Abstract

Magnetotactic bacteria (MTB) are endowed with an exquisite orientation mechanism allowing them to swim along the geomagnetic field lines [1–3]. This mechanism consists of a chain of bio-synthesized magnetic nano-crystals [1, 4, 5]. Although the physics behind the minimum size of this biological compass is well understood [6], it is yet unclear what sets its maximum size [6–8]. Here, by using a macroscopic experiment inspired in these microorganisms, we show that larger magnetic moments will drive the collective behavior of MTB into a phase where bacteria are unable to swim freely, in detriment of their evolutive fitness [3, 9]. Simple macroscopic experiments, numerical simulations, and analytic estimates are used to explain the upper limit for the size of the chain of nano-crystals in MTB. Our macroscopic bio-inspired experiment, and physical model provide new opportunities to explore and understand the phases of magnetic active matter at all scales.

* andres.physics.research@gmail.com

Magnetotactic bacteria (MTB) contain magnetosomes, which are intracellular, ferrimagnetic nano-crystals of magnetite or greigite. Magnetosomes are usually arranged in a linear chain within each bacterium (e.g: *Magnetospirillum magneticum*, *Magnetospirillum magnetotacticum*)[1, 4–6, 10], with few known exceptions (*Magnetobacterium bavaricum*) [11]. This linear chain provides a net magnetic moment, \vec{M} , that allows MTB to align to the geomagnetic field, \vec{H} , in a noisy environment [6]. The reason for this, is that oxygen is toxic for these microaerophilic or anaerobic organisms, and it is beneficial for them to be directed toward and kept in the sediments away from the water surface where oxygen is abundant [1, 3]. This mechanism can be understood as the competition between the aligning dipolar energy, $\vec{M} \cdot \vec{H}$, and the thermal noise $k_B T$. Thus, for MTB to align respect to the Earth’s magnetic field, both quantities should be comparable. This well known and accepted criterion provides a lower bound for the magnetosome chain size [6, 8, 12]. In the same spirit, we should expect that the larger the dipolar moment of MTB, the better. However, MTB with large magnetic moments have not been observed in nature. Inspired by this apparent paradox, and the general subject of the effect of long range interactions in active matter, we have built an artificial system that allows for the exploration of these questions, and provide a flexible tabletop experiment to investigate magnetic active matter (MAM), Fig.1.

In this article, we demonstrate that there is a strong physical constraint for the maximum dipolar moment of single magnetosome chains. This constraint arises from the fact that MTB need to be able to swim into regions of low oxygen, but for large dipolar moments a collection of MTB will enter into a phase where they will form magnetic clusters making it impossible for them to efficiently swim (See Figs.1-4). Thus, if mutants grow magnetosome chains with extremely large magnetic moments they will self-assemble into dimers, or magnetic clusters (See Figs. 1, 3 and 4), generating a new compound object in which flagellar motion will be suppressed, decreasing their ability to swim. Thus, MTB with extremely large magnetic moments will not prevail.

The generic formation of clusters of particles being them inanimate or active shows up in a plethora of phenomena ranging from chemistry to physics, biology to astrophysical objects [15–21]. The existence and evolution of these structures at different length scales are intimately tied to the type of interactions between their basic constituents, particle symmetries, and emergent symmetries that may show up due to interactions [22–24]. For

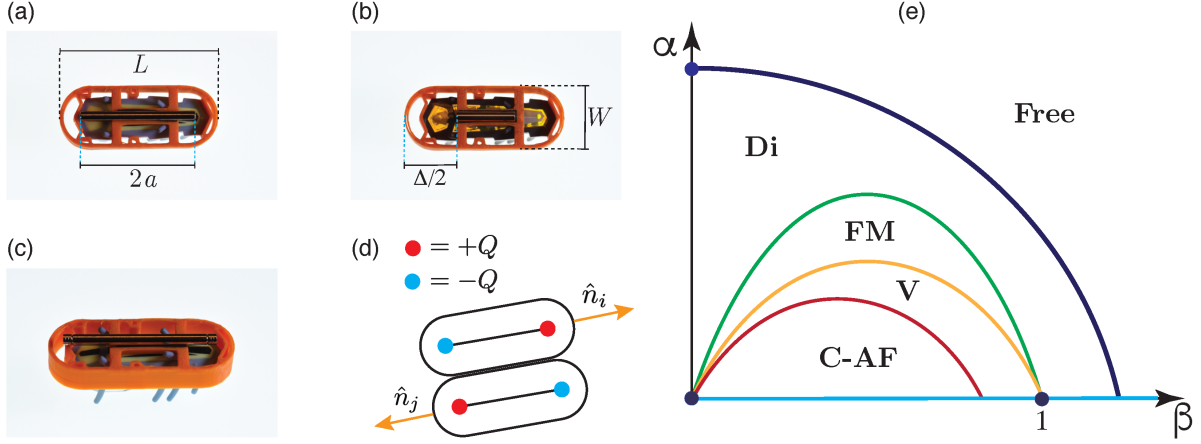

FIG. 1. Magnetic Active Matter (MAM) and its phase diagram: (a – c), Models built with a Hexabug Nano covered by a 3D printed armor, and Neodymium magnets of different sizes. $L = 51.8$ mm in all cases, and Neodymium magnets have a length, $2a = 38.1$ mm, 19.05 mm, and 42.86 mm, respectively. The purpose of the armor is twofold, to hold the magnets that will generate the long range interaction, and to simplify the collisions by providing a hard and smooth boundary. Each cylindrical magnet shown has radius $r = 1.5875 \times 10^{-3}$ m, and saturation magnetization $M_s = 1.1 \times 10^6$ A/m (See Supplementary Material S5). (d) In MAM each dipole is modeled as a magnetic dumbbell [13, 14] having two magnetic charges $+Q, -Q$ at the poles of the rod, where $Q = M_s \pi r^2$. Their north and south poles are highlighted in red and blue, respectively. The shortest distance between two colinear magnets is Δ , and \hat{n}_i is the vector director for the i -th particle. See Supplementary Movies 1 to 6 for experiments. (e) Schematic phase diagram for MAM as function of the dimensionless parameters α , and β . α representing the competition between inertia and activity, and β the competition between rotational noise and magnetic interactions. We have found five phases where four of them could be relevant for MTB. (**Free**) Non-interacting regime, (**Di**) dimers, (**FM**) winding and unwinding of magnetic vortices with local ferromagnetic order, (**V**) stable vortices, and (**C – AF**) anti-ferromagnetic clusters. The $\alpha = 0$ lines (Cyan) is the region relevant for natural or artificial micro-swimmers.

active agents endowed only with self-avoidance and/or local aligning interactions, there are different phases that have been theoretically analyzed and experimentally observed [25–30]. For example, the full phase diagram of Brownian disks has been discussed [31], the effect of hydrodynamic interactions in the collective behavior of fish [32], the onset of collective

and cohesive motion [33], the existence of a spontaneously flowing crystal of self-propelled particles [34], to name a few. In the previous cases no long-range interaction has been taken into account [25–32, 35]. However, recently it has been proposed that dipolar active matter can show a rich phenomenology, where depending on several parameters fission or fusion of particle clusters have been predicted [36, 37], directed self-assembly of quadrupolar particles has been reported [38], and in ferromagnetic colloids the collective motion and its different phases experimentally analyzed [39]. The previous results are a clear call to analyze the impact of cluster formation in the evolution of swimming bacteria that contain a chain of magnetic nano-crystals endowing these organisms with a dipolar moment.

In what follows, we set a general framework to study MAM (Fig.1), provide simple methods to measure all parameters of the model, characterize the phases shown by MAM at low densities, define the relevant dimensionless parameters at play in this system (See Supplementary Information S1 and S2), and provide strong evidence for our claims about the maximum dipolar moment for MTB. We observed the evolution of a group of these active particles for several interaction strengths and activities. Using this experimental insight, we implemented a model that accurately reproduces the different dynamical structures observed in experiments (Figs.1 and 2): free single particles, quadrupolar dimers, winding of magnetic vortices, unwinding of vortices into ferromagnetic chains, and multipolar clusters (See details of experiments and numerical simulations in Supplementary Information S1-S8). We rationalize these findings using dimensionless numbers that depend on the strength of the magnetic interactions between particles, activity, and angular noise (See Supplementary Information and Eqs.1-3). We explored an enlarged parameter space by using numerical simulations and analytic estimates to understand the main factors that impact in the different phases that MAM display. The phases found in our experiments are relevant for programmed self-assembly, and they should persist across different length scales [15, 16, 40]. The latest allows us to understand the physical constraints that affect key aspects of the evolution of MTB [1, 41, 42] using the insight from our macroscopic experiments.

The system that we study is composed of bacillus shaped active particles that are built with commercially available Hexbug Nano (HEXBUG Nano, <https://www.hexbug.com/nano>). We dubbed these macroscopic agents **MagD-bots**. Even though vibration-driven vehicles of this type have been used before in several experiments [27, 29, 43–45], the sharp geometry of its body, and highly frictional material they are made, makes it unclear that

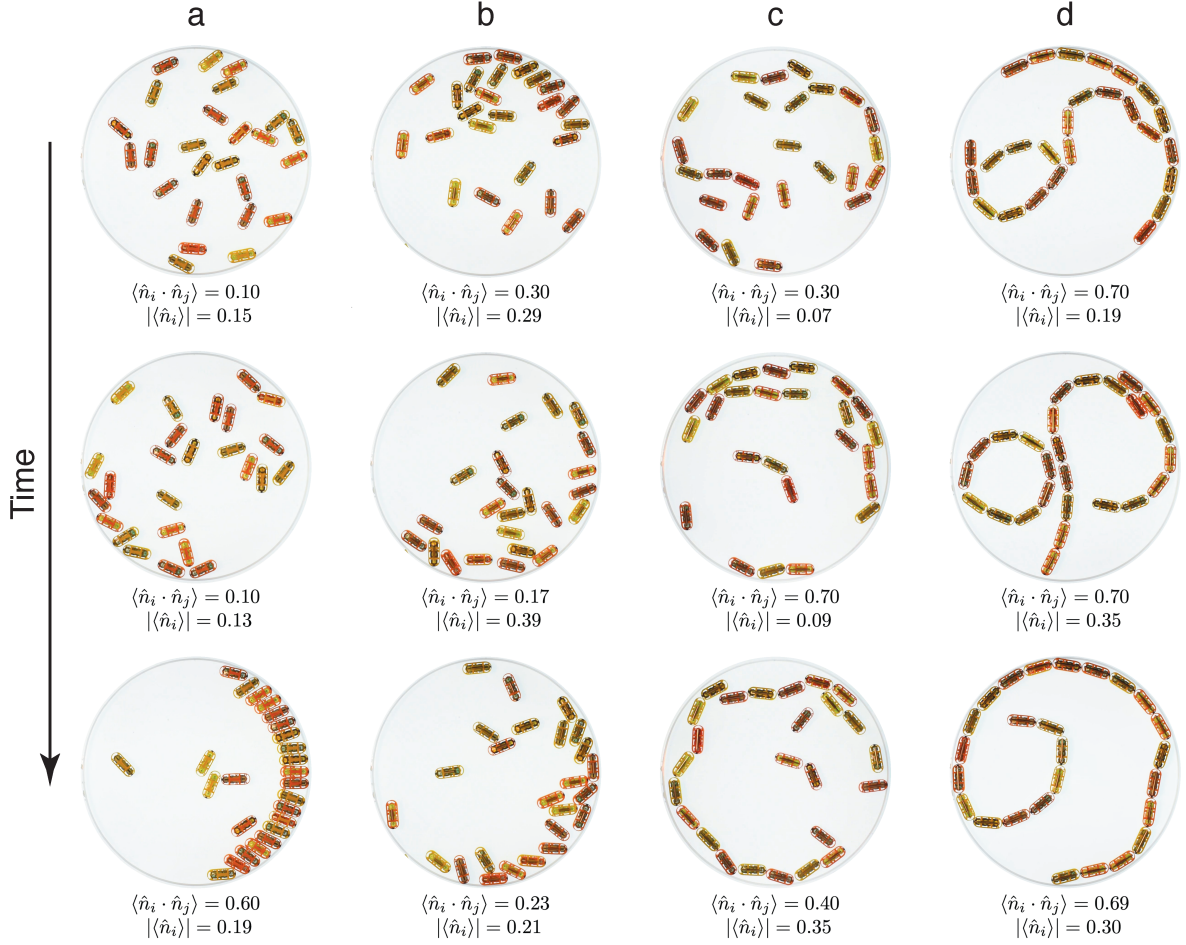

FIG. 2. Experimental configurations and correlations of magnetic active matter: (a) The case of zero magnetic interactions. (b) **MagD-bots** have been decorated with magnets of length $2a = 19.05$ mm, and diameter $2r = 3.175$ mm, $Q = 7.9$ Am and $N = 25$. (c) **MagD-bots** have been decorated with magnets of length $2a = 38.10$ mm, and diameter $2r = 3.175$ mm, $Q = 7.9$ Am and $N = 25$. (d) **MagD-bots** have been decorated with magnets of length $2a = 44.45$ mm, and diameter $2r = 3.175$ mm, $Q = 7.9$ Am and $N = 26$. Below each panel the average magnitude of the \hat{n}_i variable, and the $\langle \hat{n}_i \cdot \hat{n}_j \rangle$ correlations are shown. The domain diameter was 400 mm. See also Supplementary Movies 1 to 6.

the agreement between experiments and models is real or an artifact. To overcome this difficulty, we have dressed the Hexbugs with a 3D printed armor with a bacillus shape. The total body length $L = 51.8 \times 10^{-3}m$, width $W = 20.4 \times 10^{-3}m$, mass $M \sim 10 \times 10^{-3}kg$, and simple geometry have allowed us not only to improve the stability of the system by

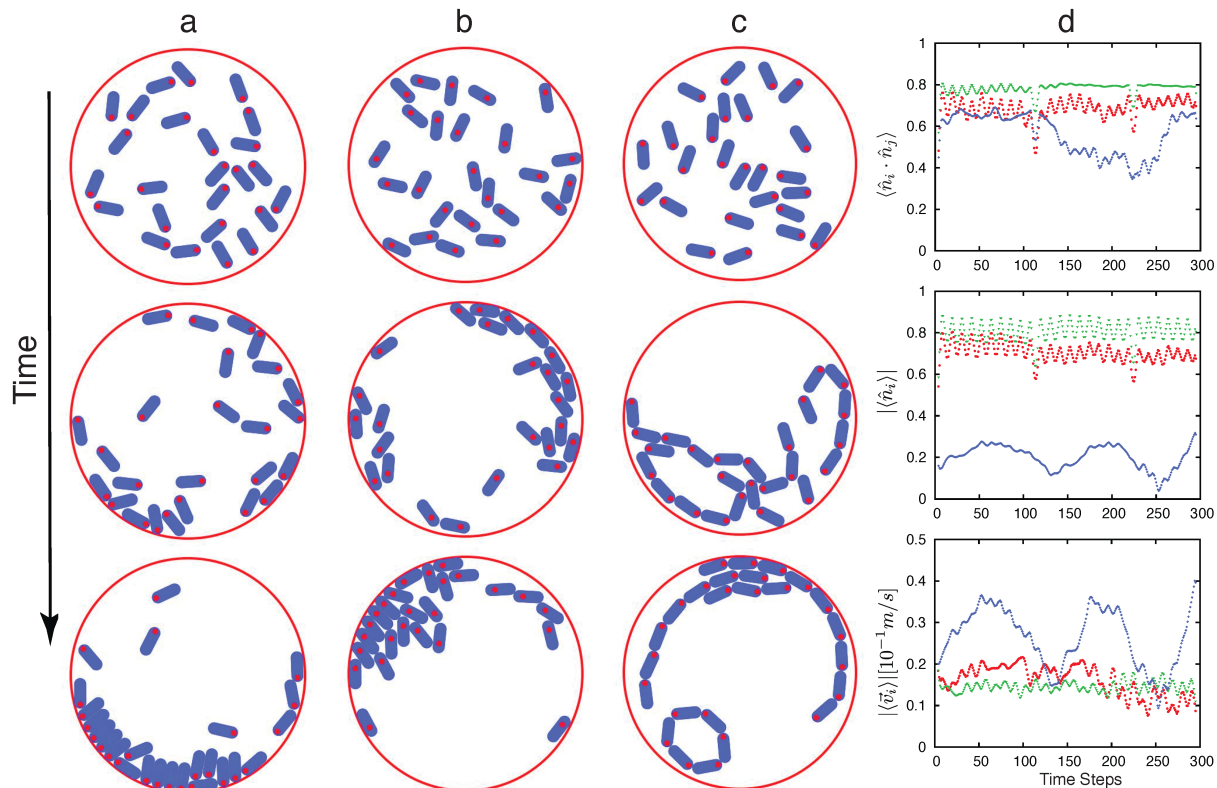

FIG. 3. Numerical configurations and correlations of magnetic active matter: We have simulated the evolution of $N = 25$ **MagD-bots** starting from a random initial condition ($t = 0$). The simulation domain diameter was 400 mm. (a) Evolution for $Q = 0$ considering the other physical parameters fixed. (b) Evolution of $Q = 8$ and $2a = 19.05$ mm for all other physical parameters fixed. (c) Evolution of $Q = 8$ and $2a = 38.10$ mm for all other physical parameters fixed. (d) From top to bottom: $\langle \hat{n}_i \cdot \hat{n}_j \rangle$ correlation, the magnitude of $\langle \hat{n}_i \rangle$, and the magnitude of the average velocity $\langle \vec{v}_i \rangle$, as function of time for the above configurations. a, b, c correspond to red dots, green triangles, and blue rhombi respectively. See also Supplementary Movies 7 to 9.

lowering its center of mass, lower the friction between walls and active agents, but also, to simplify numerical simulations. These structured armors allow for the precise positioning of a Neodymium magnet on top of them. Thus, we have built a set of active agents that interact via a magnetic field, and hard-core interactions. We emphasize that in this work the size of magnet is not small compared with the size of the object, making it mandatory to adopt a dumbbell model instead of a point-like dipole [14, 46–51].

Our main findings are summarized in Fig.1 where five qualitatively different phases are

shown. In the non-magnetic case, phase **Free** (Fig.2a and Supplementary Movie 1) we observed weak correlations and mainly geometric effects in agreement with previous reports [28]. For large activity and short magnets, we observed particles that show weak ferromagnetic correlations that influence the final state, but still without forming any spontaneously self assembled structure, phase **Di** (Fig.2b and Supplementary Movie 2). As activity decreases or increasing the strength of magnetic interactions we observed strong ferromagnetic correlations and the formation of new structures such as dimers, ferromagnetic chains, and vortices not found in the previous cases, phase **FM** (Fig.2 c and Supplementary Movie 3). As magnetic interactions increased long chains assemble and the system shows clear ferromagnetic order, stable vortices, and the fusion of different objects, phases **FM**, and **V** (Fig.2 d, Supplementary Movies 4, and 5). Finally, for low rotational noise we observe the formation of anti-ferromagnetic ordered clusters that are relevant for the quasi-static self-assembly of magnetic particles, phase **C – AF** Fig.1 (See Supplementary Movie 6).

We rationalize our findings considering the Newtonian dynamics of active magnetic matter described by

$$\begin{aligned} M \frac{d\vec{v}_i}{dt} &= F_0 \hat{n}_i - \Gamma \vec{v}_i + \vec{f}_i^a + \vec{f}_i^c \\ I_z \frac{d^2\theta_i}{dt^2} &= -\Gamma_r \frac{d\theta_i}{dt} + (\vec{\tau}_i^c + \vec{\tau}_i^a) \cdot \hat{z} + \sqrt{2D_r} \eta_i(t) \end{aligned} \quad (1)$$

where i is the particle index, θ_i is the angle between the horizontal axis and the \hat{n}_i vector shown in Fig.1d. In this model, the tip of each rod has a magnetic charge of magnitude $Q = M_s \pi r^2$ that interacts with all other magnetic poles (note that the total magnetic charge per dipole is zero). M , F_0 , Γ , I_z , Γ_r , and D_r are the **MagD-bot** mass, activity, damping, moment of inertia, rotational damping, and rotational diffusion respectively (See Supplementary Information S1-S3). \vec{f}_i^a , and $\vec{\tau}_i^a$ represents forces and torques due to contacts. \vec{f}_i^c , $\vec{\tau}_i^c$ are the force and torque due to Coulomb interactions, and $\eta_i(t)$ is a white noise with mean 0 and variance 1.

Analyzing the translational equation of motion the dimensionless numbers $F_0 \tau (M v_0)^{-1}$ and $\Gamma \tau M^{-1}$ emerge, where $\tau \sim L/v_0$ is a typical time scale for the translational motion of each **MagD-bot**. In steady-state both terms should be comparable. Therefore, it is enough to consider only one of them to understand the competition between different forcing terms.

We called the inverse of the first dimensionless number

$$\alpha = \frac{Mv_0^2}{F_0L}. \quad (2)$$

This dimensionless parameter quantify the competition between the centripetal force ($Mv_0/\tau \sim Mv_0^2/L$), and the activity, F_0 , of the **MagD-bot**. The second dimensionless number relevant in this case appears by considering the rotational dynamics. In the low mass limit, the one relevant for MTB, the main forces competing will be the Coulombic torque τ^c and the torsional noise amplitude τ^r . We called this parameter:

$$\beta = \frac{\tau^r}{\tau^c} \quad (3)$$

where $\tau^r = (2D_r)^{1/2}$ and $\tau^c = \left(\frac{\mu_o}{4\pi}\right) \frac{Q^2}{(2R)^2}a$. In this article we focus on two dimensionless parameters (α and β), but the richness of the dynamics defined by Eqs.1 is enormous. Indeed, there are five dimensionless parameters (See Supplementary Information S1, S2).

We proceed to examine the dynamics of the system in detail using molecular dynamics simulations (See Fig.3 and Supplementary Information). In this description, inertial magnets interact through the full long-range Coulomb potential in the dumbbell approach [14, 46–51].

The physical parameters employed in numerical simulations were directly measured (See details in Supplementary Information). The measurement of F_0 , and Γ was done by using an incline and analyzing quasi-1D trajectories (See Supplementary Information S4). I_z was measured using a torsion pendulum configuration (See Supplementary Information S7), and Γ_r was measured by analyzing the angular dynamics after a **MagD-bot** hits a hard wall (See Supplementary Information S8). Magnetic interactions were measured using special non magnetic holders installed on an Instron universal testing machine that measured the interaction force between magnets (Supplementary Information S6). From this information we calibrated the magnets used in our experiments obtaining a saturation magnetization as $M_s = (1.1 \pm 0.10) \times 10^6 \text{ A m}^{-1}$ which is in agreement with the available data for the magnetization of Neodymium rods, validating the dumbbell approximation when the rods are separated by a distance $z > 2r$, as previously pointed out [13, 46, 47]. That information allowed the measurement of the magnetic charge in the dumbbell approximation. The ratio between Γ_r and the rotational noise amplitude, D_r , was measured using the angular autocorrelation of $\theta(t)$ (See Supplementary Information S8). Therefore, in our simulations there are no free parameters in striking contrast with most available literature. Simulation

results for **MagD-bots** are shown in Fig.3 in good agreement with experimental results (Fig.2). The evolution of three different regimes are shown in Supplementary Movies 7-9.

We characterized the system by computing the correlations $\langle \hat{n}_i \cdot \hat{n}_j \rangle$, the magnitude of the average $|\langle \hat{n}_i \rangle|$, the magnitude of the average velocity $|\langle \vec{v}_i \rangle|$, and average speed $\langle |\vec{v}_i| \rangle$ as functions of time [28, 33, 52]. In Fig.3 we show representative frames for numerical simulations of MAM where no magnets were present (Fig.3 a), magnets of length $2a = 19.05$ mm (Fig.3 b), and magnets of length $2a = 38.1$ mm (Fig.3 c). For Fig.3 a, we found no ferromagnetic order, but from time to time a boundary driven stagnation state [28]. In Fig.3 b a signal of ferromagnetic correlations emerges, and finally it is quite clear that ferromagnetic order is present in Fig.3 c. In agreement with experiments, see Fig.2 and supplementary movies 7-9.

Our macroscopic experiment, and detailed numerical model allow us to draw conclusions and make predictions on the phases, and stability of MAM at the microscale. To analyze the impact of increasing magnetic moment in MTB we have performed detailed numerical simulations in a region of physical parameters relevant for MTB (See Supplementary Tables VIII and IX). Furthermore, the view of the magnetosome chain in MTB as a magnetic dumbbell has been directly measured using extremely sensitive Nitrogen vacancy centers [53]. For the simulations shown in Fig.4, we have used bacterium length $L = 5\mu\text{m}$, width $W = 1.6\mu\text{m}$, magnetic chain length $2a = 1.1\mu\text{m}$, $Q_o \sim 9.4 \cdot 10^{-10}$ Am, and average swimming speeds of order $v \sim 30\mu\text{m/s}$ [2, 5, 6, 10, 54, 55]. This lead to dimensionless parameters $\beta \sim 10$ and $\alpha \sim 1.5 \cdot 10^{-7}$, which are far from clustering (see Fig.1e). To increase the magnetic moment in our in-silico experiments we have increased the charge from Q_0 to $4Q_0$, and then to $10Q_0$. We obtained the dynamics of that microscale MAM, Fig.4 a-c (See Supplementary Movies 10, 11, and 12), and computed the evolution of different order parameters Fig.4 d,e. Our data shows the emergence of a **C – AF** phase at large dipolar moment ($\beta < 1.0$), and a sharp decrease in the average speed of the collective motion, which will be detrimental for MTB survival [9]. For MTB to have an efficient magnetotactic advantage, they should inhabit the **Free** phase region of the phase diagram. That means that in nature the **FM**, **V**, and **C-AF** configurations should be avoided as they strongly lower the swimming efficiency of MTB by interfering with flagella motion [56], or by forming clusters of extremely low magnetic moment.

Given that dipolar moment can be increased by increasing Q , or by increasing $2a$, we

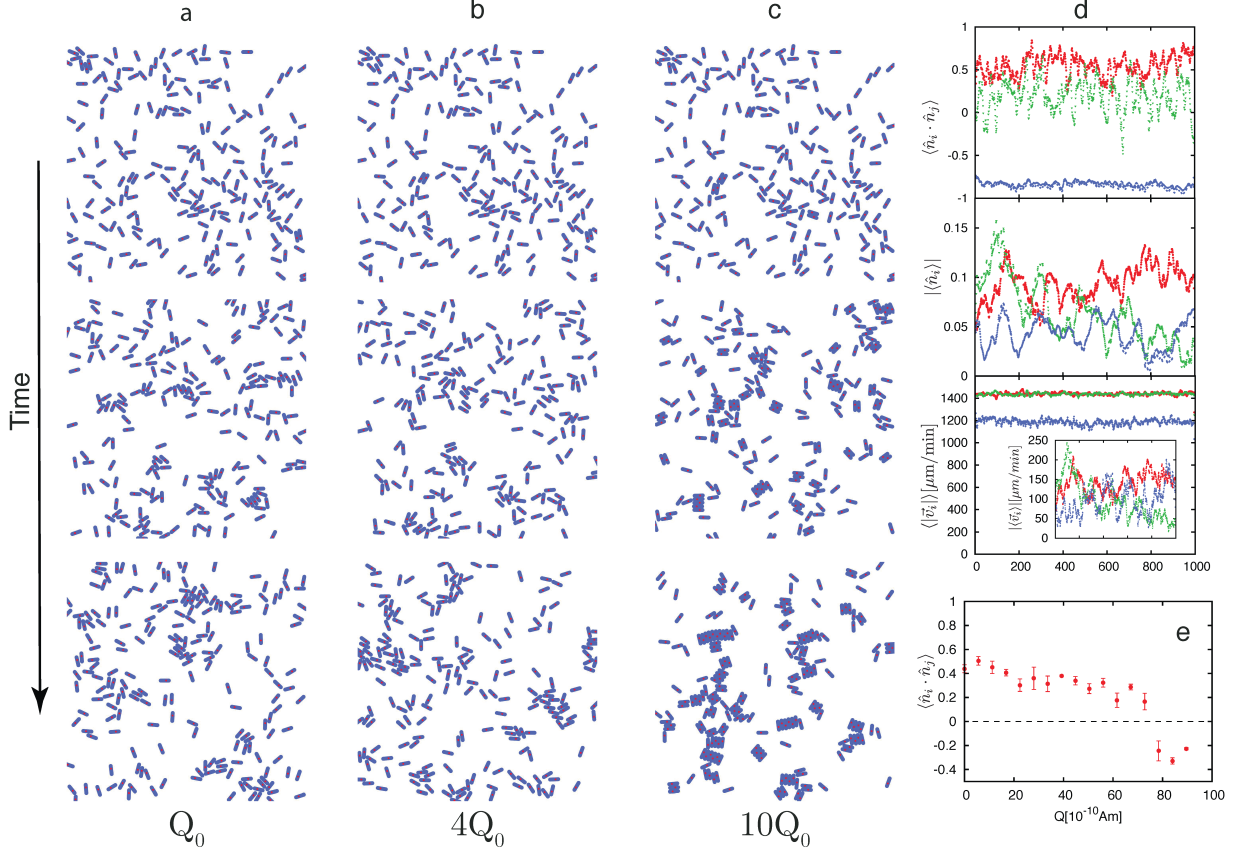

FIG. 4. Numerical simulation for parameters relevant for MTB: **(a)** Using the parameters $Q_0 = 9.4 \cdot 10^{-10} \text{Am}$, $2a = 1.1 \mu\text{m}$, $L = 5 \mu\text{m}$, $W = 1.6 \mu\text{m}$, and $M \sim 10^{-15} \text{kg}$, we simulated the dynamics of MTB. In this case, they do not self-assemble in any superstructure. **(b)** In this simulation we have increased the dipolar moment of our in-silico MTB by increasing the magnetic charge $Q = 4Q_0$, while keeping all other parameters fixed. **(c)** Case for $Q = 10Q_0$, MAM in this parameters region quickly self-assemble in clusters that show anti-ferromagnetic order, making it impossible for MTB to freely swim. **(d)** From top to bottom: Nearest neighbor correlations, average spin, and average velocity (inset: average speed) as function of time for the above configurations. **a**, **b**, **c** correspond to red dots, green triangles, and blue rhombi, respectively. See also Supplementary Movies 10 to 12. **(e)** Nearest neighbor correlations as function of magnetic charge Q . This plot shows a transition from ferromagnetic order to anti-ferromagnetic order at $Q = 7.5 \cdot 10^{-9} \text{Am}$.

provide a simple bound for Q_{max} the maximum magnetic charge that a magnetosome chain can have before going into a **C-AF** phase. Considering two MTB aligned side by side (Fig.1d), they will not form a cluster as long as $\beta > 1$. That is, $(\mu_0/2\pi)Q_{max}^2 a/(2R)^2 \leq$

$(2D_r)^{1/2}$. This bound gives $Q_{max} \sim 9 \cdot 10^{-10} \text{Am}$, for $D_r = 2.5 \cdot 10^{-38} \text{kg}^2 \text{m}^4 \text{s}^{-3}$, $R = 0.30 \mu\text{m}$, and $2a = 1.0 \mu\text{m}$, consistent with observations [4, 6, 57, 58]. On the other hand, considering a fixed the magnetic charge, we can find the maximum length for the magnetosome chain to avoid cluster formation. In this case, $a_{max} = (2\pi/\mu_0)(2D_r)^{1/2}(2R)^2/Q^2 \sim 450 \text{nm}$ in agreement with reported chain lengths [4–6, 10]. That is, MTB grow magnetic dipoles that are strong enough to align MTB to the geomagnetic field in a noisy environment, but weak enough to avoid the formation of magnetic clusters.

Our platform, physical model, and numerical simulations of MAM have allowed us to explore the effects of magnetic interactions in active matter at very dissimilar length scales, and show that increasingly large magnetic moments, which in theory should provide an evolutive advantage for MTB, will do the opposite. Large magnetic moments will promote the formation of clusters of MTB that are detrimental for these organisms. Our work paves the way not only to a better understanding of the evolution of MTB, but also to explore magnetic self-assembly at diverse length scales. We anticipate that MAM can be programmed by modifying its magnetic textures, activity, geometry, or the related dimensionless parameters that characterize this system. This is a first step towards functional bioinspired magnetic active matter at all scales.
