XX, XX, XX\} in Figure 18. These are to be compared with the precise optima reported in Figure 15 and Figure 17.

**Figure 13:** The expected infidelity of a Haar-random operator decomposed approximately into \( \delta_{\mathcal{E}} = \{CX, XX\} \). Uses an additive affine error model with offset \( b \approx 1.909 \times 10^{-3} \) and slope \( \frac{\pi}{4} \cdot m \approx 5.76 \times 10^{-3} \).

**Figure 14:** The distribution of circuit types encountered when approximately synthesizing 31,800 Haar-random two-qubit unitaries according to the additive affine error model with offset \( b \approx 1.909 \times 10^{-3} \) and slope \( \frac{\pi}{4} \cdot m \approx 5.76 \times 10^{-3} \).

**ACKNOWLEDGEMENTS**

We would like to extend our thanks to David Avis for assisting with literature [2, 3]; to Jay Gambetta, for arranging the productive environment that gave rise to this work; to Isaac Lauer, for keeping us grounded in the realities of working with superconducting hardware; to Douglas Pearson, for helpful comments on a draft of this manuscript; and to Michael Mann, for providing the musical score to which this project was carried out.

A CASE-WORK FOR THE APPROXIMATION THEOREM

In this Appendix, we chase out the requisite case work to prove Theorem 6.10. We begin with some reductions.

Lemma A.1. Let \( a = (a_1, a_2, a_3) \) be a positive canonical triple, and let \( P \subseteq \mathbb{R}^3 \) be a polyhedron satisfying the reflection-closure property
\[
P = \left\{ \left( \frac{\pi}{2} - b_1, b_2, b_3 \right) \mid b \in P \right\}.
\]
The point \( b \in P \) nearest in infidelity distance to the point \( a \in \mathbb{R}^3 \) satisfies \( b_1 \leq \frac{\pi}{4} \) if \( a_1 \leq \frac{\pi}{4} \) and \( b_1 \geq \frac{\pi}{4} \) if \( a_1 \geq \frac{\pi}{4} \).

**Proof.** In the expression
\[
\prod_j \cos^2(a_j - b_j) + \prod_j \sin^2(a_j - b_j),
\]
the bounds \( 0 \leq a_2, b_2, a_3, b_3 \leq \frac{\pi}{2} \) entail that the first summand is bounded from below by \( \frac{1}{2} \cos^2(a_1 - b_1) \) and the second summand is bounded from above by \( \frac{1}{2} \sin^2(a_1 - b_1) \). Notice that replacing \( b \) with its reflection \( \left( \frac{\pi}{2} - b_1, b_2, b_3 \right) \) trades the positions in the expression of \( \cos^2(a_1 - b_1) \) and \( \sin^2(a_1 - b_1) \). Additionally, notice that the expression is maximized when \( \cos^2(a_1 - b_1) \) takes on the larger of the two values, i.e., when \( \cos^2(a_1 - b_1) \geq \frac{1}{2} \). This then holds exactly when the conclusion of the Lemma does. \( \square \)

**Corollary A.2.** We need only handle the case \( a_1 \leq \frac{\pi}{4} \).

**Proof.** Theorem 4.1 shows that XX-circuit polytopes are reflection-invariant, so that we may apply the Lemma. Furthermore, since average infidelity is invariant under replacing both coordinates by their reflections
\[
(a_1, a_2, a_3) \mapsto \left( \frac{\pi}{2} - a_1, a_2, a_3 \right),
\]
\[
(b_1, b_2, b_3) \mapsto \left( \frac{\pi}{2} - b_1, b_2, b_3 \right),
\]
we may reduce to one case of the Lemma, and we choose the case indicated in the Corollary statement. \( \square \)

From here, we turn to the actual casework, walking first over the codimensions of the various facets of some implicitly understood XX-circuit polytope and then over their possible slopes (noting that in each codimension there is a finite set of possibilities). The codimension 0 and 3 (i.e., top- and bottom-dimensional) cases are trivial:

**Lemma A.3** (cf. Remark 6.5). The infidelity functional \( I_{\alpha} \) is extremized on the interior of a codimension 0 facet if and only if \( \alpha \) is a member of that facet. \( \square \)

**Lemma A.4.** The codimension 3 facets contribute a finite set of points at which the restricted infidelity functional \( I_{\alpha} \) may be extremized. \( \square \)

**Lemma A.5.** The infidelity functional \( I_{\alpha} \) is extremized on the interior of codimension 1 facets coincident with the outer walls of the Weyl alcove if and only if \( \alpha \) is a member of that facet.

**Proof.** We employ a strategy similar to Remark 4.5: our choice to restriction attention the alcove \( \mathbb{R}^3 \) is artificial, and it is equivalent to optimize the function \( \min_{w \in W} I(a \cdot w) \) where \( W \) denotes the group of Weyl reflections, where the domain of \( I \) is suitably extended by reflection beyond \( \mathbb{R}^3 \), and where \( b^w \) is constrained to reside in \( \bigcup_{w \in W} w \cdot P \), the closure of \( P \) under Weyl reflections. This closure is again a (possibly non-convex, possibly disconnected) polyhedron, but now the points \( b \in P \) incident on the outer alcove walls belong to the interior of a codimension 0 facet of \( \bigcup_{w \in W} w \cdot P \). Hence, the optimization condition reduces to that of the codimension 0 facet case. \( \square \)

**Lemma A.6.** The infidelity functional \( I_{\alpha} \) is extremized on the interior of the codimension 1 facets not coincident with the outer walls of the Weyl alcove exactly at the nearest point in Euclidean distance.

**Proof.** Each such facet has an associated Lagrange multipliers problem, which we solve in turn. We use the following abbreviations throughout:
\[
\partial_j I := \partial I/\partial \theta_j \quad \delta_j := a_j - b_j.
\]
The linear constraints on \( a, b \in \mathbb{R}^3 \) describe the following constraints on \( \delta \):
\[
\delta_1 \in \left[ -\frac{\pi}{2}, \frac{\pi}{2} \right], \quad \delta_2 \in \left[ -\frac{\pi}{4}, \frac{\pi}{4} \right], \quad \delta_3 \in \left[ -\frac{\pi}{4}, \frac{\pi}{4} \right].
\]

Referring to Theorem 4.1, we break into cases based on the normal vector of the facet:

1. \((0, 1, 0)\): The Lagrange multiplier constraints are \( \delta_1 = 0 \) and \( \delta_2 = 0 \), which amount to the trigonometric conditions
\[
(c_{2\delta_1} + c_{2\delta_3}) \delta_{2\delta_1} = 0, \quad (c_{2\delta_1} + c_{2\delta_3}) \delta_{2\delta_3} = 0.
\]

Taking into account the domain constraints on \( \delta \), we see that the first equation’s is satisfied either when both \( a \) and \( b \) both represent the identity unitary or when \( \delta_1 = 0 \). Taking into account the deduced constraint \( \delta_1 = 0 \), the second clause is then satisfied only when \( \delta_2 = 0 \). Finally, \( \delta_3 \) is determined by being constrained to the frustum plane.\(^{16}\)

1. \((1, 1, 0)\): The Lagrange multiplier constraints are \( \delta_1 = \delta_2 = 0 \) and \( \delta_3 = 0 \), which amount to the trigonometric conditions
\[
(c_{2\delta_1} + c_{2\delta_3}) \delta_{2\delta_1} = 0, \quad (c_{2\delta_1} + c_{2\delta_3}) \delta_{2\delta_3} = 0.
\]

These equalities are analyzed similarly to as in the previous case. The first equation is satisfied either when both \( a \) and \( b \) represent the identity unitary or when \( \delta_1 = \delta_2 \), and the second equality is similar dispatched to give \( \delta_2 = \delta_3 \).

1. \((-1, 1, 1)\): The Lagrange multiplier constraints are \( -\delta_1 = \delta_2 = 0 \) and \( -\delta_1 = \delta_3 = 0 \), which amount to the trigonometric conditions
\[
(c_{2\delta_1} + c_{2\delta_3}) \delta_{2\delta_1} = 0, \quad (c_{2\delta_1} + c_{2\delta_3}) \delta_{2\delta_3} = 0.
\]

Reasoning identically about the domains, we conclude that \( -\delta_1 = \delta_2 \) and \( -\delta_1 = \delta_3 \).

In each case, the critical points are seen to lie at the Euclidean projections onto the relevant planes.

\(^{16}\)A special case of this was previously investigated by Cross et al. [5, Equation B8] when finding the best approximant using a pair of CX gates.
Lemma A.7. The infidelity functional $l_a$ is extremized on the interior of the codimension 2 facets not coincident with the outer walls of the Weyl alcove exactly at the nearest point in Euclidean distance.

Proof. Again, we are tasked with solving a family of constrained optimization problems. This time, each nondegenerate pair of inner walls intersect at a line with tangent vector $v$, and we are looking to solve along the line for the condition $\nabla l_a \cdot v = 0$. To parameterize the line, we select a vertex $b \in \mathcal{C}_\ell$ on it and set

$$t(t) = v \cdot t + b.$$ 

We break $v$ (i.e., the choice of plane pair) into cases.

$(−1, −1, 0)$: This tangent vector $v$ arises from the intersection of planes with normal vectors $(0, 0, 1)$ and $(-1, 1, 1)$. Expanding $(\nabla l_{a_1, a_2, a_3} \cdot v)$ yields

$$(c\delta_1 - \delta_2 + 2\delta_3 + c\delta_1 - 2\delta_1 + 2c\delta_2 + 2t)\delta_1 + 2\delta_2 + 2t = 0,$$

where $t$ is constrained to

$$b_1 - \frac{\pi}{4} \leq t \leq b_2 - b_3.$$ 

$(1, −1, 0)$: This tangent vector $v$ arises from the intersection of planes with normal vectors $(0, 0, 1)$ and $(1, 1, 1)$. Expanding $(\nabla l_{a_1, a_2, a_3} \cdot v)$ yields

$$(c\delta_1 + \delta_2 + 2\delta_3 + c\delta_2 - 2\delta_1 + 2c\delta_3 - 2t)\delta_2 - 2t = 0,$$

where $t$ is constrained to

$$\frac{1}{2}(b_2 - b_1) \leq t \leq \min \left\{ b_2 - b_3, \frac{\pi}{4} - b_1 \right\}.$$ 

$(0, 1, −1)$: This tangent vector $v$ arises from the intersection of planes of normal vectors $(1, 1, 1)$ and $(-1, 1, 1)$. Expanding $(\nabla l_{a_1, a_2, a_3} \cdot v)$ yields

$$(c\delta_1 + \delta_2 + 2\delta_3 + c\delta_1 - 2\delta_1 + 2c\delta_2 - 2t)\delta_2 - 2t = 0,$$

where $t$ is constrained to

$$\frac{1}{2}(b_3 - b_2) \leq t \leq \min \left\{ b_1 - b_2, b_3 \right\}.$$ 

In each case, the first clause is not satisfied on the indicated interval, and the second clause contributes at most only the Euclidean critical point. □

Lemma A.8. The infidelity functional $l_a$ is extremized on the interior of the codimension 2 facets coincident with the outer walls of the Weyl alcove exactly at the nearest point in Euclidean distance.

Proof. As in Lemma A.7, we intend to split over the slopes of the plane-plane intersections. Two of these cases are familiar: since the outer alcove wall $b_3 \geq 0$ shares a normal with the frustum inequality of Theorem 4.1, the tangent vectors $(-1, -1, 0)$ and $(1, -1, 0)$ both reappear, and we have already dispatched them in the proof of Lemma A.7. The frustum inequality contributes one codimension 2 facet not covered by the above; its intersection with the wall $a_2 \geq a_3$ yields a line with tangent vector $(1, 0, 0)$, and the associated optimization problem is

$$(c\delta_1 + c\delta_3)\delta_2 + 2(\delta_2, -1) = 0.$$ 

The sine factor contributes the Euclidean critical point, and the cosine factor is independent of $t$.

The remaining cases correspond to “inner creases” in the Weyl-closed solid $\bigcup_{w \in \mathcal{W}} w \cdot P$, and they are treated quite differently. In each case, the strategy is to show that the facet is irrelevant (i.e., has no critical points) unless the outer alcove inequality is tight for the point $a$, then to use that tightness to simplify the expression further. Our strategy for showing irrelevance is to show that, when $a$ is not a member of an outer facet, $\nabla l_a$ has a nonnegative inner product with the inward-facing normal of the codimension 2 facet considered as part of the boundary of the inner codimension 1 facet. Taking this as given, we would learn that the extremum then would always lie on the codimension 1 facet, so that we could avoid considering the codimension 2 facet. In fact, this strategy gives us a bit more: even without the assumption that $a$ lies off of the outer wall, continuity would show that this conclusion still holds for extrema, since the assumption is only violated at limit points of open regions. Thus, we can avoid investigating even the aforementioned simplified expressions, leaving open only the task of exhibiting a positive inner product with the inward-facing normal.

$(−2, 1, 1)$: This tangent vector $v$ arises from the intersection of the inner wall with normal $n_1 = (1, 1, 1)$ and outer wall with normal $n_0 = (0, 1, −1)$. Assuming $a_2 < a_3$, we would like to show that the following quantity is positive:

$$\nabla l_{a_2, a_3} \cdot n_1 = (c_{a_2, a_3} + c_{a_2, a_3} - 2t\delta_0, (a_2, -1, 1))s_{a_2, a_3},$$

where $(b_1, 0, 0)$ lies on the line and $t$ satisfies $0 \leq t \leq \frac{1}{2}b_1$. ($1, 1, −2)$: This tangent vector $v$ arises from the intersection of the inner wall with normal $n_1 = (1, 1, 1)$ and outer wall with normal $n_0 = (0, 1, −1)$. Assuming $a_1 > a_2$, we would like to show that the following quantity is positive:

$$\nabla l_{a_1, a_2} \cdot n_1 = (c_{a_1, a_2} + c_{a_1, a_2} - 2t\delta_0, (a_2, -1, 1))s_{a_1, a_2}.$$ 

where $(b_1, b_2, 0)$ lies on the line and $t$ satisfies $-\frac{1}{2}b_1 \leq t \leq 0$. ($−2, 1, −1)$: This tangent vector $v$ arises from the intersection of the inner wall with normal $n_1 = (−1, 1, 1)$ and outer wall with normal $n_0 = (0, 1, −1)$. Assuming $a_2 > a_3$, we would like to show that the following quantity is positive:

$$\nabla l_{a_2, a_3} \cdot n_1 = (c_{a_2, a_3} + c_{a_2, a_3} - 2t\delta_0, (a_3, -2b_1, -1))s_{a_2, a_3},$$

where $(b_1, 0, 0)$ lies on the line and $t$ satisfies $\frac{1}{2}b_1 - \frac{\pi}{8} \leq t \leq 0$. 

In each case, the domain restrictions cause the arguments to sine and cosine to lie in the positive range. □

B. INCLUSION-EXCLUSION AND INCIDENCE DEGENERACY

In uncovering our main results, it was invaluable to be able to calculate the volume of a nonconvex polytope. Not only did volume calculations play an outsized role in Section 7, they also underlie primitive operations. For instance, while containment of a polytope $P$ within a convex polytope $Q$ can be checked on vertices, this is not true of two generic polytopes; instead, assuming that $P$ is of constant dimension, $P \subseteq Q$ if and only if $\text{vol}(P) = \text{vol}(P \cap Q)$. For

---

17 Importantly, we are not arguing about critical points but about extrema. Critical points can manifest on a boundary via a sequence of points on the bulk which themselves are merely approximately critical points, without exactly being critical points. However, any such critical point cannot yield a more extreme value than the value achieved by the function on a sequence of values in the bulk which are extrema for the functional constrained to planes parallel to the outer facet.
We traverse the possible depths of intersections, and at each depth we traverse the possible intersections at that depth. For each intersection we encounter a summand with vanishing volume, we can skip all summands which we have done no work, we terminate the iteration altogether; otherwise, we proceed to the next depth.

Now, we double back to reintroduce the summands which we previously double-counted, which we formulate in a way to avoid double-counting the double-countings. Traversing the Type 2 skip list in the order in which it was created, let us consider the \( t \)th mask and toggle \( (I_t, j_t) \), as well as some intermediate \( s \)th mask and toggle \( (I_s, j_s) \) with \( s < t \) and with \( j_t \in I_s \). Double-counting occurs for this pair at an intersection \( I \) when the following are met:

1. The \( t \)th mask matches \( I_t \leq I \).
2. The \( t \)th toggle is disabled: \( j_t \notin I \).
3. The \( s \)th mask matches after the toggle is enabled: \( I_s \leq I \cup \{j_t\} \).
4. For all earlier \( s' < s \), the \( s \)th mask does not include the \( t \)th toggle and additionally does not match \( I \).
5. For all later \( s < s' < t \), the \( t \)th mask does not match the toggle-on form \( I \cup \{j_t\} \).

Whenever these constraints are met, we reintroduce the summand at \( I \) to the running alternating sum. After iterating over all possible values of \( s \) and \( t \), the running sum is the true alternating sum.

For any \( s < t \), the constraints on \( I \) described above are quite strong (and often even contradictory), so that iterating over the possible ways to satisfy these constraints, rather than iterating over \( I \) and checking satisfaction, frequently results in loops with few to no iterations. In one instance “in the wild”, this strategy reduced a calculation from \( 2^{14} - 1 \approx 16,000 \) convex volume computations to a mere 27 volume computations.

18See [1] for a notable exception.
Figure 20: Four tables of inequalities describing the four regions of b-coordinates from Remark 5.6. See also Figure 21.

\[
\begin{align*}
\text{b–coord’s unreflected, } & \quad a_f = b_3, \\
\text{slant inequality on } a_h & : \begin{cases}
\alpha_+ + \beta \geq b_1 + b_2 + b_3, \\
\alpha_+ - 2\alpha' + \beta \geq -b_1 + b_2 + b_3, \\
\alpha_- - \beta \geq -b_1 + b_2 + b_3, \\
\alpha_+ - \alpha' \geq b_3, \\
\alpha_+ - \alpha' - \alpha'' + \beta \geq b_2.
\end{cases}
\end{align*}
\]

\[
\begin{align*}
\text{b–coord’s reflected, } & \quad a_f = b_3, \\
\text{strength inequality on } a_h & : \begin{cases}
\alpha_+ + 2\alpha' + \beta \geq b_1 + b_2 + b_3, \\
\alpha_- + \beta \geq -b_1 + b_2 + b_3, \\
\alpha_- - \beta \geq -b_1 + b_2 + b_3, \\
\alpha_+ - \alpha' \geq b_3, \\
\alpha_+ - \alpha' - \alpha'' + \beta \geq b_2.
\end{cases}
\end{align*}
\]

\[
\begin{align*}
\text{b–coord’s unreflected, } & \quad a_f = b_1, \\
\text{slant inequality on } a_f & : \begin{cases}
\frac{\alpha_+ + \alpha}{} + \beta \geq -b_1 + b_2 + b_3, \\
\frac{\alpha_+ + 2\alpha' + \beta}{} \geq b_1 + b_2 + b_3, \\
\frac{\alpha_- - \beta}{} \geq -b_1 + b_2 + b_3, \\
\frac{\alpha_+ - \alpha'}{} \geq b_3, \\
\frac{\alpha_+ - \alpha' - \alpha'' + \beta}{} \geq b_2.
\end{cases}
\end{align*}
\]

\[
\begin{align*}
