(Dated: November 10, 2021)

The spin-orbit interaction is the key element for electrically tunable spin qubits. Here we probe the effect of cubic Rashba spin-orbit interaction on mixing of the spin states by investigating singlet-triplet oscillations in a planar Ge hole double quantum dot. By varying the magnetic field direction we find an intriguing transformation of the funnel into a butterfly-shaped pattern. Landau-Zener sweeps disentangle the Zeeman mixing effect from the spin-orbit induced coupling and show that large singlet-triplet avoided crossings do not imply a strong spin-orbit interaction. Our work emphasizes the need for a complete knowledge of the energy landscape when working with hole spin qubits.

The spin-orbit interaction (SOI) allows electrical manipulation of individual spins and has therefore become a key ingredient for the realization of fully electrically controlled spin qubits [11, 12]. In Si, for electrons it is rather weak and synthetically boosted by means of micromagnets [3, 4]. For holes, on the other hand, it is an intrinsic property which allows to perform electron dipole spin resonance (EDSR) measurements [1, 2, 5–9]. In Ge it is particularly strong leading to Rabi frequencies beyond 100 MHz [7, 10, 11]. SOI for holes can be linear and influences the system dynamics. We tune the DQD to an effective charge transition (2,0) ↔ (1,1), with (n_L, n_R) where n_L (n_R) denotes the effective hole number in the left (right) quantum dot (see Supplementary Fig. S1). We emphasize that the real decision factor for the size of the anticrossing [18, 19].

Here we study a double quantum dot singlet triplet hole qubit realized in planar Ge. We characterize the complete spectrum of our system by observing the dynamics under different pulsing schemes and magnetic field directions. We investigate the S − T_0 avoided-crossing by means of Landau-Zener tunneling and find that a typical cubic SOI parametrized by an in-plane spin-flip tunneling term t_{SO} is insufficient to describe the observed angular B-field dependence. In fact, the different g-factor anisotropy in the two quantum dots greatly enhances ∆_{ST_0} in the in-plane magnetic field direction and influences the system dynamics.

A scanning electron microscope (SEM) image of the device under consideration is depicted in Fig. 1, and further details can be found in [14]. A hole gas confined in a Ge quantum well is buried 20 nm below the surface. A charge sensor (CS) connected to a radio-frequency (rf) reflectometry circuit is used to read out the charge state of the gate defined DQD. For qubit state selective read-out we rely on Pauli spin blockade. Fast detuning pulses are applied to gates LB and RB with an arbitrary waveform generator (AWG) which has a pulse-rise time of τ_{rise} ≈ 2 ns (inset of Fig. 1b). Throughout this work we apply a small magnetic field in a plane perpendicular to the quantum dot axis, B = (B \cos(\theta), 0, B \sin(\theta)), where \theta describes the tilt angle from the in-plane direction. We tune the DQD to an effective charge transition (2,0) ↔ (1,1), with (n_L, n_R) where n_L (n_R) denotes the effective hole number in the left (right) quantum dot (see Supplementary Fig. S1). We emphasize that the real
FIG. 1. a) SEM image of the device consisting of a double dot electrostatically defined by gates LB, L, CB, R and RB. The charge sensor (CS) is coupled to an LC-resonator for Ohmic-reflectometry via a lock-in amplifier. Pulses are applied to gates LB and RB via an arbitrary waveform generator with a minimum rise time of 2 ns (inset). b) The energy level diagram as a function of detuning highlights the relevant energy splittings between S and T₀ and S and T₋. At ϵ = ϵ*, S and T₋ anticross with a splitting 2Δ_S₋. c) Energy level diagram of the states involved in the passage over the avoided crossing (red circle in b)). The probability P_LZ to maintain the initial state after a single passage over the avoided crossing is given by the Landau-Zener formula. d) Pulsing ϵ over the S₋T₋ degeneracy will result in a mixing of the two states when ϵ = ϵ*. Here we show the resulting return signal for a magnetic field applied at an angle θ = 90° from the in-plane direction. A high signal corresponds to a larger triplet return probability. The lower inset displays the pulse sequence where only the amplitude ϵ is varied. e) At θ = 60° compared to d) the degeneracy is sharper indicating a smaller value of ∆_ST₋. f) For θ = 10° the degeneracy is not a funnel-like sharp line but rather an oscillation pattern resembling a butterfly shape. Such features appear when the S₋T₋ mixing term becomes substantial. At low ϵ S₋T₋-like oscillations are prominent. At higher detuning also S₋T₀-like oscillations become more visible.

hole number in the left dot is n_L + 2 while in the right dot we cannot determine the exact hole number. The tunnel coupling between the dots is described by t_C while the energy detuning between the S(2,0) and S(1,1) state is parametrized by ϵ. Each quantum dot is characterized by an out-of-plane and an in-plane g-factor, g⊥ and g∥, respectively. However, the dynamics of singlet-triplet qubits is only sensitive to differences in, or the average of, the Zeeman energy between the dots, and hence we define g = g_L ± g_R as the g-factor difference and sum. The energy spectrum of the system (the complete Hamiltonian H_t is derived in Supplementary section VI) is depicted in Fig. 1 as a function of ϵ. At ϵ = ϵ* the S and T₋ states anticross.

We start by mapping out the S₋T₋ degeneracy as a function of magnetic field angle with the funnel technique [20]. Here, mixing between S and T₋ is induced by pulsing the system close to ϵ = ϵ*. Mixing depends both on the size of the avoided crossing and the mixing time τ_S. We apply a rapid pulse of duration τ_S = 65 ns and varying ϵ (inset of Fig. 1). Fig. 1d,e and f depict the phase response of the charge sensor in the measurement point as a function of the pulse amplitude on ϵ and the magnetic field strength for θ = 90°, 60° and 10°, respectively. A high return signal corresponds to a larger triplet probability. In the out of plane direction we observe the expected funnel shape of the S₋T₋ degeneracy. At 60° we similarly observe a typical funnel shape, however, we notice the line to be fainter which indicates a smaller ∆_ST₋. The picture drastically changes towards the in-plane direction where the S₋T₋ degeneracy develops interference fringes with a pattern resembling a butterfly; 2 main components can be attributed to S₋T₋ oscillations at low detuning and S₋T₀ oscillations becoming more prominent at high detuning. The prominent S₋T₋ oscillations are an indication of a large coupling term in the in-plane direction. The angular anisotropy of the funnel pattern, further exemplified in Fig. S5, is the main focus of this work and requires knowledge of the full Hamiltonian and therefore an understanding of the interplay between the g-factor anisotropy and the spin-flip element t_SO.
appropriate pulses to (1,1) induce either of 20 nm according to Eq. (1). On top, we schematically show arrow highlighting the visible transition. g) Effect of the con- produce the frequencies seen in b (d) with the blue (green) 

\[ f \approx \frac{1}{2} \sqrt{J^2 + (g'\mu_B B)^2} \]

is the velocity calculated at \( \epsilon = \epsilon^* \) and \( J(\epsilon) = \sqrt{\epsilon^2 + 2\epsilon^2 - \frac{\pi}{2}} \) is the exchange energy (Fig. 1a and c). If \( \epsilon \) varies the diabatic condition \( \langle P_{LZ} \rangle \approx 1 \) \( \vec{S} - \vec{T}_0 \) oscillations with a frequency \( f = \frac{1}{2} \sqrt{J^2 + (g'\mu_B B)^2} \) will be favored. With \( P_{LZ} < 1 \) the \( \vec{S} - \vec{T}_0 \) oscillations are suppressed and the qubit is initialized in a superposition of \( S \) and \( T_- \). After a time \( \tau_s \) the system is pulsed back to the measurement point where another non-diabatic passage will cause an interference between the two states similar to a Mach-Zhender interferometer [22]. The accumulated phase difference is then given by \( \phi = 2\pi f S - T_\perp \tau_s \approx \frac{\tau_s}{\pi} |J - \frac{1}{2} g^+ \mu_B B| \) [21] (see Fig. 1b). As the oscillation frequency of the \( \vec{S} - \vec{T}_0 \) qubit is proportional to \( g^- \) while the one of the \( \vec{S} - \vec{T}_\perp \) qubit is proportional to \( g^+ \) (Fig. 1d and 2e) we can extract the individual g-factors without the need for EDSR. We fix the magnetic field at \( |B| = 2 \text{ mT} \) and observe the oscillations resulting from a fast pulse \( (\tau_{\text{rise}} = 2 \text{ ns}) \) in Fig. 2a and a ramped pulse with ramp time \( \tau_R = 100 \text{ ns} \) of amplitude \( \epsilon = 4 \text{ meV} \) and dura- tion \( \tau_S \) in Fig. 2e as we rotate the field. From the fast Fourier transform (FFT) in Fig. 2e and d we extract the oscillation frequency \( f_{S-T_0} \) (blue dots) and \( f_{S-T_\perp} \) (green dots). We notice that for \( \theta \in [-25^\circ, +25^\circ] \) in both FFT plots the \( \vec{S} - \vec{T}_\perp \) frequency is visible suggesting that a large coupling term is present at these magnetic field di- rections inducing a non-diabatic passage, in line with the observations in Fig. 1f. Moreover, in Fig. 2f the FFT power vanishes for \( \theta \approx 60^\circ \) indicating that the ramp time \( \tau_R \) induces a completely diabatic passage over the avoided crossing. This is in line with Fig. 1e where we observed a sharper \( \vec{S} - \vec{T}_\perp \) degeneracy characteristic of a smaller mixing term.

The lines arising in the FFT plots can be fit by the energy splitting between the three lowest lying states of the system depicted in Fig. 2f with \( g_+^* = 12.00, g_+^* = 2.04, g_{\perp}^+ = 0.10 \) and \( g_{\perp}^\perp = 0.43 \) and \( t_C = 11.38 \text{ µeV} \). The latter is extracted from exchange oscillation measurements (see Supplementary Fig. S2). By further fitting our model to the observed dynamics of the system under fast pulsing for magnetic field angles close to the in-plane direction (see Supplementary Sec. I) we confirm the extracted values and find good agreement between the observed frequency lines and our predictions.

Interestingly \( |g_{\perp}^-| > |g_{\perp}^+| \) while \( |g_{\perp}^-| < |g_{\perp}^+| \). This means that the g-factors in the out of plane direction have the same sign while they exhibit opposite signs in the in plane direction. To understand this observation we investigate the effect of the dot geometry on the g- factors, anticipating a particularly accentuated effect on the in-plane g-factor due to its small zeroth order value of \( g_{\perp}^0 \sim 0.2 \). This value is considered to be phenomeno- logical in the sense that it incorporates corrections due to system specific influences such as strain and mate-
Here, $\xi$, $\hbar$, $\Delta$ is the HH-LH splitting and to $\Delta$ from the fit. c) Comparison between the two contributions passage. The light colored data points are, therefore, excluded negative in one dot but not in the other for opposite Fig. 2g that the in-plane g-factor corrections can be in-plane confinement energies. It can be seen from the correction to the out-of-plane g-factor is $|g_{y,l}| < 10^{-2}$ for the values considered and hence negligible, the in-plane g-factor can be altered considerably, $g_\parallel = g_\parallel - \xi_1 \frac{\hbar(\omega_x - \omega_y)}{\hbar(\omega_x + \omega_y)} - \xi_2 \Delta$. (1)

Here, $\xi_1 \approx 20.3$ and $\xi_2 \approx 6.0$ are material specific constants, $\Delta$ is the HH-LH splitting and $\hbar \omega_{x,y}$ are the in-plane confinement energies. It can be seen from Fig. 2, that the in-plane g-factor corrections can be negligible in one dot but not in the other for opposite elliptical confinement.

We now turn to extract $t_{SO}$ by analyzing $\Delta_{ST}$ in more detail. After calibrating the sweep rate and position of the $S - T_-$ degeneracy (Supplementary Fig. 5), we perform Landau-Zener sweeps at $|B| = 20 \text{ mT}$ and extract $\Delta_{ST}$ from $P_{LZ}$ (Fig. 3). We vary $\tau_R$ during the first passage over the avoided crossing, creating a superposition of $S$ and $T_-$, and keep the return sweep diabatic in order to maintain this superposition (inset of Fig. 3). The extracted $\Delta_{ST}$ is reported in Fig. 3b. In general, $\Delta_{ST}$ may depend on effects influencing the hole spins such as the g-factor differences in the two dots, the SOI and possible effective magnetic field gradients caused by the hyperfine interaction [20]. While the hyperfine interaction can result in a strong out-of-plane hyperfine component $\delta b_{Z}$ for HH states due to a special Ising-type form [27], the inhomogeneous dephasing times extracted for $B_{\perp}$ of $\approx$ 700 ns at 1 mT in Ref. [14] give an upper limit for the hyperfine component $\delta b_{Z} < 2 \text{ neV}$, suggesting that the effects of the nuclear spin bath may safely be neglected.

In planar HH DQD systems the SOI can be parametrized by a real in-plane spin-orbit vector $t_{SO} = (t_x, t_y, 0)$. Such in-plane spin-flip tunneling terms stem from the cubic Rashba SOI [28], while this type of SOI does not induce out-of-plane terms $t_z$. In a basis in which the total Hamiltonian is diagonal in the absence of the SOI and g-factor differences, the $S - T_-$ splitting has the form [29]

$$\Delta_{ST} = \left| \Delta_{SO} \sin \left( \frac{\Omega}{2} \right) + \Delta_{E_Z} \cos \left( \frac{\Omega}{2} \right) \right|,$$ (2)

where the spin-orbit splitting $\Delta_{SO}$ and the Zeeman splitting $\Delta_{E_Z}$ due to anisotropic site-dependent g-tensors read

$$\Delta_{SO} = t_y + it_x \frac{g_\perp \sin \theta}{\sqrt{(g_\parallel \sin \theta)^2 + (g_\perp \sin \theta)^2}},$$ (3)

$$\Delta_{E_Z} = \frac{\mu B}{2\sqrt{2}} \frac{(g_\parallel g_\perp \sin \theta) \sin(2\theta)}{(g_\parallel \cos \theta)^2 + (g_\perp \sin \theta)^2},$$ (4)

and $\Omega = \arctan(2\sqrt{2} \ell C/\ell^*)$ is the mixing angle at the anticrossing. The analytical result (2) agrees well with the numerical results obtained by exact diagonalization of the system Hamiltonian for all $\theta$ except in a narrow region around $\theta = 0$ ($|\theta| < 2^\circ$, Fig. 3b). We attribute these deviations to the small in-plane Zeeman energies which violate the assumption of an isolated two-level system made when deriving (2) (see Supplementary Section VI). Due to the opposite sign g-factor corrections in the dots the Zeeman splitting $\Delta_{E_Z}$ can be the dominant contribution to $\Delta_{ST}$, exceeding the spin-orbit splitting by one order of magnitude at small angles. Even when the magnetic field has a large out-of-plane component, the effect of different g-factors can contribute crucially to $\Delta_{ST}$ (Fig. 3b).

The extracted $\Delta_{ST}$ in Fig. 3b can be fit by the model with $t_x$ and $t_y$ as free parameters and $t_C$, $g_\parallel$, $g_\perp$ extracted from previous measurements. Between -25 and -25° the splitting seems to drop to zero as the Landau-Zener assumptions of diabatic return sweeps are not met and an extraction of $\Delta_{ST}$ is not accurate. The black
FIG. 4. Funnel simulations with the master equation approach using qutip. a) Funnel for $\theta = 90^\circ$ showing the $S - T_-$ degeneracy as an increased triplet return probability. For large $\epsilon$ $S - T_0$ oscillations are visible but decay at higher fields due to relaxation processes [30]. b) Funnel for $\theta = 60^\circ$. Here the $S - T_-$ degeneracy is fainter than in a) because the interplay $t_{SO}$ and $g_{\perp}$ reduces the $S - T_-$ splitting. c) Funnel for $\theta = 10^\circ$ which now resembles a butterfly. The $S - T_-$ degeneracy evolves into an obvious oscillation pattern which interferes at large $\epsilon$ with the $S - T_0$ oscillations. The simulations take the model Hamiltonian with the experimentally extracted parameters as input and perform the time evolution calculation returning the combined triplet return probability ($(P_{T_0} + P_{T_-} + P_{T_+})$). All the simulations nicely reproduce the experimental data observed in Fig. 1. d) A simulation with $t_{SO} = 0$ but with all the other values of the model as in c) again reveals the butterfly shape of the $S - T_-$ degeneracy. Now even more oscillations can be seen as the $t_{SO}$ term does not reduce the size of $\Delta_{ST_-}$ caused by the g-factor difference at $\theta = 10^\circ$.

dashed line corresponds to the maximum $\Delta_{ST_-}$ that allows a diabatic passage with a rise time of 2 ns of our pulses ($P_{LZ,max} = 0.99 = \exp(-\frac{2\pi\Delta_{ST_-} \approx \Delta_{ST-\max}}{\hbar \epsilon})$). The model fits the dark blue datapoints with $t_x = 129.0 \pm 18.0$ neV and $t_y = -369.8 \pm 13.8$ neV, yielding the total spin-flip tunneling element $t_{SO} = \sqrt{t_x^2 + t_y^2} = 392.0$ neV. 

Having characterized all the elements in the Hamiltonian from indpendent measurements we can now reproduce the Funnel measurements in Fig. 1 (Fig. 4). In particular the sharper line at $\theta = 60^\circ$ (Fig. 4b) as well as the $S - T_-$ oscillations for $\theta = 10^\circ$ (Fig. 4c) reflect what we observe in the data. Even with $t_{SO} = 0$ the in-plane g-factor difference induces $S - T_-$ oscillations (Fig. 4d) further confirming its dominant role in determining the size of $\Delta_{ST_-}$.

Finally, we remark that in systems with a nonlinear SOI the spin-orbit length inferred from $t_{SO}$ cannot be regarded as a good figure of merit for material comparison anymore. Following Ref. [28], we express $t_{SO}$ in terms of the spin-conserving tunneling element $t_C$ using the explicit expressions obtained in Ref. [28]. We find

$$ t_{SO} = \frac{4t_C d}{3 t_{SO}} $$

where $d$ is the interdot distance and the spin-orbit length for a cubic Rashba SOI reads

$$ t_{SO} = \frac{1}{\lambda_R} \frac{4\hbar^2 + d^2 m \omega_0^2}{\sqrt{1 - S^2} d^2 m \omega_0^2} $$

for circular dots. Here, $\hbar \omega_0$ is the in-plane confinement energy, $m$ is the in-plane HH mass, $S$ is the overlap between the left and right dot states, and $\lambda_R$ is the effective cubic Rashba coefficient with units $[\lambda_R] = \text{energy/momentum}^3$. One can see that it depends not only on material parameters via $\lambda_R$ but also on the dot geometry via $\omega_0$, $d$ and $S$ (see Supplementary Sec. VII).

In conclusion, we have reconstructed the total Hamiltonian of our system from the dynamics of singlet-triplet oscillations. We have demonstrated that the g-factor anisotropy and in particular the in-plane g-factor sign difference can lead to a considerable contribution to $\Delta_{ST_-}$ in the in-plane direction. On the other hand, due to the interplay between $t_{SO}$ and the g-factors, all close to the out-of-plane direction are suitable for $S - T_0$ qubit operation as the main driving terms ($g_{\perp} \sin \theta$) are still large but the leakage to $T_-$ during initialization and read-out is suppressed (see Fig. 5). Our results emphasize that a detailed understanding of the g-factor anisotropy and the SOI are key in designing future qubit experiments in two-dimensional Ge hole gases and other systems where a strong SOI renormalizes the g-factors.

**Supplementary: Hole spin orbit physics in quantum dot systems with large g-factor differences**

**I. STABILITY DIAGRAM, PULSING, TUNNEL COUPLING**

The stability diagram around the transition of interest is reported in Fig. S1. The effective hole numbers are labelled “\((n_L, n_R)\)” while the real hole number is \((n_L + 2, 2n + n_R)\) since we do not know the exact number of holes in the right dot. The dashed triangle marks the region in which Pauli spin blockade occurs and the measurement point (M) is located at the center of it at \(\epsilon = \epsilon_M\). “I” marks the initialization point. The dispersion relation is overlaid on top of the “(1,1)” region. The avoided \(S - T_+\) crossing occurs at \(\epsilon = \epsilon^*\).

We extract the tunnel coupling from exchange oscillations. A typical pulse sequence to probe the exchange interaction \(J\) is depicted in the inset of Fig. S2a. After initialization in \(S(2,0)\) the system is pulsed rapidly to large \(\epsilon\) and left to evolve for a time corresponding to a \(\pi/2\) rotation around the x-axis of the Bloch-sphere. A subsequent pulse at lower \(\epsilon\) for a time \(\tau_S\) increases the exchange interaction \(J(\epsilon) = \sqrt{\frac{\epsilon^2}{4} + 2t_C^2 - \frac{\epsilon^2}{4}}\). Therefore, the oscillation frequency \(f = \sqrt{J(\epsilon)^2 + (g_{1,\mu_B}B)^2}\) will reflect the change in \(J\) and increase for lower \(\epsilon\). The fit in Fig. S2 therefore, allows to extract the tunnel coupling. As the coherence time for very low \(\epsilon\) tends to 0, all the points at \(\epsilon < \epsilon^*\) are not considered in the fit. \(\epsilon^*\) is highlighted by the black arrow where the \(S - T_+\) mixing is prominently visible.

**II. SINGLET-TRIPLET DYNAMICS FOR SMALL ANGLES**

We probe singlet-triplet oscillations at small angles by rapidly pulsing to large \(\epsilon\) and observing the signal of the returned state. In Fig. S3a, the resulting oscillation pattern is displayed for \(\theta = 0^\circ\). The FFT in S3b reveals several frequency components. The dotted lines are extracted from our model and the corresponding dispersion relation is depicted in S3c. The colored arrows mark the transitions we actually observe in the FFT plot. The singlet-triplet oscillation and FFT plots for \(\theta = 5, 10, 20\) and 30° are further depicted in Fig. S4. We generally find a good agreement with our theoretical model.
FIG. S2. a) The pulse sequence to obtain exchange oscillations features two short pulses at high $\epsilon$ (green) where the exchange interaction $J \ll \Delta g \mu_B B$. Here, the system rotates around the x-axis of the Bloch sphere. The exchange interaction can be turned on by pulsing to lower $\epsilon$ (orange). Here $J \gg g_\perp \mu_B B$ and the system evolves around the z-axis of the Bloch sphere. The exchange interaction can be turned on by pulsing to lower $\epsilon$ (orange). Here $J \gg g_\perp \mu_B B$ and the system evolves around the z-axis of the Bloch sphere. b) The exchange oscillations as a function of $\epsilon$ and separation time $\tau_S$ at $B_\perp = 1 \text{ mT}$ display the expected frequency increase for lower detuning as the exchange interaction becomes dominant. Around 1.2 meV the $S-T_-$ degeneracy is visible as an increase in triplet return signal (red). c) The magnitude of $J$ in MHz can be fit by $J(\epsilon, t_C) = \sqrt{\frac{\epsilon^2}{4} + 2t_C^2 - \frac{\epsilon^2}{2}}$ (black dashed line) and we extract $t_C = 11.38 \pm 0.12 \mu\text{eV}$.

FIG. S3. a) Singlet oscillations as a function of in-plane magnetic field and free evolution time under fast pulsing revealing a complicated oscillation pattern. b) A FFT of a) unveils many frequency components. The dotted lines are fits to the transition frequencies highlighted in c). We find good agreement between the data and the model. An additional set of lines appears at slightly higher frequencies which we attribute to spectral leakage due to the imperfect initialization [S31]. c) The arrows point out the transition frequencies between the eigenstates for the in-plane dispersion relation.

### III. $S-T_-$ Degeneracy as a Function of Magnetic Field Direction

We report the $S-T_-$ degeneracy for different magnetic field directions in Fig. S5. For the out-of-plane direction the typical funnel shape can clearly be observed. Towards the in-plane direction the $S-T_-$ degeneracy evolves into an oscillation pattern suggesting a large coupling term between $S$ and $T_-$. This anisotropy, which follows the g-factor anisotropy of confined HH states, indicates a dependence related to the Zeeman terms in $H_{\text{tot}}$. Indeed, our model can reproduce the plots assuming $g_\parallel > g_\perp$.

We furthermore report the effective level velocity $v = \left| \frac{dJ(\epsilon)}{d\epsilon} \right|_{\epsilon=\epsilon^*} \frac{\Delta \epsilon}{\tau_R}$ with $\Delta \epsilon = 4 \text{ meV}$, $\tau_R = 2 \text{ ns}$ as a function of the magnetic field angle $\theta$ for a magnetic field strength of 20 mT (Fig. S6). Towards the in-plane direction the velocity is reduced as the Zeeman splitting is lowered due to the g-factor anisotropy. As a result, for small angles, the shortest possible ramp time does not allow a diabatic passage over the avoided crossing as pointed out in Fig. 3b. Incidentally, this is a favorable property for single spin qubits where fast initialization in the $|\downarrow\downarrow\rangle$ state is required. Indeed, for $\theta = 0$ the ground state in (1,1) can be initialized with fidelity $F = 1 - P_{LZ} \approx 1$ at a ramp time of 20 ns (Fig. S6).
FIG. S4. Singlet-triplet oscillations as a function of B at different $\theta$. a) Oscillations at $\theta = 5^\circ$. b) FFT of a) with overlaid frequency lines for positive fields as extracted from the model. c) Oscillations at $\theta = 10^\circ$. d) FFT of c) with overlaid frequency lines as extracted from the model. e) Oscillations at $\theta = 20^\circ$. f) FFT of e) with overlaid frequency lines as extracted from the model. g) Oscillations at $\theta = 30^\circ$. h) FFT of g) with overlaid frequency lines as extracted from the model.
FIG. S5. \( S-T_- \) degeneracy funnel for different angles for \( \tau_p = 250 \text{ ns} \). Clearly the funnel is well defined for out-of-plane fields and evolves into an oscillation pattern for in-plane fields. This suggests a dependence stemming from the \( g \)-factor anisotropy of HH states. In fact, our model fits the experimentally observed funnel shapes with \( g_+^\perp = 12, g_-^\perp = 2.05, g_+^\parallel = 0.1, g_-^\parallel = 0.43 \). Moreover, the spin-orbit vector pointing along \( \theta = 60^\circ \) gives rise to an asymmetry between the sharpness of the funnel at +60° and −60°, also confirmed by single Landau-Zener sweeps. The bottom right plot shows the \( S-T_- \) degeneracy at 20 mT for positive angles. This is used to calibrate the pulse amplitude necessary to overcome the \( S-T_- \) degeneracy in the single Landau-Zener sweeps.
FIG. S6. a) Velocity $v$ as a function of $\theta$ for a magnetic field strength of 20 mT. Because of the g-factor anisotropy the Zeeman energy in the in-plane direction is lower. Consequently the velocity is reduced as $|dJ/d\epsilon|_{\epsilon=\epsilon^*}$ becomes smaller. The inset shows the simulated energy dispersion for the angles highlighted by the black arrows. For in-plane fields the avoided crossing clearly shifts to larger $\epsilon$ thereby reducing the effective level velocity. b) $1 - P_{Z,2}$ as a function of $\theta$ for different ramp times. Hence, the g-factor difference in the in-plane direction allows fast and high fidelity initialization for single spin qubits.

FIG. S7. Relaxation time of the $|T_0\rangle$ state as a function of magnetic field strength and angle. In contrast to the decay of the $T_-$ state the relaxation of the $T_0$ state is proportional to $\kappa/\Delta E_Z^2$ (dashed lines) with $\kappa$ a proportionality constant. $T_1$ generally decreases for larger magnetic fields. Only for $\theta = 30^\circ$ the relaxation time maximizes at 2 mT. This occurs because for lower magnetic fields the presence of the $S-T_-$ avoided crossing lowers the $T_0$ return probability as a diabatic passage can not be achieved with the finite rise time of our AWG. For angles $\theta < 30^\circ$ no diabatic passage can be achieved. Therefore we cannot extract $T_1$ of the $T_0$ state.

IV. DECAY OF $T_0$ STATE

The relaxation time of the $T_0$ state does not depend on the SOI (Eq. S15) and, therefore, displays a different anisotropy than the relaxation for the $T_-$ state. To probe this, we perform diabatic pulses and fit the decay of the return signal to $\Phi_{refl}(\tau_M = 0) \exp\left(-\frac{\tau_M}{T_1}\right)$. As shown in Fig. S7 the relaxation time follows $\approx \frac{1}{g_\perp \mu_B B \sin \theta}$ and is generally $< 10 \mu$s making read-out at large fields challenging. Therefore, shelved read-out [S32] could be harvested where the read-out distinguishes between $S$ and $T_-$. At $\theta = 60^\circ$ the relaxation of the $T_-$ state is maximised offering a sweet spot for shelved read-out.
V. INITIALIZATION AND SPECTRAL LEAKAGE

The fast Fourier transform plots in Fig. S3 and Fig. S4 display additional frequency components not predicted by our model which are especially evident at \( \theta = 5^\circ \) and \( 10^\circ \) and can be attributed to improper initialization of the singlet state prior to a pulse. In [S31] a similar system is analyzed and a general formula for the singlet return probability \( P_S \) of non-properly initialized state (a superposition of \( S \) and \( T_- \) is extracted as

\[
P_S = P'_SP + [1 - P'_S](1 - P),
\]

where \( P \) is the return probability with correct singlet initialization and

\[
P'_S = \frac{P \exp\left(-\frac{\tau_M}{T_1}\right) - 1}{(2P - 1) \exp\left(-\frac{\tau_M}{T_1}\right) - 1}.
\]

Here, \( \tau_M \) is the measurement time and \( T_1 \) is the relaxation time of the \( T_- \) state in the read-out point. It is clear that for \( \tau_M \gg T_1 \) we find \( P_S = P \). However, when \( \tau_M \approx T_1 \) the singlet return probability deviates significantly from \( P \). In Fig. S8a we show a line trace of Fig. S4 at \( \theta = 5^\circ \) and \( B = 8.5 \text{ mT} \). We clearly see that the oscillations are not sinusoidal. Fig. S8d displays the FFT of the line trace and 3 distinct peaks can be observed. However, more peaks are present but buried in the background. Fig. S8b shows a simulation of the time evolution of the state. The red trace assumes perfect initialization whereas the blue trace depicts the corrected singlet return probability according to Eq. S1 and S2 with \( \tau_M \approx T_1 \). The blue trace indeed resembles what we measure. Furthermore, we inspect the FFT of the simulated data and find that indeed for the improperly initialized curve we observe additional frequency components. In the red trace we find only the frequency components corresponding to the transitions highlighted in Fig. S3 of the main text. The FFT plot extracted from the simulation of the properly initialized state is depicted as a function of magnetic field in Fig. S8e. On the other hand, the improperly initialized simulated FFT is plotted in Fig. S8f. Here, several additional lines are clearly visible and follow what we measure in Fig. S4b albeit with altered Fourier amplitudes.

VI. THE MODEL

We consider a tunnel coupled double quantum dot in the presence of an external magnetic field and the spin-orbit interaction (SOI). The system is modelled by the Hamiltonian

\[
H_{\text{tot}} = H_{\text{orb}} + H_Z + H_{SO},
\]

where \( H_Z \) is the Zeeman Hamiltonian and \( H_{SO} \) describes the SOI. The orbital part \( H_{\text{orb}} \) reads

\[
H_{\text{orb}} = \epsilon |S_{20}\rangle\langle S_{20}| + \sqrt{2}t_C (|S_{11}\rangle\langle S_{20}| + |S_{20}\rangle\langle S_{11}|),
\]

where \( |S_{20}\rangle \) is the singlet with double occupancy in the left dot which is detuned by an amount \( \epsilon \) from the \((1,1)\) configuration, \( t_C \) is the tunnel element in the one-particle picture, and \( |S_{11}\rangle \) is the singlet with one hole in each dot. Diagonalizing (S4) yields the hybridized singlet states

\[
|S_E\rangle = \cos\left(\frac{\Omega}{2}\right)|S_{20}\rangle + \sin\left(\frac{\Omega}{2}\right)|S_{11}\rangle,
\]

\[
|S_G\rangle = \cos\left(\frac{\Omega}{2}\right)|S_{11}\rangle - \sin\left(\frac{\Omega}{2}\right)|S_{20}\rangle,
\]

where \( \Omega = \arctan(2\sqrt{2}t_C/\epsilon) \) is the orbital mixing angle and the corresponding energies are \( E(S_{E/G}) = \epsilon/2 \pm \sqrt{\epsilon^2/4 + 2t_C^2} \). In the following we consider a regime where the excited singlet is far detuned and may be neglected. Defining \( |S\rangle \equiv |S_G\rangle \), we may focus on the four dimensional space spanned by the states \( |S\rangle, |T_+\rangle, |T_0\rangle \) and \( |T_-\rangle \), where \( |T_{\pm}\rangle \) denote the triplet states in the \((1,1)\) configuration.

For a magnetic field of magnitude \( B \) and angle \( \theta \) as measured from the plane defined by the heterostructure, the Zeeman Hamiltonian \( H_Z \) reads,

\[
H_Z = \frac{\mu_B B}{2} \left\{ \sin \theta \left[ \sum_{\pm} \pm g_{\parallel}^+ |T_{\pm}\rangle\langle T_{\pm}| + g_{\perp}^- (|S\rangle\langle T_0| + |T_0\rangle\langle S|) \cos \left( \frac{\Omega}{2} \right) \right] \\
+ \frac{\cos \theta}{\sqrt{2}} \left[ \sum_{\pm} \left( g_{\parallel}^+ |T_0\rangle\langle T_{\pm}| + g_{\perp}^- |S\rangle\langle T_{\pm}| \cos \left( \frac{\Omega}{2} \right) + \text{H.c.} \right) \right] \right\},
\]

(S6)
FIG. S8. a) Line trace at 8 mT from Fig. S4a featuring a non-sinusoidal oscillation pattern. b) FFT of a) highlighting its frequency components. c) Simulated time evolution for the conditions in a) with proper initialization in a singlet (red) and improper initialization (blue). d) FFT of c) highlighting the frequency components of the blue and red trace (blue is offset for clarity). Comparing the 2 curves we notice additional frequency components arising in the blue one which can be mapped to the observed spectral peaks of b). The red and blue trace, however, both display peaks at the transition frequencies expected from our model. e) FFT of the simulated time evolution with proper initialization. All the transitions highlighted in Fig. S3c are visible. f) FFT of the simulated time evolution under improper initialization. The additional frequency lines resemble what we measure in Fig. S1b.
where $g^\pm_j = g^x_j \pm g^y_j$. Note that the axes are labelled such that $y$ is the double quantum dot axis, and the magnetic field is applied in the $x$-$z$-plane.

Finally, we consider a SOI parametrized by an in-plane spin-orbit vector, $t_{SO} = (t_x, t_y, 0)$, where all entries are real. Such in-plane spin-flip tunneling terms stem from the cubic Rashba SOI [28], while this type of SOI does not induce out-of-plane terms $t_z$. Consequently, the spin-orbit Hamiltonian $H_{SO}$ reads,

$$H_{SO} = \sin \left( \frac{\Omega}{2} \right) \sum_{\pm} (t_x \pm it_y) |T_{\pm}\rangle \langle S| + \text{H.c.},$$  \hspace{1cm} (S7)

An appropriate basis for studying the singlet-triplet anticrossing is given by the eigenstates of the total Hamiltonian [S3] for equal g-factors and in the absence of the SOI. Transforming the total Hamiltonian in the presence of the SOI and g-factor differences into this basis, we find for the singlet-triplet splitting,

$$\Delta_{ST} = \left| \Delta_{SO} \sin \left( \frac{\Omega}{2} \right) + \Delta E_Z \cos \left( \frac{\Omega}{2} \right) \right|,$$   \hspace{1cm} (S8)

where the spin-orbit splitting $\Delta_{SO}$ and the Zeeman splitting $\Delta E_Z$ are given by

$$\Delta_{SO} = t_y - it_x \frac{g_+^z \sin \theta}{\sqrt{(g_+^z \cos \theta)^2 + (g_-^z \sin \theta)^2}},$$   \hspace{1cm} (S9a)

$$\Delta E_Z = \frac{\mu_B B}{4\sqrt{2}} \frac{(g_+^z - g_-^z) \sin(2\theta)}{\sqrt{(g_+^z \cos \theta)^2 + (g_-^z \sin \theta)^2}}.$$   \hspace{1cm} (S9b)

In Landau-Zener measurements the mixing angle $\Omega$ is a function of the detuning at the anticrossing between the singlet and the low-energy polarized triplet, which is described by the equation

$$\epsilon - \sqrt{\epsilon^2 - 4t_C^2} = -\frac{\mu_B B}{2} G(\theta),$$ \hspace{1cm} (S10)

where $G(\theta) = \sqrt{(g_+^z \cos \theta)^2 + (g_-^z \sin \theta)^2}$. Rearranging gives the detuning at which the anticrossing is located,

$$\epsilon_\ast = \frac{8t_C^2 - (\mu_B B G(\theta))^2}{2\mu_B B G(\theta)},$$ \hspace{1cm} (S11)

and consequently the mixing angle at the anticrossing reads

$$\Omega_\ast = \Omega(\epsilon_\ast) = \arctan \left( \frac{4\sqrt{2}t_C \mu_B B G(\theta)}{8t_C^2 - (\mu_B B G(\theta))^2} \right).$$ \hspace{1cm} (S12)

In Fig. 3 we show a comparison between the analytical result for $\Delta_{ST}$ evaluated at the detuning at the anticrossing and simulated results obtained by exact numerical diagonalization of the total system Hamiltonian [S3]. For the latter, we obtain the splitting as the minimum difference between the two lowest eigenenergies. We find excellent agreement for all angles except in a narrow region around $\theta = 0$. The dip predicted by the analytical formula is not present in the simulations. We attribute this deviation to the small in-plane Zeeman energies $\sim g_0^z$ which violate the assumption of a well separated two-level system. In this case the splitting is not given by the simple expression (S8), which describes the coupling between the ground state singlet and the low-energy polarized triplet. Instead, the contributions of the remaining two triplet states must be taken into account near $\theta = 0$, and the coupling is altered.

**VII. SPIN-ORBIT VECTOR, FIELD AND LENGTH**

In Eq. (S7) we model the SOI using the spin-orbit vector $t_{SO} = (t_x, t_y, t_z)$ [S3] which contains genuine spin-flip tunneling terms. In our structure we consider an in-plane spin-orbit vector, but different forms with $t_z \neq 0$ are possible in other systems. The most general effective form in the basis $B$ defined in Sec. VII is

$$H_{SO} = \sin \left( \frac{\Omega}{2} \right) \left( i\sqrt{2}t_z |T_0\rangle \langle S| + \sum_{\pm} (t_x \pm it_y) |T_{\pm}\rangle \langle S| + \text{H.c.} \right).$$ \hspace{1cm} (S13)
Often, however, the SOI is parametrized by a spin-orbit field $\mathbf{M}_d^l$ in dot $d \in \{L, R\}$,

$$H_{SO} = \frac{\mu_B}{2} \sum_d \mathbf{M}_d^l \cdot \sigma^d,$$

(S14)

where $\sigma^d$ is a vector containing the Pauli matrices in dot $d$. A general argument shows that the spin-orbit vector $t_{SO}$ cannot be mapped to the spin-orbit field $\mathbf{M}_d^l$. On the one hand, the Hamiltonian in Eq. (S14) is time reversal invariant while the Zeeman type Hamiltonian (S14) with a real spin-orbit field is not. On the other hand, a complex spin-orbit field would make (S14) non-Hermitian, and hence the two quantities $t_{SO}$ and $\mathbf{M}_d^l$ cannot be related. Taking the spin-orbit field to be a function of the crystal momenta, $\mathbf{M}_d^l(k)$, can restore time reversal symmetry but is not an appropriate description for the confined hole spin states considered here. Another quantity is based on an effective approach to first order in the SOI, explicitly taking into account phonons [S34], and use this expression as a working definition of the spin-orbit length. The spin-orbit length along $x$ is then defined to be

$$l_{SO} := \frac{\langle p_x \rangle_\psi}{m} \tau = \frac{\hbar (k_x)_\psi}{m} \tau = \frac{\pi}{2} \frac{\hbar^2 z^n}{m} \frac{(k_x)_\psi}{n_x \psi},$$

(S21)

where $\alpha_n$ is the coupling strength with units energy/momentum$^n$, $k_z$ the crystal momentum along $x$ and $\sigma_y$ a Pauli matrix. We may then work with an effective spin Hamiltonian by averaging over the crystal momentum,

$$\langle H_{SO} \rangle_\psi = \alpha_n \hbar^n \langle k_z \rangle_\psi \sigma_y,$$

(S20)

where the state $\psi$ is only required to satisfy the condition $\langle k_z \rangle_\psi \neq 0$ to allow for finite spin flip times. In this case the time evolution generated by this Hamiltonian in spin space will cause a spin flip in time $\tau = \pi/(2\alpha_n h^{n-1}(k_z)_\psi)$. The spin-orbit length along $x$ is then defined to be

$$l_{SO} = \frac{1}{\lambda_R \sqrt{1 - S^2}} \frac{4 \omega_0 + d^2 m^2 \omega_0^2}{d^2 m^2 \omega_0^2}.$$ (S18)

Ref. [S26] considers a DQD with a linear SOI, and we find that the spin-orbit length is rather different for systems with a cubic Rashba SOI. In particular, it depends not only on material parameters via $\lambda_R$ but also on the dot geometry via $\omega_0$, $d$, $S$, and $\gamma$. This dependence on the dot geometry can be understood from the definition of the spin-orbit length as the distance travelled by a particle before its spin is flipped. Assume for simplicity a particle travelling along $x$ (e.g. the DQD axis) and an $n$th order Rashba type SOI of the form

$$H_{SO} = \alpha_n (h k_z)^n \sigma_y,$$

(S19)

where the real number $\alpha_n$ is the coupling strength with units energy/momentum$^n$, $k_z$ the crystal momentum along $x$ and $\sigma_y$ a Pauli matrix. We may then work with an effective spin Hamiltonian by averaging over the crystal momentum,

$$\langle H_{SO} \rangle_\psi = \alpha_n \hbar^n \langle k_z \rangle_\psi \sigma_y,$$

(S20)

where the state $\psi$ is only required to satisfy the condition $\langle k_z \rangle_\psi \neq 0$ to allow for finite spin flip times. In this case the time evolution generated by this Hamiltonian in spin space will cause a spin flip in time $\tau = \pi/(2\alpha_n h^{n-1}(k_z)_\psi)$. The spin-orbit length along $x$ is then defined to be

$$l_{SO} := \frac{\langle p_x \rangle_\psi}{m} \tau = \frac{\hbar (k_x)_\psi}{m} \tau = \frac{\pi}{2} \frac{\hbar^2 z^n}{m} \frac{(k_x)_\psi}{n_x \psi},$$

(S21)
For \( n = 1 \), the final fraction equals one and the spin-orbit length is a well defined quantity which only depends on material parameters. However, for \( n > 1 \) the expectation values must be evaluated given a specific state of the system. This introduces two problems: Firstly, since the state must be chosen by hand there is a degree of arbitrariness in the definition of the spin-orbit length. Secondly, given a specific setup, the state chosen for computing the expectation value will depend on the system geometry, and hence the spin-orbit length loses its character as a geometry independent quantity as was explicitly shown above for the case of the cubic \((n = 3)\) Rashba SOI. It is therefore necessary to treat the spin-orbit length with caution for nonlinear SOI as it can possibly no longer be considered a good figure of merit for material comparison.

VIII. EFFECT OF THE DOT GEOMETRY ON THE \( g \)-FACTORS

Heavy-hole (HH) and light-hole (LH) states confined in a germanium heterostructure in the presence of a magnetic field \( \mathbf{B} \) are well described by the Hamiltonian

\[
H = -\frac{\hbar^2}{2m_0} \left[ \left( \gamma_1 + \frac{5}{2} \gamma_3 \right) \mathbf{k}^2 - 2\gamma_s (\mathbf{k} \cdot \mathbf{J})^2 \right] + 2\mu_B \left( \kappa \mathbf{B} \cdot \mathbf{J} + q \sum_{n=1}^{3} B_n J_n^3 \right) + V(z) + U(x, y).
\]  

(S22)

Here, the first term is the Luttinger–Kohn Hamiltonian in spherical approximation featuring the Luttinger parameters \( \gamma_1 \) and \( \gamma_3 \), the bare electron mass \( m_0 \) and the spin 3/2 matrices \( J_n \). The second term describes the effect of a magnetic field in the context of the envelope function approximation, \( \kappa \) and \( q \) being constants that depend on system specific influences such as strain and material composition \([S23–S25]\). We model the heterostructure by an infinite hard wall confinement potential, \( V(z) \) in the out-of-plane direction, and realize the quantum dot in the \( x-y \)-plane by an ellipsoidal harmonic confinement potential,

\[
U(x, y) = \frac{m}{2} \left( \omega_x^2 x^2 + \omega_y^2 y^2 \right).
\]  

(S23)

Note that the confinement energies \( \omega_x \) and \( \omega_y \) are defined with respect to the in-plane HH mass \( m = m_0/(\gamma_1 + \gamma_3) \). In the following we assume small magnetic fields in the mT range and neglect orbital effects arising from the canonical momentum. This is valid for in-plane fields \( B_{x,y} \) if \( \epsilon || = \hbar e B_{x,y}/2m \ll \Delta = 2\gamma_3 \hbar^2 \pi^2 / m_0 d^2 \), where \( \Delta \) is the HH-LH splitting with the quantum well width \( d \). At \( d \approx 20 \) nm one finds \( \Delta \approx 17 \) meV and hence \( \epsilon || \ll \Delta \) for \( B_{x,y} \leq 1 \) T. On the other hand, for out-of-plane fields \( B_z \) we require \( \epsilon_\perp = \hbar e B_z/2m \ll \min\{\hbar \omega_x, \hbar \omega_y\} \). For a typical minimal in-plane confinement energy \( \min\{\hbar \omega_x, \hbar \omega_y\} \approx 0.5 \) meV, we have \( \epsilon_\perp/\min\{\hbar \omega_x, \hbar \omega_y\} < 0.05 \) at \( B_z = 20 \) mT which is the maximal field applied in this work.

The eigenstates of the Hamiltonian (S22) in the absence of HH-LH mixing and at zero in-plane magnetic field have the form \( \langle \Psi_h \rangle \langle j_z \rangle \) \((\langle \Psi_i \rangle \langle j_z \rangle)\) for \( j_z = \pm 3/2 \) \((j_z = \pm 1/2)\), where \( j_z \) is the magnetic quantum number of the total angular momentum, and the position states \( \langle \Psi_h \rangle \) are a product of simple harmonic oscillator states in \( x \) and \( y \) and trigonometric functions satisfying the boundary conditions set by \( V(z) \) at \( z = \pm d/2 \). We proceed to project the Hamiltonian (S22) onto the space spanned by the orthonormal orbital ground state basis \( \{|\Psi^0 \rangle |3/2\rangle, |\Psi^0 \rangle |1/2\rangle, |\Psi^0 \rangle |1/2\rangle, |\Psi^0 \rangle |3/2\rangle\} \) with

\[
\begin{align*}
\psi_{h,i}(x, y, z) &= \psi_{h,i}(x, y) \phi(z), \\
\psi_{h,i}(x, y) &= \sqrt{\frac{m_{h,i} \omega_x \omega_y}{\hbar \pi}} \exp \left( -\frac{m_{h,i}}{2\hbar} \left[ \omega_x x^2 + \omega_y y^2 \right] \right), \\
\phi(z) &= \sqrt{\frac{2}{d}} \cos \left( \frac{\pi z}{d} \right) \Theta \left( \frac{d}{2} - |z| \right),
\end{align*}
\]  

(S24)

where \( \Theta \) is the Heaviside step function, \( m_h = m \) and \( m_l = \sqrt{Mm} \) with in-plane LH mass \( M = m_0/(\gamma_1 - \gamma_3) \). Note that \( m < M \) for in-plane motion. One obtains a \( 4 \times 4 \) matrix (labelled by angular momentum) in which the HH and LH spaces are separated in energy by the HH-LH splitting \( \Delta \) and can mix due to the intrinsic SOI,

\[
\langle H \rangle = \begin{pmatrix}
3 \kappa + \frac{7}{4} q \mu & \sqrt{3} \left( \kappa + \frac{7}{4} q \right) \mu \mu B_z & \sqrt{3} \left( \kappa + \frac{7}{4} q \right) \mu \mu B_z & \sqrt{3} \left( \kappa + \frac{7}{4} q \right) \mu \mu B_z \\
-\sqrt{3} \gamma_3 \mu \mu B_z & \mu + \left( \kappa + \frac{7}{4} q \right) \mu \mu B_z & (5 \kappa + 2 \kappa) \mu \mu B_z & (5 \kappa + 2 \kappa) \mu \mu B_z \\
\frac{1}{2} q \mu \mu B_z & -\sqrt{3} \gamma_3 \mu \mu B_z & \mu + \left( \kappa + \frac{7}{4} q \right) \mu \mu B_z & (5 \kappa + 2 \kappa) \mu \mu B_z \\
\frac{1}{2} q \mu \mu B_z & -\sqrt{3} \gamma_3 \mu \mu B_z & \mu + \left( \kappa + \frac{7}{4} q \right) \mu \mu B_z & (5 \kappa + 2 \kappa) \mu \mu B_z
\end{pmatrix},
\]  

(S25)

where we introduce the quantities

\[
b = B_x + i B_y, \quad \epsilon = \frac{\hbar (\omega_x + \omega_y)}{2} \left( \frac{m}{M} - 1 \right) + \Delta, \quad \mu_1 = \langle \psi_h | \psi_i \rangle = \frac{2 \langle m M \rangle^{1/4}}{\sqrt{m + M}}, \quad \mu_2 = \frac{m^{3/2} (m M)^{3/4}}{m_0 (m + m M)^{3/2}}.
\]  

(S26)
Note that any additional part of the Hamiltonian that is linear in the momentum (e.g. a Rashba type SOI) vanishes upon projection onto the space spanned by the symmetric ground state wave functions. Assuming the HH-LH splitting to be the largest relevant energy scale, \( \Delta \gg \mu_B |B|, \hbar \omega_x, \hbar \omega_y \), we may perform a Schrieffer-Wolff transformation to decouple the LH subspace. We find an effective 2 \( \times \) 2 HH Hamiltonian with a Zeeman term (i.e., a term linear in \( B \)) containing the renormalized g-factors

\[
\begin{align*}
g_x &= g_x^0 - \xi_1 \frac{\hbar(\omega_x - \omega_y)}{\hbar(\omega_x + \omega_y) - \xi_2 \Delta}, \\
g_y &= g_y^0 + \xi_1 \frac{\hbar(\omega_x - \omega_y)}{\hbar(\omega_x + \omega_y) - \xi_2 \Delta}, \\
g_z &= g_z^0 - \xi_1 \left[ \frac{\hbar(\omega_x - \omega_y)}{\hbar(\omega_x + \omega_y) - \xi_2 \Delta} \right]^2,
\end{align*}
\]

where \( g_x^0 = g_y^0 = 3q, \) \( g_z^0 = 6\kappa + 27q/2 \) are the effective zeroth order values and

\[
\begin{align*}
\xi_1 &= (12\kappa + 21q) \frac{\sqrt{\gamma_1^2 - \gamma_s^2}}{\gamma_1 + \sqrt{\gamma_1^2 - \gamma_s^2}}, \\
\xi_2 &= \frac{2\sqrt{\gamma_1 + \gamma_s}}{\sqrt{\gamma_1 + \gamma_s} - \sqrt{\gamma_1 - \gamma_s}}
\end{align*}
\]

are material specific constants, \( \xi_1 \approx 20.3 \) and \( \xi_2 \approx 6.0 \) in (bulk) germanium. While \( g_x \) is always reduced by the HH-LH mixing, the sign of the correction to \( g_x \) and \( g_y \) depends on the relative in-plane confinement strength. In particular, \( g_x \neq g_y \) due to the broken in-plane symmetry. It is therefore possible that one in-plane g-factor becomes negative. This effect can be observed even in a perturbative approach because the zeroth order in-plane g-factors in germanium are small, \( g_x^0 = g_y^0 = 3q \approx 0.2 \). In contrast, we find that the correction to the out-of-plane g-factor is \( |\delta g_z| \lesssim 10^{-2} \) for the values considered here and hence negligible. The smallness of the correction to the out-of-plane g-factor compared to the correction to the in-plane g-factors can be understood as follows: The HH and LH subspaces are mixed by the effect of elliptical confinement (\( \sim [\omega_x - \omega_y] \)) and the in-plane magnetic fields, and the corrections to the matrix elements in the effective HH Hamiltonian are given by a product of these effects. The effective in-plane g-factor corrections then effectively contain only one of the two small mixing terms (\( \delta g_{x,y} \sim [\omega_x - \omega_y] \)) because one factor contains the in-plane magnetic field, while the out-of-plane g-factor correction contains two small factors (\( \delta g_z \sim [\omega_x - \omega_y]^2 \)).
