GIT STABILITY OF LINEAR MAPS ON PROJECTIVE SPACE WITH MARKED POINTS

MAX WEINREICH

Abstract. We construct moduli spaces of linear self-maps of \( \mathbb{P}^N \) with marked points, up to projective equivalence. That is, we let \( SL_{N+1} \) act simultaneously by conjugation on projective linear maps and diagonally on \( (\mathbb{P}^N)^n \), and we take the geometric invariant theory (GIT) quotient. These moduli spaces arise in algebraic dynamics in two ways: first, as ambient varieties of degree 1 portrait spaces; second, as the domains of discrete integrable systems such as the pentagram map. Our main result is a dynamical characterization of the GIT semistable and stable loci in the space of linear maps with marked points. The proof is combinatorial: to describe the weight polytopes for this action, we compute the vertices and facets of certain convex polyhedra generated by roots of the \( A_N \) lattice.

1. Introduction

In this paper, we use geometric invariant theory (GIT) to construct moduli spaces \( \mathcal{M}^{N}_{1,n} \) of linear self-maps of \( \mathbb{P}^N \) with \( n \) marked points, considered up to projective equivalence.

We are motivated by two applications to algebraic dynamics. First, our moduli spaces are the degree \( d = 1 \) analogue of the moduli spaces \( \mathcal{M}^{N}_{d,n} \) of degree \( d \geq 2 \) dynamical systems on \( \mathbb{P}^N \) with marked points, introduced by Doyle-Silverman [7]. We show that \( \mathcal{M}^{N}_{1,n} \) exists and admits a dynamically meaningful compactification \( \bar{\mathcal{M}}^{N}_{1,n} \) with subtle combinatorics at the boundary. In this way, our moduli problem resembles the widely-studied moduli space of curves of genus 0 or 1 with \( n \) marked points.

Second, our moduli space \( \mathcal{M}^{N}_{1,n} \) is the domain of a wide class of integrable systems, especially the pentagram map and its generalizations [4, 9, 10, 13, 16, 19, 21]. In this context, the space \( \mathcal{M}^{N}_{1,n} \) is usually studied as a real or complex manifold, and its points are called twisted polygons. Our main result shows that \( \mathcal{M}^{N}_{1,n} \) can be equipped with the structure of an algebraic variety over any algebraically closed field, and describes the degenerate twisted polygons that are included in the compactification \( \bar{\mathcal{M}}^{N}_{1,n} \).

We work over a fixed algebraically closed field \( k \). Fix integers \( N, n \in \mathbb{N} \). Let \( Mat_{N+1} \) be the space of linear endomorphisms of the vector space \( k^{N+1} \), and let \( \mathbb{P}(Mat_{N+1}) = \mathbb{P}^{N^2+2N} \) be its projectivization. In coordinates, the elements of \( \mathbb{P}(Mat_{N+1}) \) are \( (N+1) \times (N+1) \) nonzero matrices, up to scale. We consider the variety

\[
\mathcal{X}_{N,n} := \mathbb{P}(Mat_{N+1}) \times (\mathbb{P}^N)^n,
\]
equipped with the following action of \( SL_{N+1} \): for each \( A \in SL_{N+1} \),
\[ A \cdot (T, v_1, \ldots, v_n) := (ATA^{-1}, Av_1, \ldots, Av_n). \] (1)

The GIT quotient of \( X_{N,n} \) by action (1) is defined relative to a choice of very ample, \( SL_{N+1} \)-linearized invertible sheaf \( \mathcal{L} \). Note that any very ample invertible sheaf \( \mathcal{L} \) has a unique \( SL_{N+1} \)-linearization. We write \( (X_{N,n}/\!/SL_{N+1})(\mathcal{L}) \) for the GIT quotient of \( X_{N,n} \) by the action (1) relative to \( \mathcal{L} \).

Our main objects of study are the GIT quotients for various sheaves \( \mathcal{L} \),
\[ \mathcal{M}^N_{1,n}(\mathcal{L}) := (X_{N,n}/\!/SL_{N+1})(\mathcal{L}). \]

The price of working with GIT is that some geometric objects are so degenerate that they cannot be represented in a quotient variety. Points of \( X_{N,n} \) are classified as unstable, semistable, or stable relative to the sheaf \( \mathcal{L} \). Stable points have the desirable property that their orbits are in bijection with the points of a geometric quotient variety. The semistable points are certain degenerations of families of stable points, and they can be used to construct a natural compactification of the stable quotient.

Generally, a geometric object in \( \mathbb{P}^N \) is GIT unstable if it has too high an order of contact with some flag in \( \mathbb{P}^N \). The classic example is due to Mumford [14]: a configuration \((v_1, \ldots, v_n) \in (\mathbb{P}^N)^n \) of \( n \) points in \( \mathbb{P}^N \) is semistable relative to the diagonal action of \( SL_{N+1} \) and the sheaf \( \mathcal{O}(1, \ldots, 1) \) if, for each nontrivial proper subspace \( H \subsetneq k^{N+1} \),
\[ \# \{ i : v_i \in H \} \leq \frac{n}{N+1} (\dim H). \] (2)

Our main theorem characterizes the GIT stable and semistable points of \( X_{N,n} \), in the spirit of Mumford’s example. We show that the GIT stability of a point \((T, v_1, \ldots, v_n) \in X_{N,n} \) can be determined by counting the points \( v_i \) lying on certain flags that play a special dynamical role relative to \( T \).

**Theorem 1.1.** Let \( k \) be an algebraically closed field, and let \( N,n,q \in \mathbb{N} \). Consider the variety \( X_{N,n} = \mathbb{P}(Mat_{N+1}) \times (\mathbb{P}^N)^n \) equipped with the action (1) of \( SL_{N+1} \), the sheaf \( \mathcal{L} = \mathcal{O}(q,1, \ldots, 1) \), and the unique \( SL_{N+1} \)-linearization. For each \( T \in \mathbb{P}(Mat_{N+1}) \), each flag \( \mathcal{H} \) in \( k^{N+1} \) belongs to at most one of three types I, II, or III relative to \( T \), defined below.

A point \((T, v) = (T, v_1, \ldots, v_n) \in X_{N,n} \) is GIT semistable if and only if, for every \( \nu \in \mathbb{N} \) and every flag
\[ \mathcal{H} = 0 \subsetneq H_1 \subsetneq \ldots \subsetneq H_\nu \subsetneq k^{N+1} \]
of type I, II, or III relative to \( T \), we have
\[ \sum_{j=1}^{\nu} \# \{ i : v_i \in H_j \} \leq \frac{n}{N+1} \sum_{j=1}^{\nu} (\dim H_j) + q c(T, \mathcal{H}), \] (3)

where
\[ c(T, \mathcal{H}) = \begin{cases} 0, & \text{if } \mathcal{H} \text{ is type I relative to } T, \\ 1, & \mathcal{H} \text{ is type II relative to } T, \\ -1, & \mathcal{H} \text{ is type III relative to } T. \end{cases} \]

A point \((T, v) \in X_{N,n} \) is GIT stable if and only if, for every flag \( \mathcal{H} \), the inequality (3) is strict.

The three types of a flag \( \mathcal{H} \) relative to \( T \) are defined as follows:
• Type I: we have \( \nu = 1 \), and \( \mathcal{H} = H_1 \) satisfies either

\[
0 \neq TH_1 \subseteq H_1
\]
or

\[
TH_1 \subseteq H_1 \quad \text{and} \quad T(k^{N+1}) \not\subseteq H_1.
\]

• Type II: Let \( H_{\nu+1} = k^{N+1} \). For all \( t \) in the range \( 1 \leq t \leq \nu \), we have

\[
TH_t \not\subseteq H_t \quad \text{and} \quad TH_t \subseteq H_{t+1}.
\]

• Type III: Let \( H_0 = 0 \) and \( H_{\nu+1} = k^{N+1} \). We have

\[
TH_{t+1} \subseteq H_t, \quad (0 \leq t \leq \nu) \quad \text{and} \quad TH_{t+1} \not\subseteq H_{t-1}, \quad (1 \leq t \leq \nu).
\]

We deduce Theorem 1.1 as a special case of Theorem 4.2, which describes GIT stability and semistability relative to any very ample invertible sheaf \( \mathcal{L} = \mathcal{O}(q, m_1, \ldots, m_n) \), where \( q, m_1, \ldots, m_n \in \mathbb{N} \).

**Example 1.2.** We now give some examples of type I, II, and III flags.

• For any \( T \in \mathbb{P}(\text{Mat}_{N+1}) \), every flag consisting of just one subspace \( H \) is of type I, II, or III.

• Any non-nilpotent \( T \in \mathbb{P}(\text{Mat}_{N+1}) \) has flags of type I: take \( H = H_1 \) to be the eigenspace of any nonzero eigenvalue.

• If \( T = 1 \), then every flag is type I, and we recover the condition (2) of Mumford’s example.

• Suppose \( T \neq 1 \) and \( T \) is invertible. Then there is some vector \( v \) such that \( v \neq T(v) \neq 0 \). Let \( H_1 = \text{Span}(v) \) and \( H_2 = \text{Span}(v, T(v)) \). The flag \( H_1 \not\subseteq H_2 \) is type II.

• Suppose the Jordan form of \( T \) has all 1’s on the diagonal and all 1’s on the first off-diagonal. Then \( T \) has a cyclic vector; that is, there exists \( v \in k^{N+1} \) such that \( v, T(v), \ldots, T^{N-1}(v) \) form a basis. For each \( i = 1, \ldots, N \), let

\[
H_i = \text{Span}(v, T(v), \ldots, T^{i-1}(v)).
\]

The flag \( H_1 \not\subseteq \cdots \not\subseteq H_N \) is type II.

• Suppose the Jordan form of \( T \) has all 0’s on the diagonal and all 1’s on the first off-diagonal. Then there exists \( v \in k^{N+1} \), such that for all \( 0 \leq i < N \), we have \( T^i(v) \neq 0 \), and \( T^N(v) = 0 \). Let

\[
H_i = \text{Span}(v, T(v), \ldots, T^{i-1}(v)).
\]

The flag \( H_1 \not\subseteq \cdots \not\subseteq H_N \) is type III.

• Type III flags exist only if \( T \) is nilpotent. But a nilpotent map \( T \) may still have flags of type I and II.

The proof of Theorem 1.1 is via polyhedral combinatorics. There is a standard method in GIT for checking stability of a point: to any maximal torus in \( \text{SL}_{N+1} \) and point \( p \in X_{N,n} \), we associate a convex polytope called the **weight polytope** or state polytope. A point \( p \) is GIT stable if and only if its weight polytope contains the origin. We find that the weight polytopes arising from the conjugation action of \( \text{SL}_{N+1} \) on \( \mathbb{P}(\text{Mat}_{N+1}) \) are root polytopes of \( A \) type \([5]\). The vertices of these polytopes are root vectors of the \( A_N \) lattice.

Our argument differs from the usual approach to GIT via weight polytopes in two important ways. First, we introduce a variant of the weight polytope called the **corner polyhedron** (Definition 3.7), which is the Minkowski sum of the weight polytope and the nonnegative
orthant. The idea is that, since the Weyl group of the $A_N$ lattice is the symmetric group $S_N$, every 1-parameter subgroup in $SL_{N+1}$ can be put in a nice form, and the corner polyhedron describes stability relative to these nice 1-parameter subgroups. Second, we do not just need to know whether the origin belongs to each corner polyhedron; we really do need to compute every facet, because the action of $SL_{N+1}$ on the factor $(\mathbb{P}^N)^n$ has the effect of translating the corner polyhedron for the factor $\mathbb{P}^{(\text{Mat}_{N+1})}$.

Our results on the vertices and facets of corner polyhedra of type $A_N$ are contained in Proposition 3.13 and 3.16; these are necessary for our proof, but also are of purely combinatorial interest. In Corollary 3.15, we count corner polyhedra in terms of Catalan numbers.

Our work is a starting point for describing the structure of $\mathcal{M}_{1,n}^N$ in more detail. Mumford and Suominen showed that the stable locus for the conjugation action of $SL_{N+1}$ on $\mathbb{P}^{(\text{Mat}_{N+1})}$ is empty [15]. In contrast, we have the following application of Theorem 1.1.

**Corollary 1.3.** Let $n \geq 1$, $N \geq 1$, and $q \geq n$. The stable locus in $\mathcal{X}_{N,n}$, relative to the sheaf $\mathcal{L} = \mathcal{O}(q, 1, \ldots, 1)$ with its unique linearization, is nonempty.

In previous work, we showed that, in the planar case ($N = 2$), if $n \geq 4$, the moduli space $\mathcal{M}_{1,n}^2$ is birational to $\mathbb{P}^{2n}$, by working in explicit coordinates [22, Theorem 3.2]. This generalizes:

**Theorem 1.4.** For any $n, N \in \mathbb{N}$, and any very ample invertible sheaf $\mathcal{L}$, if the stable locus of $\mathcal{X}_{N,n}$ relative to $\mathcal{L}$ is nonempty, the variety $\mathcal{M}_{1,n}^N(\mathcal{L})$ is rational of dimension $nN$.

Rationality of the moduli space of dynamical systems of degree $d$ without marked points is only known in dimension 1, and is a central open problem in algebraic dynamics for higher dimension [11].

The remainder of the introduction describes the motivation for studying $\mathcal{M}_{1,n}^N$ in detail. Section 2 contains standard preliminaries from geometric invariant theory. Section 3 introduces the corner polyhedron, classifies the corner polyhedra of type $A_N$, and includes a menagerie of examples. In Section 4 we prove Theorem 1.1, Corollary 1.3, and Theorem 1.4.

### 1.1. Motivation from dynamical moduli spaces.

A dynamical system of degree $d$ on $\mathbb{P}^N$ is a morphism $\mathbb{P}^N \to \mathbb{P}^N$ of degree $d$. Since conjugating a morphism by a projective transformation produces a morphism with the same dynamics, the moduli space $\mathcal{M}_d^N$ of degree $d$ dynamical systems on $\mathbb{P}^N$ is defined as the space of morphisms $\mathbb{P}^N \to \mathbb{P}^N$ up to the action of $SL_{N+1}$ by conjugation. These moduli spaces were constructed with GIT by Silverman [20] in degree $d \geq 2$ and dimension $N = 1$, and by Levy and Petsche-Szpiro-Tepper in degree $d \geq 2$ and dimension $N > 1$ [11, 17]. The analogous moduli space in degree $d = 1$ is impossible to construct because the GIT stable locus is empty [15], rather like the situation for curves of genus 0 or 1.

The moduli space $\mathcal{M}_d^N$ admits a GIT semistable compactification $\bar{\mathcal{M}}_d^N$ that includes some morphisms of lower degree and rational maps; these degenerate objects are represented in the GIT boundary of the quotient, that is, $\bar{\mathcal{M}}_d^N \setminus \mathcal{M}_d^N$. One might speculate that these rational maps are somehow dynamically special. However, there is evidence that the GIT boundary is not dynamically meaningful, since the natural iteration maps between these moduli spaces have indeterminacy $[8]$. Our main result, Theorem 1.1, demonstrates that, in degree 1 with marked points, there is a dynamical characterization of the GIT boundary.
Doyle-Silverman introduced level structure to these dynamical moduli spaces [7]. They define the moduli space $\mathcal{M}_N^d(P)$ of degree $d \geq 2$ dynamical systems on $\mathbb{P}^N$ with portrait $P$. A portrait is a weighted digraph that prescribes dynamical relations on the marked points. Our moduli space $\mathcal{M}_{1,n}$ is a special case of this construction, where $d = 1$ and $P$ has $n$ vertices and no edges. Thus our moduli space $\mathcal{M}_{1,n}$ is an ambient variety for the degree 1 moduli spaces associated to other portraits. Doyle-Silverman obtained a partial description of GIT stability in degree $d \geq 2$ [7, Theorem 8.1]; our Theorem 1.1 is a complete description in degree $d = 1$. In principle, our techniques would give an exact characterization GIT stability in degree $d \geq 2$, but the weight polyhedra will be much more complicated.

1.2. Motivation from integrable systems. Mumford studied the diagonal action of $\text{SL}_{N+1}$ on the space $(\mathbb{P}^N)^n$ of polygons, that is, $$A \cdot (v_1, \ldots, v_n) := (Av_1, \ldots, Av_n).$$ This action describes projective equivalence of polygons, since the orbits of $\text{SL}_{N+1}$ and $\text{PGL}_{N+1}$ are the same. The action of $\text{SL}_{N+1}$ on $X_{N,n}$ also has a geometric meaning.

**Definition 1.5.** Let $N, n \geq 1$ be integers. A twisted $n$-gon $v$ in $\mathbb{P}^N$ is a bi-infinite sequence $(v_i)_{i \in \mathbb{Z}}$ of points in $\mathbb{P}^N$, called vertices, such that there exists a unique projective transformation $T$ with the property that, for all $i \in \mathbb{Z}$, $T v_i = v_{i+n}$.

The transformation $T$ is called the monodromy of the twisted $n$-gon $v$.

One can describe a twisted $n$-gon by specifying its first $n$ vertices $v_1, \ldots, v_n$ and the monodromy $T$. We identify the set of twisted $n$-gons in $\mathbb{P}^N$ with a Zariski dense open subset of $X_{N,n}$, via $v \mapsto (T, v_1, \ldots, v_n)$.

Then our $\text{SL}_{N+1}$-action (1) describes the effect of changing of coordinates on $\mathbb{P}^N$.

The pentagram map, introduced by Schwartz first for classical polygons [18] and later for twisted polygons [19], is a dynamical system $\mathcal{M}_{1,n}^2 \rightarrow \mathcal{M}_{1,n}^2$. Fixing $n \geq 4$ and cyclically ordering the vertices, we send each sufficiently generic twisted polygon $(v_i)$ to $(v'_i)$, where $$v'_i = v_{i-2}v_{i+1} \cap v_{i-1}v_{i+2}.$$ The map is projectively natural, so it defines a rational self-map of $\mathcal{M}_{1,n}^2$. Note that the $\text{SL}_3$-equivalence class of the monodromy $T$ is an invariant of the pentagram map, providing two algebraically independent conserved quantities. In fact, the pentagram map is a discrete algebraic completely integrable system: it has an iterate which is birational to a translation on a family of abelian varieties [21, 22]. But this is only a description of the generic behavior of the map. To understand the behavior of the pentagram map on degenerate polygons, one could restrict to the GIT boundary characterized in Theorem 1.1.

In addition to the pentagram map, there are a wide assortment of maps on $\mathcal{M}_{1,n}^N$ that are known or believed to be integrable, including generalized pentagram maps [9, 10, 12], cross-ratio dynamics [3], and maps associated to moves on triple-crossing diagrams [1]. More generally, the following recipe produces discrete dynamical systems on $\mathcal{M}_{1,n}^N$. Choose an integer $n' \leq n$, and let $\phi : (\mathbb{P}^N)^{n'} \rightarrow \mathbb{P}^N$ be any rational map which respects projective
transformations of $\mathbb{P}^N$. Then we get a (partially defined) self-map of the set of sequences $\mathbb{Z} \to \mathbb{P}^N$, defined by the rule $(v_i) \mapsto (v'_i)$, where

\[ v'_i = \phi(v_i, \ldots, v_{i+n'-1}). \]

As with the pentagram map, there is an induced map $\Phi$ on $\mathcal{M}_{l,n}^N$ that admits at least $N$ independent integrals. Silverman, in a talk at the 2021 Joint Mathematics Meetings, proposed studying the integrability of $\Phi$ when $\phi$ is chosen to be the Cayley-Bacharach map $(\mathbb{P}^2)^8 \to \mathbb{P}^2$.

Thus we have the following curious observation: the moduli space $\mathcal{M}_{l,n}^N$ both is a moduli space of dynamical systems with marked points, and itself admits many interesting dynamical systems.

1.3. Acknowledgements. The author thanks his advisor, Joe Silverman, for many thought-provoking discussions. Further thanks to Niklas Affolter, Madeline Brandt, Han-Bom Moon, and Mariel Supina for helpful conversations. The author was supported by an NSF Graduate Research Fellowship.

2. Preliminaries

In this section, we recall some standard concepts from geometric invariant theory. For a detailed development, see [6, Chapter 6–9].

Let an algebraic group $G$ act algebraically on a variety $V$, and let $\alpha : G \times V \to V$ denote the action. A categorical quotient is a pair $(V', \chi)$ consisting of a variety $V'$ and a $G$-invariant morphism $V \to V'$, such that for each variety $V''$, every $G$-invariant morphism $V \to V''$ factors through $\chi$ uniquely. We typically suppress the map $\chi$ from the notation.

A geometric quotient is a categorical quotient $(V', \chi)$ with the additional property that if $v, v' \in V$ have the same image in $V'$, then they share a $G$-orbit.

A categorical or geometric quotient $(V', \chi)$ is called good if it satisfies the additional properties:

1. For any open subset of $U$ of $V'$, the homomorphism $\chi^* : \mathcal{O}(U) \to \mathcal{O}(\chi^{-1}(U))^G$ of $G$-invariant sections.
2. If $W$ is a closed $G$-invariant subset of $V$, then $\chi(W)$ is a closed subset of $V'$.
3. If $W_1, W_2$ are closed $G$-invariant subsets of $V$ with empty intersection, then their images in $V'$ have empty intersection.

Let $V$ be a projective variety acted on by a geometrically reductive group $G$. Let $\mathcal{L}$ be an invertible sheaf on $V$, and equip $\mathcal{L}$ with a $G$-linearization. If $\mathcal{L}$ is very ample, this data is more or less equivalent to a choice of embedding of $V$ into a projective space so that $G$ acts via a linear group. An extension of the $G$-action on $V$ to a linear action on that projective space is called a $G$-linearization. A $G$-linearized sheaf is a very ample invertible sheaf together with a choice of $G$-linearization.

Proposition 2.1. For any very ample invertible sheaf $\mathcal{L}$ on a projective variety $V$ acted on by $\text{SL}_{N+1}$, there exists a unique $\text{SL}_{N+1}$-linearization of $\mathcal{L}$.

Remark 2.2. Our work fits into this setup, since $V = \mathcal{X}_{N,n}$ is projective and $G = \text{SL}_{N+1}$ is geometrically reductive over any algebraically closed field. The very ample invertible sheaves up to isomorphism are classified by tuples $(q, m_1, \ldots, m_n) \in \mathbb{N}^{n+1}$; they are of the form $\mathcal{O}(q, m_1, \ldots, m_n)$. Thus these also tuples classify $\text{SL}_{N+1}$-linearized sheaves on $\mathcal{X}_{N,n}$. 

Definition 2.3. Let \( \mathcal{L} \) be a \( G \)-linearized sheaf on \( V \). A point \( v \in V \) is semistable with respect to \( \mathcal{L} \) if there exists a tensor power \( \mathcal{L}^{\xi} \) and a global section \( s \in \Gamma(V, \mathcal{L}^{\xi})^G \) such that

\[
V_s := \{ y \in V : s(y) \neq 0 \}
\]
is affine and contains \( v \).

Call \( v \in V \) stable if it is semistable and the set \( V_s \) may be chosen such that the stabilizer of \( v \) in \( G \) is finite and all orbits of \( G \) in \( V_s \) are closed.

Call \( v \in V \) unstable if it is not semistable.

Denote the sets of stable, semistable, and unstable points with respect to \( \mathcal{L} \) (with its \( G \)-linearization) by

\[
V^s(\mathcal{L}), V^{ss}(\mathcal{L}), V^{us}(\mathcal{L}).
\]

In general, any of these sets could be empty.

Note that there is some variation in the literature regarding these definitions. In our notation, “not stable” and “unstable” mean different things. One could also consider the closely related concept of polystability, but we do not pursue this.

The following theorem shows that the semistable quotient is a compactification of the stable quotient.

Theorem 2.4. Let \( V \) be a variety with an algebraic action of a geometrically reductive group \( G \). Let \( \mathcal{L} \) be a \( G \)-linearized sheaf.

1. There exists a categorical quotient \( \overline{V^{ss}(\mathcal{L})}/G \) and it is quasi-projective. If \( V \) is projective, then \( \overline{V^{ss}(\mathcal{L})}/G \) is projective.
2. There exists a geometric quotient \( \overline{V^s(\mathcal{L})}/G \).
3. The stable locus \( V^s(\mathcal{L}) \) is a Zariski open subset of the semistable locus \( V^{ss}(\mathcal{L}) \), which is in turn an open subset of \( V \). The geometric quotient \( \overline{V^s(\mathcal{L})}/G \) is an open subset of the categorical quotient \( \overline{V^{ss}(\mathcal{L})}/G \).

Say a \( G \)-linearized sheaf \( \mathcal{L} \) embeds \( V \) in \( \mathbb{P}^D \). Then \( G \) acts via a linear representation in \( \text{SL}_{D+1} \). Let \( \mathbb{G}_m \) denote the multiplicative group scheme over \( k \). Let \( \ell : \mathbb{G}_m \to \text{SL}_{D+1} \) be a 1-parameter subgroup. Every 1-parameter subgroup of \( \text{SL}_{D+1} \) is diagonal in some basis of \( \mathcal{L} \). Such a basis is called a diagonalizing basis for \( \ell \). Choose a diagonalizing basis for \( \ell \). Its matrix is of the form

\[
\ell(\tau) = \begin{bmatrix}
\tau^{\lambda_1} \\
\tau^{\lambda_2} \\
\vdots \\
\tau^{\lambda_{D+1}}
\end{bmatrix}.
\]

Say \( v \in V \) and, in the diagonalizing basis for \( \ell \), the homogeneous coordinates of \( v \) are \( v = [X_1 : \ldots : X_{D+1}] \). The numerical invariant of \( \ell \) at \( v \) (with respect to \( \mathcal{L} \) with the chosen linearization) is

\[
\mu(v, \ell) := \min_{1 \leq i \leq D+1} \{ \lambda_i : X_i \neq 0 \}.
\]

This quantity is independent of choice of diagonalizing basis for \( \ell \). Note that the sign on \( \mu \) varies in the literature.

Now we can state the Hilbert-Mumford numerical criterion.
Theorem 2.5 (Mumford). With notation as above,

\[ V^{ss} = \{ v : \mu(v, \ell) \leq 0 \text{ for all } \ell \}, \]
\[ V^s = \{ v : \mu(v, \ell) < 0 \text{ for all } \ell \}. \]

A desemistabilizing 1-parameter subgroup for \( v \in V \) is a 1-parameter subgroup \( \ell \) for which \( \mu(v, \ell) \not< 0 \). A destabilizing 1-parameter subgroup for \( v \in V \) is a one-parameter subgroup \( \ell \) for which \( \mu(v, \ell) \not< 0 \). By Theorem 2.5, semistability of \( v \in V \) is equivalent to having no desemistabilizing 1-parameter subgroups. Similarly, stability is equivalent to having no destabilizing 1-parameter subgroups.

We set more notation:
- \( \Theta \), a maximal torus in \( \text{SL}_{N+1} \);
- \( W_Z \), the character lattice of \( \Theta \);
- \( W \), the \( \mathbb{R} \)-vector space \( W_Z \otimes \mathbb{R} \);
- \( R_Z \), the lattice of 1-parameter subgroups of \( \Theta \);
- \( R \), the \( \mathbb{R} \)-vector space \( R_Z \otimes \mathbb{R} \);
- \( \langle \cdot, \cdot \rangle : W \times R \to \mathbb{R} \) is the pairing defined as follows: for any \( \chi \in W_Z \) and \( \ell \in R_Z \), let \( \langle \chi, \ell \rangle \) be the integer \( \lambda \) such that the composed map \( \chi \circ \ell : \mathbb{G}_m \to \mathbb{G}_m \) is \( \tau \mapsto \tau^\lambda \).

Extend linearly.

A choice of isomorphism \( \Theta \cong \mathbb{G}_m^N \) induces an identification \( W_Z \cong \mathbb{Z}^{N+1} \). We also get an embedding \( r : R_Z \hookrightarrow \mathbb{Z}^{N+1} \) onto the hyperplane in \( \mathbb{Z}^{N+1} \) where the coordinates sum to 0. Note that \( R_Z \) is isomorphic to the \( A_N \) lattice rather than a free abelian group. With these identifications, the inner product \( \langle \cdot, \cdot \rangle \) is computed by dot product in \( \mathbb{R}^{N+1} \).

The \( \text{SL}_{N+1} \)-linearization of \( L \) induces a representation \( \Theta \hookrightarrow \text{GL}_{D+1} \). Any such representation splits completely, because \( \Theta \) is linearly reductive. Therefore we can choose a diagonalizing basis \( X_1, \ldots, X_{D+1} \) for the action of \( \Theta \) on \( L \). Each basis element \( X_i \) has an associated character \( \chi_i \in W_Z \).

The weight of \( X_i \), denoted \( \text{wt}(X_i) \), is the image of the character \( \chi_i \) in \( \mathbb{Z}^{N+1} \). The weight set \( \text{wt}(v) \subset W_Z \) of \( v \in V \), relative to the maximal torus \( \Theta \) and the choice of identification \( \Theta \cong \mathbb{G}_m^N \), is the set

\[ \text{wt}(v) = \{ \text{wt}(X_i) : X_i(v) \neq 0, \text{ for each } i = 1, \ldots, D+1 \} \].

The weight polytope of \( v \), denoted \( \Pi(v) \), is the convex hull of \( \text{wt}(X_i) \) in \( \mathbb{R}^{N+1} \). It is a convex polytope. We denote its interior by \( \Pi(v)^o \).

We further define

\[ V^{ss}_\Theta = \{ v : \mu(v, \ell) \leq 0 \text{ for all } \ell \subseteq \Theta \}, \]
\[ V^s_\Theta = \{ v : \mu(v, \ell) < 0 \text{ for all } \ell \subseteq \Theta \}. \]

The weight polytope of a point \( v \) depends on the identification \( \Theta \cong \mathbb{G}_m^N \), but the weight set viewed in \( W \) is basis-independent, so the statements \( 0 \in P(v) \) and \( 0 \in P(v)^o \) are basis-independent. In fact, we have the following consequence of Proposition 2.5.

Proposition 2.6. Given a maximal torus \( \Theta \) of \( \text{SL}_{N+1} \) and an identification \( \Theta \cong \mathbb{G}_m^N \), and a point \( v \in V \), the following are equivalent:

1. \( v \in V^{ss}_\Theta \),
2. \( 0 \in \Pi(v) \) for some diagonalizing basis of \( \Theta \).

Similarly, the following are equivalent:
Suppose $SL_{N+1}$ acts on a projective variety $V$, equipped with sheaf $\mathcal{L}$. Let $B$ be a basis of $k^{N+1}$. The basis $B$ has an associated maximal torus $\Theta$ in $SL_{N+1}$ containing all the 1-parameter subgroups of $SL_{N+1}$ that are diagonal in $B$. A basis $B'$ for $\mathcal{L}$ is called $B$-aligned if the representation of $\Theta$ in $GL_{D+1}$ is diagonal in $B'$.

The next two lemmas are standard; they describe how weight polytopes relate to the Segre and Veronese maps.

**Lemma 2.7.** Suppose $SL_{N+1}$ acts on two projective varieties $V_1, V_2$ via the linearized sheaves $\mathcal{L}_1, \mathcal{L}_2$. We consider the product action of $SL_{N+1}$ on $V_1 \times V_2$. Say $B$ is a basis of $k^{N+1}$ and $B_1, B_2$ are $B$-aligned bases of $\mathcal{L}_1, \mathcal{L}_2$. There is a $B$-aligned basis $B_1 \times B_2$ formed of all products of the form $b_1 b_2$, where $b_1 \in B_1$ and $b_2 \in B_2$.

The weight polytope of $(p_1, p_2)$ with respect to $B_1 \times B_2$ is the Minkowski sum

$$\Pi(p_1, p_2) = \Pi(p_1) + \Pi(p_2).$$

**Lemma 2.8.** Suppose $SL_{N+1}$ acts on a projective variety $X$ via the sheaf $\mathcal{L}$. For any $m \in \mathbb{N}$, we consider the induced action of $SL_{N+1}$ on $X$ with the tensor power sheaf $\mathcal{L} \otimes^m$. Let $B$ be a basis of $k^{N+1}$, and say $B'$ is a $B$-aligned basis of $\mathcal{L}$. There is a $B$-aligned basis $B''$ on $\mathcal{L} \otimes^m$ consisting of all $m$-fold products of elements of $B'$.

Let $\Pi(p)$ denote the weight polytope of $p$ for $\mathcal{L}$, and let $\Pi^{(m)}(p)$ denote the weight polytope of $p$ for $\mathcal{L} \otimes^m$. Then

$$\Pi^{(m)}(p) = m\Pi(p).$$

### 3. Corner polyhedra and stability

In this section, we introduce our key technical tool, the corner polyhedron.

We recall some terminology. The setting is any $\mathbb{R}$-vector space. Unless stated otherwise, half-spaces are assumed to be closed.

- A **convex polyhedron** is an intersection of finitely many half-spaces. All polyhedra we consider are convex, so we may just write polyhedron.
- A **convex polyhedral cone** is an intersection of finitely many half-spaces, all of which contain the origin at the boundary.
- A **polytope** is a bounded polyhedron.
- A **supporting halfspace** of a polyhedron is a halfspace containing the polyhedron and containing some point on its boundary.
- A **face** of a polyhedron is any set which is the intersection of that polyhedron with a supporting halfspace.
- For any $D \in \mathbb{N}$, a **facet** of a $D$-dimensional polyhedron is a face of dimension $D - 1$.
- Each facet has an **associated supporting halfspace**.
- A **vertex** is a 0-dimensional face.
- A polyhedron is **full-dimensional** if it is a polyhedron with topological dimension equal to the ambient vector space.
- A polyhedron is **pointed** if it has at least one vertex.
- A polytope is **integral** with respect to an integral lattice if its vertices are lattice points.
• A polyhedron is rational if the associated supporting halfspace of each facet is defined over $\mathbb{Q}$.

We will use the following basic principles of convex polyhedra throughout. For any set $\zeta$ in an $\mathbb{R}$-vector space, let $\text{Conv}(\zeta)$ denote its convex hull. We use $+$ to denote Minkowski sum.

• The convex hull of a finite set is a polytope.
• A convex polyhedron is equal to the intersection of the associated supporting halfspaces of its facets.
• Given convex polyhedra $\Pi_1, \Pi_2$, the Minkowski sum $\Pi_1 + \Pi_2$ is a polyhedron. Each face of $\Pi_1 + \Pi_2$ is the Minkowski sum of some face of $\Pi_1$ and some face of $\Pi_2$.
• Every convex polyhedron can be expressed as the Minkowski sum of a convex polyhedral cone and a convex polytope.
• Any functional on a polytope achieves its minimum at some vertex.
• An integral polytope is also rational as a polyhedron.
• The Minkowski sum of rational polyhedra is rational.

For any $N \in \mathbb{N}$, let $\mathbb{R}_+^N$ denote the nonnegative orthant. The corner hull of a set $\zeta \subseteq \mathbb{R}^N$, denoted $\text{Cor}(\zeta)$, is defined by

$$\text{Cor}(\zeta) = \text{Conv}(\zeta) + \mathbb{R}_+^N,$$

where $\mathbb{R}_+^N$ denotes the nonnegative orthant.

We will repeatedly use the following properties of the corner hull:

(1) The corner hull of a finite set is a finite, full-dimensional, pointed, unbounded, convex polyhedron. The vertices of the corner hull of a set $\zeta$ are themselves elements of $\zeta$.

(2) For any sets $\zeta, \zeta' \subset \mathbb{R}^N$,

$$\text{Cor}(\zeta + \zeta') = \text{Cor}(\zeta) + \text{Cor}(\zeta').$$

(3) For any real number $m > 0$, and any set $\zeta \subset \mathbb{R}^N$,

$$\text{Cor}(m\zeta) = m\text{Cor}(\zeta).$$

**Lemma 3.1** (Positive hyperplane separation). Let $(\mathbb{R}^N)_+^\vee$ denote the nonnegative orthant in the dual space to $\mathbb{R}^N$, with respect to the dual basis. Let $(\mathbb{Z}^N)_+^\vee$ denote the set of standard lattice points within it.

(1) For any finite set $\zeta \subset \mathbb{R}^N$, we have $0 \in \text{Cor}(\zeta)$ if and only if there is no $r \in (\mathbb{R}^N)_+^\vee \setminus \{0\}$ such that, for all $w \in \zeta$,

$$r(w) > 0.$$

(2) For any finite set of lattice points $\zeta \subset \mathbb{Z}^N$, we have $0 \in \text{Cor}(\zeta)$ if and only if there is no lattice point $r \in (\mathbb{Z}^N)_+^\vee \setminus \{0\}$ such that, for all $w \in \zeta$,

$$r(w) > 0.$$

(3) For any finite set $\zeta \subset \mathbb{R}^N$, we have $0 \in \text{Cor}(\zeta) \circ$ if and only if there is no $r \in (\mathbb{R}^N)_+^\vee \setminus \{0\}$ such that, for all $w \in \zeta$,

$$r(w) \geq 0.$$
For any finite set of lattice points $\zeta \subset \mathbb{Z}^N$, we have $0 \in \text{Cor}(\zeta)^\circ$ if and only if there is no lattice point $r \in (\mathbb{Z}^N)^_+ \setminus \{0\}$ such that, for all $w \in \zeta$, $r(w) \geq 0$.

Proof. (1) Say $0 \in \text{Cor}(\zeta)$. Then there exists some point $w_0 \in \text{Conv}(\zeta)$ such that, for all $r \in (\mathbb{R}^N)^_+$, $0 \geq r(w_0)$. Functionals on $\text{Conv}(\zeta)$ achieve their minima on an element of $\zeta$. So, for each $r \in (\mathbb{R}^N)^_+$, there exists some $w \in \zeta$, depending on $r$, such that $r(w_0) \geq r(w)$. Thus $0 \geq r(w)$.

For the other direction, say $0 \not\in \text{Cor}(\zeta)$. There exists some shortest-length vector $w_0$ in $\text{Cor}(\zeta)$. By the hyperplane separation theorem, the functional $r$ dual to $w_0$ takes only positive values on $\text{Cor}(\zeta)$. In particular we know that $r$ takes only positive values on $\zeta$. The coordinates of $w_0$ are non-negative, since otherwise the negative coordinates could be replaced by 0 to obtain a shorter-length vector in $\text{Cor}(\zeta)$. The coordinates of $w_0$ are rational, since the points of $\zeta$ are lattice points. Thus some positive integer multiple of $r$ is in $(\mathbb{R}^N)^_+ \setminus \{0\}$.

(2) One direction follows immediately from (1). For the other direction, note that in the proof of (1), since $\text{Cor}(\zeta)$ is the sum of an integral polytope and a rational polyhedral cone, all its facets are rational. Thus the shortest vector $w_0$ has rational coordinates, so a sufficiently high multiple of its dual is the desired lattice point $r$.

(3) We have $\text{Cor}(\zeta)^\circ = (O^+)^\circ + \text{Conv}(\zeta)$. Thus if $0 \in \text{Cor}(\zeta)^\circ$, then there exists some point $w_0 \in \text{Conv}(\zeta)$ such that, for all $r \in (\mathbb{R}^N)^_+ \setminus \{0\}$,

$$0 > r(w_0).$$

Following the same argument as in (1), for each $r$ there exists some $w \in \zeta$ such that $r(w_0) \geq r(w)$, so $0 > r(w)$.

For the other direction, we already proved it in (1), except for the case that 0 is on the boundary of $\text{Cor}(\zeta)$. Then 0 belongs to a facet of $\text{Cor}(\zeta)$. Take $r$ to be the functional defining that facet’s associated supporting halfspace.

(4) Similar to (2) and (3); omitted.

Let $N \in \mathbb{N}$. We consider the lattice $\mathbb{Z}^{N+1}$ embedded in $W = \mathbb{R}^{N+1}$. We denote the standard basis vectors by $e_1, \ldots, e_{N+1}$. We denote the dual space of $\mathbb{R}^{N+1}$ by $R = (\mathbb{R}^{N+1})^\vee$. The space $R$ is spanned by the dual coordinates to the standard basis vectors, denoted $x_1, \ldots, x_{N+1}$.

Let $1 = (1, \ldots, 1) \in W$. Let $\tilde{W}$ be the hyperplane orthogonal to $1$. The elements of $W$ that belong to $\tilde{W}$ are vectors with coordinates that sum to 0.

Let $\tilde{R} = (\tilde{W})^\vee$. We consider the basis $s_1, \ldots, s_N$ of $\tilde{R}$ defined by

$$s_i = \sum_{j=1}^{i} x_j.$$

Let $\tilde{R}^+$ denote the nonnegative $\mathbb{R}$-span of $s_1, \ldots, s_N$. 

11
We work with this particular basis $s_1, \ldots, s_N$ because it has the following convenient property. There is a restriction map $R \to \hat{R}$ defined by restricting functionals from $W$ to $\hat{W}$. For any $r \in R$, we denote its restriction by $\bar{r}$. If $r = (r_1, \ldots, r_{N+1})$, we have $r_1 \geq \ldots \geq r_{D+1}$ if and only if $\bar{r} \in \hat{R}^+$. Further, if $r(1) = 0$, then we have $\bar{r} = 0$ if and only if $r_1 = \ldots = r_{D+1} = 0$.

Let $O^+$ denote the nonnegative orthant in $\hat{W}$ relative to the dual basis $s_1, \ldots, s_N$. Its interior $(O^+)^\circ$ is the strictly positive orthant.

The corner hull of a set $\zeta \subseteq \hat{W}$, denoted $\text{Cor}(\zeta)$, is defined as the corner hull of the image of $\zeta$ in $\mathbb{R}^N$ via the identification $\hat{W} \cong \mathbb{R}^N$ from the preferred basis $s_1, \ldots, s_N$. That is,

$$\text{Cor}(\zeta) = \text{Conv}(\zeta) + O^+.$$  

**Definition 3.2.** Consider a projective variety $V$ equipped with a $\text{SL}_{N+1}$-linearized sheaf. Let $B$ be a basis of $k^{N+1}$. Let $W \cong \mathbb{R}^{N+1}$ be the vector space over the character lattice corresponding to basis $B$, and let $\hat{W}$ be the hyperplane of points of $Z$ with coordinates that sum to 0. Let $\Pi(v) \subset W$ denote the weight polytope of $v$ with respect to this basis. Let $\bar{\Pi}(v)$ denote the projection of $\Pi(v)$ to $\hat{W}$. The corner polyhedron of $v \in V$, denoted $\Pi_+(v)$, is the corner hull

$$\text{Cor}(\bar{\Pi}(v)) \subseteq \mathbb{R}^N.$$  

We call the vertices of $\Pi_+(v)$ the control points. The set of control points is denoted $\text{Ctrl}(v)$.

We emphasize that the weight polytope $\Pi(v)$ is a subset of the vector space $W$, which has dimension $N + 1$, whereas the corner polyhedron $\Pi_+(v)$ is a subset of the subspace $\hat{W}$, which has dimension $N$.

Let $B$ be a basis, with vectors $b_1, \ldots, b_{N+1}$. We emphasize that $B$ is ordered. A 1-parameter subgroup of $\text{SL}_{N+1}$ is said to be along $B$ if, written in basis $B$, it is of the form $\text{diag}[\tau^1, \tau^2, \ldots, \tau^{N+1}]$, where $r_1 \geq \ldots \geq r_{N+1}$. Every 1-parameter subgroup of $\text{SL}_{N+1}$ is along some basis $B$ because we can permute basis vectors to get a new basis.

Let $V$ be a variety acted on by $\text{SL}_{N+1}$, equipped with a linearized sheaf $\mathcal{L}$. Given an ordered $B$, an element $v \in V$ is called $B$-stable if there is no destabilizing 1-parameter subgroup of $\text{SL}_{N+1}$ along $B$. Similarly, a point $v$ is $B$-semistable if there is no desemistabilizing 1-parameter subgroup along $B$.

Now we interpret the Hilbert-Mumford criterion in these terms.

**Proposition 3.3.** Suppose $\text{SL}_{N+1}$ acts on a projective variety $V$ via the sheaf $\mathcal{L}$. Let $B$ be a basis of $k^{N+1}$. Then $v \in V$ is $B$-semistable if and only if

$$0 \in \Pi_+(v).$$

The point $v \in V$ is $B$-stable if and only if

$$0 \in \Pi_+(v)^\circ.$$ 

**Proof.** One checks $B$-semistability by computing the numerical invariant $\mu(v, \ell)$ for every 1-parameter subgroup $\ell$ along $B$. We have

$$\mu(v, \ell) = \min_{w \in \text{wt}(v)} r(\ell)(w).$$

For any $w \in W$, let $\bar{w}$ denote the projection of $w$ to $\hat{W}$. For any $\ell$, the vector $r(\ell)$ is orthogonal to $(1, \ldots, 1)$. So, for any $\ell$ and $w$, we have

$$r(\ell)(w) = r(\ell)(\bar{w}) = \bar{r}(\ell)(\bar{w}).$$
As \( \ell \) ranges over 1-parameter subgroups along \( B \), the vector \( \bar{r}(\ell) \) ranges over nonzero lattice points in \( \mathbb{R}^+ \).

Thus \( v \) is \( B \)-semistable if and only if, for all nonzero lattice points \( \bar{r} \in \mathbb{R}^+ \), there exists \( w \in \text{wt}(v) \) such that

\[
\bar{r}(w) \leq 0.
\]

By the choice of basis \( s_1, \ldots, s_N \) on \( \mathbb{R} \) and Lemma 3.1 (2), this is equivalent to

\[
0 \in \Pi_+(v).
\]

The \( B \)-stability claim follows from the same argument, but applying Lemma 3.1 (4) instead.

\[ \square \]

3.1. First application: configurations of points. In this section, we show how to analyze the diagonal action of \( \text{SL}_N+1 \) on \( (\mathbb{P}^N)^n \) with the corner polyhedron. These results are essential for our proof of Theorem 1.1, and we recover a classical result of Mumford as Theorem 3.6 along the way.

For any \( m \in \mathbb{N} \), let \( [m] \subset \mathbb{N} \) denote the set \( \{1, \ldots, m\} \).

**Proposition 3.4.** Consider the action of \( \text{SL}_N+1 \) on \( \mathbb{P}^N \), with \( \mathcal{L} = \mathcal{O}(m) \) for some \( m \geq 1 \). Choose a basis \( B \) of \( k^{N+1} \), let \( X_1, \ldots, X_{N+1} \) be induced coordinates on \( \mathbb{P}^N \), and let \( B' \) be the induced \( B \)-aligned basis from the Segre map. Given a point \( v \in \mathbb{P}^N \), let \( i \) be the largest index such that \( X_i(v) \neq 0 \). Then

\[
\text{Ctrl}(v, \mathcal{L}) = \left\{ m \cdot \left( -\frac{1}{N+1}, \ldots, -\frac{i-1}{N+1}, 1 - \frac{i}{N+1}, \ldots, 1 - \frac{N}{N+1} \right) \right\}.
\]

**Proof.** Assume \( m = 1 \), since then the general case follows from Lemma 2.8.

Let \( \ell \) be a 1-parameter subgroup along a basis \( B \), with \( r(\ell) = (r_1, \ldots, r_{N+1}) \). Let \( X_1, \ldots, X_{N+1} \) be generators of \( \mathcal{O}(1) \) obtained from \( B \). Then, for all \( i \in [N+1] \), the weight of \( X_i \) is the standard basis vector

\[
\text{wt}(X_i) = e_i.
\]

Therefore, we have

\[
s_j(\text{wt}(X_i)) = \begin{cases} 
0 & \text{if } j < i, \\
1 & \text{otherwise}. 
\end{cases}
\]

Since the sum of the entries of \( \text{wt}(X_i) \) is 1, we calculate

\[
\overline{\text{wt}}(X_i) = \text{wt}(X_i) - \frac{1}{N+1}.
\]

We have \( s_j(1) = j \). This gives us

\[
s_j(\overline{\text{wt}}(X_i)) = \begin{cases} 
-\frac{j}{N+1} & \text{if } j < i, \\
1 - \frac{j}{N+1} & \text{otherwise.}
\end{cases}
\]

Thus, for all \( (i, i', j) \) such that \( i < i' \), we have

\[
s_j(\overline{\text{wt}}(X_i)) \leq s_j(\overline{\text{wt}}(X_{i'})).
\]

It follows that every element of \( \overline{\text{wt}}(v) \) belongs to the nonnegative orthant at \( \overline{\text{wt}}(X_i) \), where \( i \) is the largest index for which \( X_i(v) \neq 0 \). \[ \square \]
Let $m = (m_1, \ldots, m_n)$ be an $n$-tuple of positive integer weights. Each such vector determines a very ample sheaf $\mathcal{O}(m)$ on $(\mathbb{P}^N)^n$. For present and later use, we define a vector

$$\eta(v) := \left( \sum_{i=1}^n \frac{-jm_i}{N+1} + \sum_{i \in [n]: x_{j+1}(v_i) = \ldots = x_{N+1}(v_i) = 0} m_i \right).$$

(4)

**Proposition 3.5.** Consider the diagonal action of $\text{SL}_{N+1}$ on $(\mathbb{P}^N)^n$, with $\mathcal{L} = \mathcal{O}(m)$. Choose a basis $B$ of $k^{N+1}$, and let $B'$ be the induced $B$-aligned basis from the Segre map. Then, for each $v = (v_1, \ldots, v_n) \in (\mathbb{P}^N)^n$.

$$\text{Ctrl}(v, \mathcal{L}) = \{ \eta(v) \}.$$

*Proof.* The case $n = 1$ is the result of Proposition 3.3. By Lemma 2,4, the set $\text{Ctrl}(v, \mathcal{L})$ consists of just one vector, and we can compute it as the sum, for $1 \leq i \leq n$, of the control vector of $v$ relative to $\mathcal{O}(m_i)$. The result follows. 

We can obtain as a corollary the following theorem of Mumford, which serves as the template for Theorem 1.1.

**Theorem 3.6 (Mumford, [14]).** Consider the diagonal action of $\text{SL}_{N+1}$ on $(\mathbb{P}^N)^n$, with $\mathcal{L} = \mathcal{O}(m)$. Then $v = (v_1, \ldots, v_n)$ is semistable if and only if, for every nonzero proper subspace $H \subset k^{N+1}$, we have

$$\sum_{i \in [n]: v_i \in H} m_i \leq \frac{\dim H}{N+1} \left( \sum_{i=1}^n m_i \right).$$

(5)

The configuration $v$ is stable if and only if the inequality (5) is strict.

*Proof.* By Proposition 3.3, the point $v$ is semistable if and only if, in each basis $B$ of $k^{N+1}$, there is a $B$-aligned basis $B'$ of $\mathcal{L}$ such that $0 \in \Pi_+(v)$. For any given basis $B$, we let $B'$ be the natural one coming from the Segre and Veronese embeddings (Proposition 3.5). By Proposition 3.5, a point $v$ is $B$-semistable if and only if each entry of $\eta(v)$ is nonpositive. So, for each $j \in [N]$, the $j$-th coordinate of $\eta(v)$ imposes the condition

$$\sum_{i \in [n]: x_{j+1}(v_i) = \ldots = x_{N+1}(v_i) = 0} m_i \leq \sum_{i=1}^n \frac{jm_i}{N+1}.$$

Let $H_j = \text{Span}(X_1, \ldots, X_j)$, viewed as a subspace of $k^{N+1}$. Then $j = \dim H_j$, and the condition $x_{j+1}(v_i) = \ldots = x_{N+1}(v_i) = 0$ is equivalent to $v \in H_j$. Therefore, $B$-semistability is equivalent to satisfying (5) for the sequence of subspaces $H_1, \ldots, H_N$ coming from basis $B$. Every nontrivial proper subspace appears this way for some basis $B$, so the result follows.

For stability, the same argument works using strict inequalities. 

3.2. **Corner polyhedra of type $A_N$.** Consider the action of $\text{SL}_{N+1}$ by conjugation on $\mathbb{P}(\text{Mat}_{N+1})$. Let $B$ be some basis of $k^{N+1}$. Let $a_{ij}$, $1 \leq i, j \leq N + 1$, be the basis of $\mathcal{O}(1)$ on $\mathbb{P}(\text{Mat}_{N+1})$ corresponding to matrix entries in basis $B$. Any 1-parameter subgroup $\ell$ that is diagonal in $B$ has an associated vector $r(\ell) = (r_1, \ldots, r_{N+1})$, and we have $\ell(\tau) \cdot a_{ij} = \tau^{r_i-r_j}$. It follows that, with the choice of sheaf $\mathcal{L} = \mathcal{O}(1)$,

$$\text{wt}(a_{ij}) = e_i - e_j.$$
In this section, we classify the corner polyhedra that can arise for the conjugation action. We introduce the following definition.

**Definition 3.7.** A corner polyhedron of type $A_N$ is the corner hull $\text{Cor}(\zeta)$ of a finite, nonempty set $\zeta$ of vectors of the form $e_i - e_j$, where $i, j \in [N + 1]$. Note that we allow $i = j$.

By Definition 3.2, the corner polyhedra of type $A_N$ are exactly the polyhedra of the form $\Pi_+(M)$, for some $M \in \mathbb{P}(\text{Mat}_{N+1})$.

To motivate the terminology, recall that a root polytope of type $A_N$ is the convex hull of a nonempty set of vectors of the form $e_i - e_j$, where $i, j \in [N + 1]$. These vectors are roots of the $A_N$ lattice. The full root polytope of type $A_N$ is the root polytope defined with all possible vectors $e_i - e_j$. The combinatorics of full root polytopes is known in detail; see [2, 5]. Full root polytopes are orbit polytopes, since their vertices are the orbit of $(1, -1, 0, \ldots, 0)$ by the symmetric group $S_{N+1}$. Our setting is much more flexible: we work with *any* nonempty set of roots.

We briefly recall our notation:

- $W$, the $\mathbb{R}$-vector space over the character lattice in basis $B$, identified with $\mathbb{R}^{N+1}$ by the basis $e_1, \ldots, e_{N+1}$.
- $\bar{W} \subset W$, the hyperplane orthogonal to $1$.
- $R$, the dual space to $W$, identified with $\mathbb{R}^{N+1}$ by the basis $x_1, \ldots, x_{N+1}$.
- $s_i$, for each $i \in [N]$, defined as the functional $x_1 + \ldots + x_i$.
- For any $w \in W$, we write $\bar{w}$ for the projection of $w$ to $\bar{W}$, identified with $\mathbb{R}^N$ by the dual basis to $s_1, \ldots, s_N$.
- $\bar{R}$, the dual space of $\bar{W}$, identified with $\mathbb{R}^N$ by the basis $s_1, \ldots, s_N \in \bar{R}$.
- $\Pi_+(M)$, the corner polyhedron associated to $M$.

**Lemma 3.8.** Let $a_{ij}$ be an entry coordinate of $\text{Mat}_{N+1}$. Then $\bar{\text{wt}}(a_{ij})$ depends on the $a_{ij}$ location relative to the main diagonal, as follows:

1. If $i = j$, then $\bar{\text{wt}}(a_{ij}) = 0$.
2. If $i > j$, then
   \[
   \bar{\text{wt}}(a_{ij}) = (0, \ldots, 0, -1, \ldots, -1, 0, \ldots, 0),
   \]
   where the $-1$-block runs from $j$ to $i - 1$ inclusive.
3. If $i < j$, then
   \[
   \bar{\text{wt}}(a_{ij}) = (0, \ldots, 0, 1, \ldots, 1, 0, \ldots, 0),
   \]
   where the 1-block runs from $i$ to $j - 1$ inclusive.

**Proof.** First, notice that $\text{wt}(a_{ij}) = e_i - e_j$ is in $\bar{W}$ already, so $\bar{\text{wt}}(a_{ij}) = \text{wt}(a_{ij})$. The result follows from evaluating the functionals $s_1, \ldots, s_N$ on $\bar{\text{wt}}(a_{ij})$.

We now discuss the simplest examples in dimension $N = 1, 2, 3$. We include a catalogue of more elaborate examples in Section 3.4

**Example 3.9.** Let $M \in \text{Mat}_{N+1}$ be a matrix with all entries nonzero. Then the weight polytope $\Pi(M)$ is the full root polytope of type $A_N$.

- If $N = 1$, then $\Pi(M)$, viewed as a subset of $W = \mathbb{R}^2$, is the line segment from $(-1, 1)$ to $(1, -1)$. In the preferred basis $s_1$ on $W$, the polytope $\Pi(M)$ is the interval $[-1, 1]$. The corner polyhedron $\Pi_+(M)$ is the ray $[-1, \infty)$. 

15
Lemma 3.10. Let $N = 2$, then $\Pi(M)$ is a regular hexagon in $W = \mathbb{R}^2$. Its vertices in $W$ are
\[-1, 0, 1), (-1, 1, 0), (0, -1, 1), (1, 0, -1), (1, -1, 0), (0, 1, -1).\]
Note that $(0, 0, 0) \in \text{wt}(M)$ is not a vertex of $\Pi(M)$ because it is in the interior. In the basis $s_1, s_2$ on $W$, the vertices of $\Pi(M)$ are
\[-1, -1), (-1, 0), (0, -1), (1, 1), (0, 1), (0, 1).\]
We see from this description that the corner polyhedron $\Pi_+(M)$ is the nonnegative orthant translated by $(-1, -1)$.

If $N = 3$, then $\Pi(T)$ is a cuboctahedron. In $W$, its vertices are the 12 vectors with entries 0, 0, −1, 1 in some order. In $W$, its vertices are
\[-1, -1, -1), (-1, -1, 0), (-1, -1, 0), (-1, 0, 0), (0, 0, -1),
(1, 1, 1), (1, 1, 0), (0, 1, 1), (1, 0, 0), (0, 1, 0), (0, 0, 1).\]
Thus $\Pi_+(M)$ is the nonnegative orthant translated by $(-1, -1, -1)$.

As the examples show, the corner polyhedron $\Pi_+(M)$ is generally much simpler than the weight polytope $\Pi(M)$.

Given $(i, j), (i', j') \in [N + 1]^2$, we say $(i, j)$ outweighs $(i', j')$ if $\text{wt}(a_{ij'}) \in \text{wt}(a_{ij}) + O^+$ and $\text{wt}(a_{ij'}) \neq \text{wt}(a_{ij})$. Equivalently, entry $(i, j)$ outweighs $(i', j')$ if $\text{wt}(a_{ij'}) \neq \text{wt}(a_{ij})$ and, for each functional $s = s_1, \ldots, s_N$, we have
\[s(\text{wt}(a_{ij})) \leq s(\text{wt}(a_{ij'})).\]

The outweighing relation is a strict partial order on $[N + 1]^2$. That is, outweighing is irreflexive, transitive and antisymmetric.

A minimal element with respect to outweighing is an entry that is not outweighed by any other entries. To describe $\Pi_+(M)$, we only need to know the nonzero entries $(i, j)$ of $M$ that are minimal with respect to outweighing, among all nonzero entries of $M$.

Outweighing can be described explicitly by cases depending on the location of the entries $(i, j), (i', j')$ relative to the main diagonal.

**Lemma 3.10.** Let $(i, j), (i', j') \in [N + 1]^2$.

1. If $i > j$ and $i' > j'$, then $(i, j)$ outweighs $(i', j')$ if and only if $(i, j) \neq (i', j')$ and $i \geq i'$ and $j \leq j'$.
2. If $i > j$ and $i' \leq j'$, then $(i, j)$ outweighs $(i', j')$.
3. If $i < j$ and $i' < j'$, then $(i, j)$ outweighs $(i', j')$ if and only if $(i, j) \neq (i', j')$ and $i \geq i'$ and $j \leq j'$.

**Proof.** These results follow immediately from Lemma 3.8.

**Example 3.11.** Say $N = 3$, so $M \in \text{Mat}_4$.

- The entry $(4, 2)$ outweighs every entry on or above the main diagonal, and also outweighs $(4, 3)$ and $(3, 2)$.
- The entry $(2, 4)$ only outweighs $(3, 4)$ and $(4, 4)$.
- The entry $(2, 2)$ outweighs every entry above the main diagonal.

A path in an $(N + 1) \times (N + 1)$ matrix is a word of length $2N + 2$ in the letters $\downarrow$ and $\rightarrow$, consisting of $N + 1$ instances of each letter. We identify each path with the corresponding sequence of down-directed and right-directed line segments in the gridlines between entries.
A Dyck path is a path that does not cross the main diagonal, but may meet it. A lower Dyck path is a Dyck path beginning with ↓, and an upper Dyck path is a Dyck path beginning with →. Note that the first letter determines whether the Dyck path is below or above the main diagonal.

A path contains a pair \((i, j) \in [N + 1]^2\) if \((i, j)\) is above the path.

The profile of a matrix \(M\), denoted \(\text{Prof}(M)\), is defined as follows.

1. Say \(M\) is not strictly-upper-triangular. Then \(\text{Prof}(M)\) is defined to be the upper Dyck path in the grid lines of \(M\) that contains the fewest entries among all upper Dyck paths that contain all nonvanishing entries.
2. Say \(M\) is strictly upper-triangular. Then \(\text{Prof}(M)\) is defined as the lower Dyck path that contains the fewest entries among all lower Dyck paths that contain all nonvanishing entries.

We call \(\text{Prof}(0)\) the trivial profile.

A pivotal entry of a matrix \(M\) is a pair \((i, j), \text{ where } i, j \in [N + 1]\), such that the path \(\text{Prof}(M)\) follows the closest gridlines to the left of \((i, j)\) and below \((i, j)\). In other words, the pivotal entries correspond to appearances of the subword ↓→ in \(\text{Prof}(M)\).

Lemma 3.12. Let \(M \in \text{Mat}_{N+1}\) be a nonzero matrix. Let \(E(M)\) denote the set of nonvanishing entries \((i, j) \in [N + 1]^2\) of \(M\) that are minimal with respect to outweighing among all nonvanishing entries of \(M\). Then \(E(M)\) is a subset of the set of pivotal entries of \(M\), as follows:

1. If \(M\) is upper-triangular but not strictly-upper-triangular, then \(E(M)\) is the set of nonvanishing diagonal entries of \(M\).
2. If \(M\) is not upper-triangular, then \(E(M)\) is the set of pivotal entries \((i, j)\) of \(M\) such that \(i > j\).
3. If \(M\) is strictly upper-triangular, then \(E(M)\) is the set of pivotal entries of \(M\).

Proof. (1) Since \(M\) is upper-triangular but not strictly-upper-triangular, it has a nonvanishing diagonal entry, so by Lemma 3.10, no entry \((i, j)\) with \(i < j\) is minimal. Since \(M\) is upper-triangular, by Lemma 3.10, all the diagonal nonvanishing entries are minimal.

(2) Since \(M\) is not upper-triangular, it has a nonvanishing entry below the main diagonal. By Lemma 3.10, that entry outweighs every entry on or above the main diagonal. So every element of \(E(M)\) is below the main diagonal. Now, consider a nonvanishing entry \((i', j')\) below the main diagonal. The entry \((i', j')\) is outweighed by some entry \((i, j)\) if and only if \((i', j')\) is not pivotal.

(3) Consider an entry \((i', j')\) above the main diagonal. Since \(M\) is strictly upper-triangular, by Lemma 3.10, the entry \((i', j')\) is outweighed by some entry \((i, j)\) if and only if \((i', j')\) is not pivotal. □

The set of pivotal entries of \(M\) has a natural ordering, namely the order in which the pivotal entries appear along the path from upper-left to bottom-right.

Recall that the set \(\text{Ctrl}(M)\) of control points is the set of vertices of the corner polyhedron \(\Pi_+(M)\). The next proposition shows how to calculate \(\text{Ctrl}(M)\).

Proposition 3.13. For any nonzero matrix \(M \in \text{Mat}_{N+1}\), there is a canonical ordering on the elements of \(\text{Ctrl}(M)\).
• If $M$ is upper triangular but not strictly-upper-triangular, then $\text{Ctrl}(M) = \{0\}$, so the ordering is the trivial one.

• For any other nonzero $M$, the off-diagonal pivotal entries of $M$ are in bijection with $\text{Ctrl}(M)$ by the map

$$ (i, j) \mapsto \overline{\text{wt}}(a_{ij}). $$

The canonical ordering on $\text{Ctrl}(M)$ can be defined in any of the following equivalent ways:

- Take the ordering inherited from the natural ordering on the pivotal entries;
- Take the ordering by the index of the first nonzero coordinate;
- Take the ordering by the index of the last nonzero coordinate.

**Proof.** Let $E(M)$ be as defined in Lemma 3.12. Let

$$ \overline{\text{wt}}(E(M)) = \{ \overline{\text{wt}}(a_{ij}) : (i, j) \in E(M) \}. $$

We consider the same three cases.

(1) Suppose $M$ is upper triangular but not strictly-upper-triangular. Then it follows immediately from Lemma 3.38 that $\text{Ctrl}(M) = \{0\}$.

(2) Suppose $M$ is not of the form of case (1). We claim that $\text{Ctrl}(M) = \overline{\text{wt}}(E(M))$. The containment $\text{Ctrl}(M) \subseteq \overline{\text{wt}}(E(M))$ follows from the definition of $E(M)$, since if some entry $(i, j)$ is outweighed by a nonvanishing entry $(i', j')$, then $\overline{\text{wt}}(a_{ij}) \in \overline{\text{wt}}(a_{ij}) + O^+$ and $\overline{\text{wt}}(a_{ij}) \neq \overline{\text{wt}}(a_{ij})$, so $\overline{\text{wt}}(a_{ij})$ is not a vertex.

By Lemma 3.12, there is an induced ordering on $E(M)$ from the canonical ordering on the pivotal entries. Since $\overline{\text{wt}}$ is injective on $E(M)$, we also obtain an ordering on $\overline{\text{wt}}(E(M))$, and by restriction, on $\text{Ctrl}(M)$. This is the canonical ordering in the theorem statement. The canonical ordering on the set of pivotal entries can equivalently be described as ordering by increasing row or increasing column in $M$. Combining this observation with the explicit description of the weights in Lemma 3.38 gives us the three equivalent definitions of the ordering on $\text{Ctrl}(M)$.

Now, we claim $\text{Ctrl}(M) \supseteq \overline{\text{wt}}(E(M))$. To prove this, we subdivide into two cases.

(2a) Assume $M$ is non-upper-triangular. Then $\text{Prof}(M)$ is a lower Dyck path.

Now, given $w \in \overline{\text{wt}}(E(M))$, we must show that $w$ is a vertex of $\Pi_+(M)$. This is true if there are $N$ independent linear functionals $r \in \bar{R}^+$ which achieve their minimum on $\Pi_+(M)$ at $w$. Say $\kappa = \#\overline{\text{wt}}(E(M))$. Using the canonical ordering, let $w_c$ be the $c$-th element of $\overline{\text{wt}}(E(M))$. It is of the form

$$ (0, \ldots, 0, -1, \ldots, -1, 0, \ldots, 0), $$

where, for some $t_c, u_c \in [N]$ with $t_c \leq u_c$, the $-1$’s run from index $t_c$ to $u_c$ inclusive. It follows from the canonical ordering that, for any $c', c'' \in [\kappa]$ with $c' < c''$, we have $t_{c'} < t_{c''}$ and $u_{c'} < u_{c''}$. Therefore, the following $N$ functionals on $\overline{\text{wt}}(E(M))$ are minimized at $w_c$.

- For all $i$ in the range $1 \leq i < t_c$, the functional $s_i + s_{uc}$ on $\overline{\text{wt}}(E(M))$ achieves its minimum value $-1$ at $w_c$.
- For all $i$ in the range $t_c \leq i \leq u_c$, the functional $s_i + s_{uc}$ on $\overline{\text{wt}}(E(M))$ achieves its minimum value $-2$ at $w_c$.
- For all $i$ in the range $u_c < i \leq N$, the functional $s_{tc} + s_i$ on $\overline{\text{wt}}(E(M))$ achieves its minimum value $-1$ at $w_c$. 18
The $N$ functionals named above are easily seen to be independent, so $w_c$ is a vertex of the corner hull $\Pi_+(M)$ of $\widetilde{wt}(E(M))$.

(2b) Assume $M$ is strictly upper-triangular. Then $\Prof(M)$ is an upper Dyck path. As in (2a), we claim $\Ctrl(M) \supseteq \widetilde{wt}(E(M))$. Given $w \in \widetilde{wt}(E(M))$, we seek $N$ independent linear functionals $r \in \mathbb{R}^+$ which achieve their minimum on $\Pi_+(M)$ at $w$. Say $\kappa = \# \widetilde{wt}(E(M))$. Using the canonical ordering, let $w_c$ be the $c$-th element of $\widetilde{wt}(E(M))$. It is of the form $(0, \ldots, 0, 1, \ldots, 1, 0, \ldots, 0)$, where for some $t_c, u_c \in [N]$ with $t_c \leq u_c$, the 1’s run from index $t_c$ to $u_c$ inclusive. It follows from the canonical ordering that, for any $c', c'' \in [\kappa]$ with $c' < c''$, we have $t_{c'} < t_{c''}$ and $u_{c'} < u_{c''}$. Then the following $N$ functionals are independent and simultaneously minimized at $w_c$.

- For all $1 \leq i < t_c$ and $i > u_c$, the functional $s_i$ on $\widetilde{wt}(E(M))$ achieves its minimum value 0 at $w_c$.
- For all $i$ in the range $t_c \leq u_c$, the functional
  
  $s_1 + \ldots + s_{t_c-1} + s_i + s_{u_c+1} + \ldots + s_\kappa$

  achieves its minimum value 1 at $w_c$.

\[\square\]

Corollary 3.14. Two nonzero matrices in $\Mat_{N+1}$ have the same corner polyhedron if and only if they have the same profile.

Proof. Let $M_1, M_2 \in \Mat_{N+1}$. By the basic properties of the corner hull operation, we have $\Pi_+(M_1) = \Pi_+(M_2)$ if and only if $\Ctrl(M_1) = \Ctrl(M_2)$. By Lemma 3.13 two matrices $M_1$ and $M_2$ satisfy $\Ctrl(M_1) = \Ctrl(M_2)$ if and only if $\widetilde{wt}(E(M_1)) = \widetilde{wt}(E(M_2))$. The set $\widetilde{wt}(E(M))$ is determined by the off-diagonal pivotal entries of $M$, which is determined by $\Prof(M)$.

\[\square\]

Corollary 3.15. Let $C_N$ be the $N$-th Catalan number. The number of corner polyhedra of type $A_N$ is $2C_{N+1} - 1$.

Proof. The corner polyhedra of type $A_N$ all arise as corner polyhedra associated to matrices by Corollary 3.14 and so it suffices to count the set

\{ $\Prof(M) : 0 \neq M \in \Mat_{N+1}$ \}

instead. Any lower Dyck path and nontrivial upper Dyck path may appear as a matrix profile. By definition, the Catalan numbers count Dyck paths, so there are $C_{N+1}$ lower Dyck paths and $C_{N+1} - 1$ nontrivial upper Dyck paths.

\[\square\]

For another connection between Catalan numbers and $A_N$ root polytopes, see [5, Theorem 8].

3.3. Facets of corner polyhedra of type $A_N$. We have now calculated the vertices of $\Pi_+(M)$ for any nonzero matrix $M \in \Mat_{N+1}$ (Proposition 3.13). The remainder of this section is dedicated to calculating the facets of $\Pi_+(M)$. These results are the key input for proving Theorem 1.1: the facets of $\Pi_+(M)$ roughly correspond to type I, II, and III flags relative to the linear map $M$. 

19
We will work with halfspaces in $W$, which are of the form \( \{ w \in W : s(w) \geq c \} \) for some \( s \in R^+, c \in R \). For convenience, we write halfspaces as \( \{ s \geq c \} \).

For any nonempty \( I \subseteq [N] \), we define a functional

\[
s_I := \sum_{i \in I} s_i.
\]

For a given matrix \( M \), the flag associated to \( M \) is the sequence \( 0 = S_0 \subset S_1 \subset \ldots \subset S_{N+1} \) of subspaces of \( k^{N+1} \), where for each \( \rho \in [N] \), the subspace \( S_\rho \) is the span of the first \( \rho \) columns of \( M \).

The following proposition is the main result of this section.

**Proposition 3.16.** Let \( M \in \text{Mat}_{N+1} \) be a nonzero matrix. Let \( 0 = S_0 \subset S_1 \subset \ldots \subset S_{N+1} \) be the flag associated to \( M \). The facets of the corner polyhedron \( \Pi_+(M) \) are of four kinds, called (F-1A), (F-1B), (F-2A), and (F-2B), as follows. For each nonempty subset \( I = \{i_1, \ldots, i_\gamma\} \subseteq [N] \), where by convention we let \( \gamma = \# I \) and

\[
0 = i_0 < i_1 < \ldots < i_\gamma < i_{\gamma+1} = N + 1,
\]

there is at most one facet of \( \Pi_+(M) \).

If \( M \) is not strictly-upper-triangular:

- (F-1A): If \( \gamma = 1 \) and \( MS_{i_1} \subseteq S_{i_1} \),

\[
\{s_I \geq 0\}.
\]

- (F-1B): If

\[
MS_{i_t} \not\subseteq S_{i_t} \quad \text{and} \quad MS_{i_t} \subseteq S_{i_{t+1}}, \quad (1 \leq t \leq \gamma),
\]

there is a facet

\[
\{s_I \geq -1\}.
\]

If \( M \) is strictly upper-triangular:

- (F-2A): If \( \gamma = 1 \) and \( MS_{N+1} \not\subseteq S_{i_1} \) or \( MS_{i_1} \neq 0 \),

\[
\{s_I \geq 0\}.
\]

- (F-2B): If

\[
MS_{i_{t+1}} \subseteq S_{i_t}, \quad (0 \leq t \leq \gamma) \quad \text{and} \quad MS_{i_{t+1}} \not\subseteq S_{i_{t-1}}, \quad (1 \leq t \leq \gamma),
\]

there is a facet

\[
\{s_I \geq 1\}.
\]

Before proving Proposition 3.16, we need some lemmas.

We set some notation. For any nonzero matrix \( M \in \text{Mat}_{N+1} \), we view \( \text{Ctrl}(M) \) as a matrix by ordering its elements according to the canonical ordering of Proposition 3.13. Let \( \kappa = \# \text{Ctrl}(M) \). Then \( \text{Ctrl}(M) \) is a \( N \times \kappa \) matrix. The form of \( \text{Ctrl}(M) \) is one of three kinds.
(1) If $M$ is upper-triangular, but not strictly so, then $\text{Ctrl}(M) = 0$.

(2) If $M$ is not upper-triangular, then the entries of $\text{Ctrl}(M)$ are each $0$ or $-1$. For each $c \in [\kappa]$, say the $c$-th off-diagonal pivotal entry of $M$ is $(t_c, u_c - 1)$. Then column $c$ of $\text{Ctrl}(M)$ consists of a single block of $-1$’s running from $t_c$ to $u_c$ inclusive, and has all other entries $0$. By Proposition 3.13, if $c', c'' \in [\kappa]$ satisfy $c' < c''$, then $t_{c'} < t_{c''}$ and $u_{c'} < u_{c''}$.

(3) If $M$ is strictly upper-triangular, then the entries of $\text{Ctrl}(M)$ are each $0$ or $1$. For each $c \in [\kappa]$, say the $c$-th off-diagonal pivotal entry of $M$ is $(u_c, t_c - 1)$; note the difference from the previous case. Then column $c$ of $\text{Ctrl}(M)$ consists of a single block of $1$’s running from $t_c$ to $u_c$ inclusive, and has all other entries $0$. By Proposition 3.13, if $c', c'' \in [\kappa]$ satisfy $c' < c''$, then $t_{c'} < t_{c''}$ and $u_{c'} < u_{c''}$.

For examples, see Section 3.3.

Let $y_1, \ldots, y_N \in \tilde{W}$ be the dual vectors to $s_1, \ldots, s_N$. Given any subset $I \subseteq [N]$, let $\tilde{W}_I$ be the subspace of $\tilde{W}$ generated by the $y_i$, $i \in I$. If $i' \not\in I$, then $s_{i'}$ is identically $0$ on $\tilde{W}_I$. Let $\gamma = \#I$. Taking $s_i$ for each $i \in I$ as coordinates identifies $\tilde{W}_I$ with $\mathbb{R}^\gamma$. Define $\Pi_+^I(M)$ to be the projection of $\Pi_+(M)$ onto $\tilde{W}_I$.

Observe that $\Pi_+^I(M)$ is itself a corner polyhedron in $\tilde{W}_I$ with this choice of basis. We denote the set of control points of $\Pi_+^I(M)$ in $\tilde{W}_I$ by $\text{Ctrl}_I(M)$. It follows that there is a canonical ordering on $\text{Ctrl}_I(M)$, so writing $\kappa' = \#\text{Ctrl}_I(M)$, the set $\text{Ctrl}_I(M)$ can be identified with a $\gamma \times \kappa'$ matrix.

The matrix $\text{Ctrl}_I(M)$ can be obtained from $\text{Ctrl}(M)$, as follows. Take the $\gamma \times \kappa$ minor $\text{Ctrl}_I^r(M)$ of $\text{Ctrl}(M)$ consisting of the rows with indices in $I$. If there are two columns $w_1, w_2$ with distinct indices such that $w_1 \in w_2 + O_+$ in $\tilde{W}_I$, then remove $w_1$ from $\text{Ctrl}_I^r(M)$. Repeat the previous step until no such pairs exist, and the result is $\text{Ctrl}_I(M)$.

**Lemma 3.17.** Let $M \in \text{Mat}_{N+1}$ be not strictly-upper-triangular. The facets of the corner polyhedron $\Pi_+(M)$ are as follows.

- (F-1A): For each all-zero row $\rho$ of $\text{Ctrl}(M)$, there is a facet
  \[
  \{s_\rho \geq 0\}.
  \]

- (F-1B): For each nonempty subset $I \subseteq [N]$ such that $\text{Ctrl}_I(M) = -1$, there is a facet
  \[
  \{s_I \geq -1\}.
  \]

**Proof.** First, we check that these halfspaces are facets of $\Pi_+(M)$.

If we have an all-zero row $\rho$ of $\text{Ctrl}(M)$, then writing $I = \{\rho\}$, we find $\text{Ctrl}_I(M) = 0 \in \text{Mat}_1$. Thus $\Pi_+^I(M)$ has one facet $F_1$, defined by $\{s_\rho \geq 0\}$. We can see that $\{s_\rho \geq 0\}$ is a supporting halfspace of $\Pi_+(M)$. To check that it defines a facet, we show

\[
\dim(\Pi_+(M) \cap \{s_\rho = 0\}) \geq N - 1.
\]

To see this, notice that the functional $s_\rho$ is identically $0$ on the convex cone $F'$ generated by $y_i$, $i \not\in I$. Since $F$ and $F'$ are orthogonal, we have $\dim F + F' = N - 1$, and

\[
F + F' \subseteq \Pi_+(M) \cap \{s_\rho = 0\}.
\]

Now say a nonempty subset $I \subseteq [N]$ satisfies $\text{Ctrl}_I(M) = -1 \in \text{Mat}_N$. Then $\{s_I = -1\}$ contains $\gamma$ vertices of $\text{Ctrl}_I(M)$, and $\Pi_+^I(M) \subset \{s_I \geq -1\}$, so $\{s_I \geq -1\}$ defines a facet $F$. \hfill \square
of $\Pi_+^I(M)$. Thus $\{s_I \geq -1\}$ is a supporting halfspace of $\Pi_+(M)$. To check that it defines a facet, we show

$$\dim(\Pi_+(M) \cap \{s_I = -1\}) \geq N - 1.$$ 

To see this, notice that the functional $s_I$ is identically 0 on the convex cone $F'$ generated by $y_i, i \not\in I$. Since $F$ and $F'$ are orthogonal, we have

$$\dim F + F' = \gamma - 1 + (N - \gamma) = N - 1,$$

and

$$F + F' \subseteq \Pi_+(M) \cap \{s_I = -1\}.$$ 

It remains to show that every facet of $\Pi_+(M)$ is of one of these two forms. Suppose that $\{r > c\}$ is a facet, where $r \in \mathbb{R}^+$ is a nonzero functional and $c \in \mathbb{R}$. Let $I \subseteq [N]$ be the set of indices $i \in [N]$ such that $r(y_i) \neq 0$. Since $r \neq 0$, the set $I$ is nonempty. Projecting to $\tilde{W}_I$, the halfspace $\{r > c\}$ defines a facet $F$ of $\Pi_+^I(M)$. We claim that $\Pi_+^I(M)$ has $\#I$ vertices. Since $\mathrm{Ctrl}_I(M)$ has $\#I$ rows, by the canonical ordering, it has at most $\#I$ columns, so $\Pi_+^I(M)$ has at most $\#I$ vertices. On the other hand, the facet $F$ is the Minkowski sum of some face $F''$ of $O^+$ in $\tilde{W}_I$ and a face of $\text{Conv}(\mathrm{Ctrl}_I(M))$. But $F''$ is necessarily the origin, by construction of the set $I$. It follows that $F$ is a facet of the convex polytope $\text{Conv}(\mathrm{Ctrl}_I(M))$. Since $\dim F = \#I - 1$, at least $\#I$ elements of $\mathrm{Ctrl}_I(M)$ lie on $F$, supplying the claimed number of vertices of $\Pi_+^I(M)$.

Since $\mathrm{Ctrl}_I(M)$ is a square matrix, it follows from the canonical ordering that either $\mathrm{Ctrl}_I(M) = 0$ or $\mathrm{Ctrl}_I(M) = -1 \in \text{Mat}_{\#I}$, where $\gamma = \#I$. If $\mathrm{Ctrl}_I(M) = 0$, then $I$ is some singleton $\{\rho\}$, and this determines the facet; we conclude $\{r \geq c\} = \{s_\rho \geq 0\}$. If $\mathrm{Ctrl}_I(M) = -1$, then the facet containing the necessary $\gamma$ vertices is given explicitly by $\{r \geq c\} = \{s_i \geq -1\}$. □

**Lemma 3.18.** Let $M \in \text{Mat}_{N+1}$ be strictly upper-triangular and nonzero. The facets of the corner polyhedron $\Pi_+(M)$ are as follows.

- (F-2A): For each $\rho \in [N]$ such that $\mathrm{Ctrl}_I(M) = 0 \in \text{Mat}_1$, there is a facet

  $$\{s_\rho \geq 0\}.$$ 

- (F-2B): For each nonempty subset $I \subseteq [N]$ such that $\mathrm{Ctrl}_I(M) = 1 \in \text{Mat}_\#I$, there is a facet

  $$\{s_I \geq 1\}.$$ 

**Proof.** The argument resembles the proof of Lemma 3.17 First, we check that these halfspaces are facets of $\Pi_+(M)$.

Say $I = \{\rho\}$ satisfies $\mathrm{Ctrl}_I(M) = 0 \in \text{Mat}_1$. By the proof of Lemma 3.17, the supporting halfspace $\{s_\rho \geq 0\}$ defines a facet of $\Pi_+(M)$.

Say a nonempty subset $I \subseteq [N]$ satisfies $\mathrm{Ctrl}_I(M) = 1 \in \text{Mat}_\gamma$, where $\gamma = \#I$. Then $\{s_I = 1\}$ contains all $\gamma$ vertices of $\Pi_+^I(M)$, so again by the proof of Lemma 3.17, there is a facet of $\Pi_+(M)$ defined by $\{s_I \geq 1\}$.

It remains to show that every facet of $\Pi_+(M)$ is of one of these two forms. By the proof of Lemma 3.17 if $\{r > c\}$ defines a facet of $\Pi_+(M)$, and $I = \{i \in [N] : r(y_i) \neq 0\}$, then $\mathrm{Ctrl}_I(M)$ is a square matrix. It follows from the canonical ordering that either $\mathrm{Ctrl}_I(M) = 0$ or $\mathrm{Ctrl}_I(M) = 1 \in \text{Mat}_\gamma$, where $\gamma = \#I$. If $\mathrm{Ctrl}_I(M) = 0$, then $I$ is some singleton $\{\rho\}$, and this determines the facet; we conclude $\{r \geq c\} = \{s_\rho \geq 0\}$. If $\mathrm{Ctrl}_I(M) = 1$, then the facet containing the necessary $\gamma$ vertices is given explicitly by $\{r \geq c\} = \{s_I \geq 1\}$. □
Finally, we prove the main result of this section.

**Proof of Proposition 3.16.** By Lemma 3.17 and Lemma 3.18, it suffices to prove the equivalence of the conditions for each facet type.

We start with an observation: for any not strictly-upper-triangular $M$, and for any $\rho \in [N]$ and $c \in [\kappa]$, 

$$\text{Ctrl}(M)_{\rho c} = \begin{cases} 
-1, & \text{the } c\text{-th element of } E(M) \text{ is in rectangle } [\rho + 1, N + 1] \times [1, \rho], \\
0, & \text{otherwise}. 
\end{cases}$$

Similarly, for any strictly-upper-triangular $M$,

$$\text{Ctrl}(M)_{\rho c} = \begin{cases} 
1, & \text{the } c\text{-th element of } E(M) \text{ is in rectangle } [1, \rho] \times [\rho + 1, N + 1], \\
0, & \text{otherwise}. 
\end{cases}$$

(F-1A) We must show that, for a given nonempty subset $I \subseteq [N]$, the condition (3.16.1A) is equivalent to $\text{Ctrl}_I(M) = 0 \in \text{Mat}_1$. Since $\gamma = 1$ is equivalent to $\text{Ctrl}_I$ having exactly one row, we must show that under this condition,

$$\text{Ctrl}_I(M) = [0] \iff MS_{i_1} \subseteq S_{i_1}.$$ 

Say $\text{Ctrl}_I(M) = [0]$. By the canonical ordering, row $i_1$ of $\text{Ctrl}_M$ is all zeroes. By the observation, there are no pivotal entries of $M$ in rectangle $[i_1 + 1, N + 1] \times [1, i_1]$. Then, all entries of $M$ in that rectangle must be 0. It follows that $MS_{i_1} \subseteq S_{i_1}$.

For the reverse implication, say $MS_{i_1} \subseteq S_{i_1}$. All entries of $M$ in the rectangle $[i_1 + 1, N + 1] \times [1, i_1]$ are zero, so in particular, there are no pivotal entries of $M$ in that rectangle. Then, by the observation, we deduce that $\text{Ctrl}(M)$ has an all-0 row $i_1$, so $\text{Ctrl}_I(M) = [0]$.

(F-1B) For each nonempty $I \subseteq [N]$, we must prove the equivalence

$$\text{Ctrl}_I(M) = -1 \iff (3.16.1B).$$

If $I$ satisfies (3.16.1B), we claim there at least $\#I$ elements of $\text{Ctrl}_I(M)$. To each $i \in I$, we can associate an element of $E(M)$, as follows: in column $i$ of $M$, let $(i', i)$ be the bottommost nonzero entry; then consider the left-most nonzero entry in row $i'$; call this entry $\iota(i)$. The entry $(i', j')$ is in $E(M)$ since the path $\text{Prof}(M)$ borders it to the left and below. By (3.16.1B), the map $\iota : I \to E(M)$ is injective. We may compute the entries of $\text{Ctrl}_I(M)$ using the observation to directly calculate that $\text{Ctrl}_I(M) = -1$.

Say $I$ does not satisfy (3.16.1B). Then there is some $i \in I$ such that $S_i = MS_i$ or $MS_i \nsubseteq S_{i'}$, where $i'$ is the next element in $I$. In the first case, the rectangle $[i + 1, N + 1] \times [1, i]$ of $M$ is all zero. By the observation, row $i$ of $\text{Ctrl}_I(M)$ is all 0, so $\text{Ctrl}_I(M) \neq -1$. In the second case, there exists a nonzero entry of $M$ in $[i' + 1, N + 1] \times [1, i]$, so there is a pivotal entry in that rectangle. By the observation, the corresponding column of $\text{Ctrl}(M)$ has a -1 in row $i$ and $i'$, so $\text{Ctrl}_I(M) \neq -1$.

(F-2A) We must show that, for nonzero strictly-upper-triangular $M$,

$$\text{Ctrl}_I(M) = [0] \iff (3.16.2A).$$

Say $\text{Ctrl}_I(M) \neq [0]$. By the canonical ordering, row $i_1$ of $\text{Ctrl}(M)$ is all 1’s. By the observation, every pivotal entry of $M$ is in the rectangle $[1, i_1] \times [i_1 + 1, N + 1]$. Then every nonzero entry of $M$ is in that rectangle, so (3.16.2A) does not hold. For the reverse implication, if
does not hold, then every entry of $M$ is in that rectangle, so every pivotal entry of $M$ is in that rectangle, so $\text{Ctrl}(M) = [1]$. (F-2B) We must show that, for nonzero strictly-upper-triangular $M$, for each nonempty $I \subseteq [N]$, 

$$\text{Ctrl}_I(M) = 1 \Leftrightarrow (3.16.2B).$$

Suppose that $\text{Ctrl}_I(M) = 1$. Then, using the observation, in the notation of Proposition 3.16, for each $0 \leq t \leq \#I$, the rectangle $[i_t + 1, N + 1] \times [1, i_{t+1}]$ of $M$ has no pivotal entries, and for each $1 \leq t \leq \#I$, there is a pivotal entry of $M$ in $[i_{t-1} + 1, i_t] \times [1, i_{t+1}]$. It follows that the rectangle $[i_t + 1, N + 1] \times [1, i_{t+1}]$ is all 0’s and there is a nonzero entry in $[i_{t-1} + 1, i_t] \times [1, i_{t+1}]$, implying (3.16.2B).

Conversely, say (3.16.2B) holds. For each $0 \leq t \leq \#I$, the rectangle $[i_t + 1, N + 1] \times [1, i_{t+1}]$ is all 0’s, and for each $1 \leq t \leq \#I$, there is a nonzero entry in $[i_{t-1} + 1, i_t] \times [1, i_{t+1}]$. It follows that the map $\iota$ of (F-1B) is injective, so there are at least $\#I$ elements of $\text{Ctrl}(M)$. Using the observation, we calculate explicitly that $\text{Ctrl}_I(M) = 1$. □

3.4. Examples. In the following examples, we will fix some $N \geq 1$ and consider some $(N + 1) \times (N + 1)$ matrix $M$. We mark nonzero entries by $\ast$, and entries with no conditions on them by $\cdot$.

Example 3.19. Say entry $(N + 1, 1)$ of $M$ is nonzero. Then the profile $\text{Prof}(M)$ is the lower Dyck path

$$\begin{bmatrix}
\ast & \ldots & \ast \\
\vdots & \ddots & \vdots \\
\ast & \ldots & \ast 
\end{bmatrix}. $$

By Proposition 3.13, the control matrix $\text{Ctrl}(M)$ is the $N \times 1$ matrix with every entry equal to $-1$. Thus the facets of $\Pi_+(M)$ are, for each $i \in [N]$, 

$$\{s_i \geq -1\}. $$

This is obvious because $\text{Ctrl}(M)$ has just one column, but we can also see it as a special case of Proposition 3.16: the facets are all of type (F-1B).

This is the least degenerate matrix $M$, and the corner polyhedron is as simple as can be. But note that, even though a generic matrix is described by this example, a generic linear transformation $T$ is not, since there is always some basis in which $T$ is of a different form.

Example 3.20. Say the only nonzero entry of $M$ is $(1, N + 1)$. Then the profile $\text{Prof}(M)$ is the upper Dyck path

$$\begin{bmatrix}
0 & \ldots & 0 & \ast \\
0 & \ddots & 0 & 0 \\
\vdots & \ddots & \ddots & \vdots \\
0 & \ldots & 0 & 0
\end{bmatrix}. $$

We can think of this matrix $M$ as the worst-case scenario for stability. By Proposition 3.13, the control matrix $\text{Ctrl}(M)$ is the $N \times 1$ matrix with every entry equal to 1. Since there is only one column of $\text{Ctrl}(M)$, the corner polyhedron $\Pi_+(M)$ has facets $\{s_i \geq 1\}$, for each $i \in [N]$. As a special case of Proposition 3.16, the facets are all of type (F-2B).
Example 3.21. Say $M$ is upper-triangular and entry $(1, 1)$ is nonzero. This example includes the case $M = 1$. Since there is a nonzero entry on the main diagonal, the profile $\text{Prof}(M)$ is a lower Dyck path, specifically

\[
\begin{bmatrix}
\ast & \ast & \ldots & \ast \\
0 & \ast & \ldots & \ast \\
0 & 0 & \ddots & \ast \\
0 & 0 & \ldots & 0 \\
\end{bmatrix}.
\]

By Proposition 3.13, the control matrix $\text{Ctrl}(M)$ is the $N \times 1$ matrix with every entry equal to 0. Thus $\Pi_+(M)$ is just the nonnegative orthant. The corner polyhedron $\Pi_+(M)$ has facets $\{s_i \geq 0\}$, for each $i \in [N]$. As a special case of Proposition 3.16, all the facets are of type (F-1A).

When $N = 2$, we can draw $\Pi_+(M)$ in the plane:

Now we get to some more interesting examples.

Example 3.22. Say $M$ has entry $(i + 1, i)$ nonzero for each $1 \leq i < N + 1$, and the entries $(i, j)$ with $j > i + 1$ are all 0. Then the profile of $M$ is the lower Dyck path shown:

\[
\begin{bmatrix}
\ast & \ast & \ldots & \ast & \ast & \ast \\
\ast & \ast & \ldots & \ast & \ast & \ast \\
0 & \ast & \ldots & \ast & \ast & \ast \\
\vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\
0 & 0 & \ldots & \ast & \ast & \ast \\
0 & 0 & \ldots & 0 & \ast & \ast \\
\end{bmatrix}
\]

By Proposition 3.13, we have $\text{Ctrl}(M) = -1 \in \text{Mat}_N$. Thus there are $N$ vertices of $\Pi_+(M)$.

By Proposition 3.16 the facets of $\Pi_+(M)$ are, for each nonempty subset $I \subseteq [N]$, given by

\[
\left\{ \sum_{i \in I} s_i \geq -1 \right\}.
\]

Therefore there are $2^N - 1$ facets, all of type (F-1B).

When $N = 2$, we can draw $\Pi_+(M)$ in the plane:
Example 3.23. Say $M$ has entry $(i, i + 1)$ nonzero for each $1 \leq i < N + 1$, and all entries on or below the main diagonal are equal to 0. Then $\text{Prof}(M)$ is the upper Dyck path shown:

$$
\begin{bmatrix}
0 & * & \cdots & * \\
0 & 0 & * & \cdots & * \\
\vdots & \ddots & \ddots & \vdots & \vdots \\
0 & 0 & 0 & \ddots & * \\
0 & 0 & 0 & \cdots & 0 \\
0 & 0 & 0 & \cdots & 0
\end{bmatrix}
$$

By Proposition 3.13, we have $\text{Ctrl}(M) = 1 \in \text{Mat}_N$. Thus there are $N$ vertices of $\Pi_+(M)$. By Proposition 3.16 there are $N + 1$ facets: a type (F-2A) facet $\{s_i \geq 0\}$ for each $i \in [N]$, and a type (F-2B) facet $\{\sum_{i \in I} s_i \geq 1\}$ corresponding to $I = [N]$. Comparing with Example 3.22, we see that the seemingly dual cases $\text{Ctrl}(M) = 1$ and $\text{Ctrl}(M) = -1$ produce quite different corner polyhedra.

When $N = 2$, we can draw $\Pi_+(M)$ in the plane:

![Diagram](image)

Example 3.24. Let $N = 7$. We present a more elaborate example of matrix with a lower Dyck path as its profile:

$$
M = 
\begin{bmatrix}
* & * & * & * & * & * & * & * \\
* & * & * & * & * & * & * & * \\
* & * & * & * & * & * & * & * \\
* & * & * & * & * & * & * & * \\
0 & * & * & * & * & * & * & * \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0
\end{bmatrix}
$$

We emphasize that entry $(6, 6)$ is 0, but that the profile is a lower Dyck path by definition, thus must go below entry $(6, 6)$. By Proposition 3.13

$$
\text{Ctrl}(M) = 
\begin{bmatrix}
-1 & 0 & 0 \\
-1 & -1 & 0 \\
0 & -1 & 0 \\
0 & 0 & 0 \\
0 & 0 & 0 \\
0 & 0 & -1
\end{bmatrix}
$$

By Proposition 3.16 there are type (F-1A) facets

$$
\{s_5 \geq 0\}, \quad \{s_6 \geq 0\},
$$

and there are type (F-1B) facets $\{s_I \geq -1\}$ for each

$I \in \{\{1\}, \{2\}, \{3\}, \{4\}, \{7\},$

$\{1, 3\}, \{1, 4\}, \{1, 7\},$

$\{1, 3, 7\}, \{1, 4, 7\}$.  

Example 3.25. Consider

\[
M = \begin{bmatrix}
0 & 0 & * & * \\
0 & 0 & 0 & * & * \\
0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 \\
\end{bmatrix}.
\]

By Proposition 3.13

\[
\text{Ctrl}(M) = \begin{bmatrix}
1 & 0 \\
1 & 1 \\
0 & 1 \\
0 & 0 \\
\end{bmatrix}.
\]

By Proposition 3.16 the type (F-2A) facets are \( \{ s_i \geq 0 \} \) for each \( i \in \{1, 3, 4\} \), and the type (F-2B) facets are \( \{ s_I \geq 1 \} \) for each \( I \in \{\{2\}, \{1, 3\}\} \).

4. Linear Maps with Marked Points

In this section, we prove Theorem 1.1.

We recall our setting. Let \( N, n \in \mathbb{N} \). We define \( \text{Mat}_{N+1} \cong \mathbb{A}^{N^2+2N+1} \) to be the space of linear endomorphisms \( k^{N+1} \to k^{N+1} \). We write \( \mathbb{P}(\text{Mat}_{N+1}) \) for the projectivization of the nonzero elements of \( \text{Mat}_{N+1} \). Let \( \mathcal{X}_{N,n} = (\mathbb{P}^N)^n \times \mathbb{P}(\text{Mat}_{N+1}) \). Its elements will be written \( (T, v) = (T, v_1, \ldots, v_n) \).

Note that \( \mathbb{P}(\text{Mat}_{N+1}) \) is not a group, but it nevertheless admits the conjugation action of \( \text{SL}_{N+1} \). We study the action (1) of \( \text{SL}_{N+1} \) on \( \mathcal{X}_{N,n} \), which we restate for convenience:

\[
A \cdot (T, v) = (ATA^{-1}, Av_1, \ldots, Av_n).
\]

A flag \( \mathcal{H} \) in \( k^{N+1} \) is a sequence, of some length \( \nu \in [N+1] \), of linear subspaces

\[
0 \subsetneq H_1 \subsetneq \ldots \subsetneq H_{\nu} \subset k^{N+1}.
\]

A flag is complete if \( \nu = N + 1 \) and \( H_{\nu} = k^{N+1} \). Equivalently, a flag is complete if, for all \( i \in [\nu] \), we have \( \dim V_i = i \).

A completion of a flag \( \mathcal{H} \) is a complete flag \( \mathcal{H}' \) such that every subspace appearing in \( \mathcal{H} \) also appears in \( \mathcal{H}' \). A completed flag pair \( (\mathcal{H}, \mathcal{H}') \) is a pair of flags such that \( \mathcal{H}' \) is a completion of \( \mathcal{H} \).

Each basis \( b_1, \ldots, b_{N+1} \) of \( k^{N+1} \) has an associated flag: for each \( i = 1, \ldots, N + 1 \), let

\[
H_i = \text{Span}(b_1, \ldots, b_i).
\]

If \( \mathcal{H} \) is a complete flag, a flag basis is any basis which has \( \mathcal{H} \) as its associated flag. Every complete flag has a flag basis.

Fix \( T \in \mathbb{P}(\text{Mat}_{N+1}) \). We now define some special types (P-1A), (P-1B), (P-2A), (P-2B) of completed flag pair, with respect to \( T \). Note that some completed flag pairs do not belong to any of these types.

- A completed flag pair \( (\mathcal{H}, \mathcal{H}') \) is type (P-1A) if:
  - \( \mathcal{H} \) consists of just one space \( H_1 \), and
  - In any associated basis of \( \mathcal{H}' \), the matrix \( M \) of \( T \) is not strictly-upper-triangular, and
  - the matrix \( M \) has property (3.16.1A), where \( i_1 \in [N] \) is the value such that \( H'_{i_1} = H \).
- A completed flag pair \( (\mathcal{H}, \mathcal{H}') \) is of type (P-1B) if:
In any associated basis of $\mathcal{H}'$, the matrix $M$ of $T$ is not strictly-upper-triangular, and

- The matrix $M$ has property (3.16.1B), where $I$ is the set of indices determined by the inclusion of $\mathcal{H}$ in $\mathcal{H}'$.

- A completed flag pair $(\mathcal{H}, \mathcal{H}')$ is type (P-2A) if:
  - $\mathcal{H}$ consists of just one space $H$, and
  - The matrix $M$ of $T$ in any associated basis of $\mathcal{H}'$ is strictly upper triangular, and
  - The matrix $M$ has property (3.16.2A), where $i_1 \in [N]$ is the value such that $H'_{i_1} = H$.

- A completed flag pair $(\mathcal{H}, \mathcal{H}')$ is of type (P-2B) if:
  - In any associated basis of $\mathcal{H}'$, the matrix $M$ of $T$ is not strictly-upper-triangular, and
  - The matrix $M$ has property (3.16.2B), where $I$ is the set of indices determined by the inclusion of $\mathcal{H}$ in $\mathcal{H}'$.

We recall the four types I, II, III, IV of a flag $\mathcal{H}$ relative to $T$ that were defined in Theorem 1.1. We set the convention that $\mathcal{H}$ consists of $H_1 \subset \ldots \subset H_\nu$, and $H_0 = 0$ and $H_{\nu+1} = k^{N+1}$.

- Type I: we have $\nu = 1$, and $\mathcal{H} = H_1$ satisfies either
  
  \[ 0 \neq TH_1 \subset H_1 \]

  or

  \[ TH_1 \subset H_1 \quad \text{and} \quad T(k^{N+1}) \not\subset H. \]

- Type II: For all $1 \leq t \leq \nu$, we have
  
  \[ TH_t \not\subset H_t \quad \text{and} \quad TH_t \subset H_{t+1}. \]

- Type III: For all $0 \leq t \leq \nu$, we have
  
  \[ TH_{t+1} \subset H_t, \]

  and for all $1 \leq t \leq \nu$, we have

  \[ TH_{t+1} \not\subset H_{t-1}. \]

For any point $v \in \mathbb{P}^N$ and flag $\mathcal{H}$, we define

\[ \Omega(v, \mathcal{H}) := \sum_{j \in [n]} \left( \sum_{i=1}^n \frac{-jm_i}{N+1} + \sum_{i \in [n]: x_{i+j+1}(v_i) = \ldots = x_{N+1}(v_i) = 0} m_i \right). \]

It arises in our calculations as follows. Recall the notation $\eta(v)$ from (4). If $\mathcal{H}'$ is any completion of $\mathcal{H}$, and the spaces in $\mathcal{H}$ have indices corresponding to $I \subseteq [N]$ in $\mathcal{H}'$, we have

\[ \Omega(v, \mathcal{H}) = s_I(\eta(v)). \quad (6) \]

**Remark 4.1.** The function $\Omega(v, \mathcal{H})$ measures how much the tuple $v$ intersects the flag $\mathcal{H}$. The more intersections there are between points of $v$ and subspaces in $\mathcal{H}$, the larger the value of $\Omega(v, \mathcal{H})$. Notice that the weighted count $\Omega(v, \mathcal{H})$ is unrelated to the space $\mathbb{P}({\text{Mat}}_{N+1})$; it is solely a function of the $n$-tuple $v$ and the flag $\mathcal{H}$. To give an idea of how the quantity $\Omega(v, \mathcal{H})$ behaves, observe that the following are equivalent:

1. The tuple $v \in (\mathbb{P}^N)^n$ is semistable relative to $O(m))$. 

For every linear subspace $H$, we have $\Omega(v, H) \leq 0$.

(2) For every flag $H$, we have $\Omega(v, H) \leq 0$.

The equivalence of (1) and (2) is just the result of Theorem 3.6. The equivalence of (2) and (3) follows from the fact that, for any flag $H$, the sum $\Omega(v, H)$ is computed over the individual subspaces making up $H$.

Finally we prove the following result, which contains Theorem 1.1 as a special case.

**Theorem 4.2.** Consider $X_{N,n}$ with the action of $\text{SL}_{N+1}$ and sheaf $\mathcal{L} = \mathcal{O}(q, m)$. For each flag $H$ in $k^{N+1}$ of type I, II, or III, define

$$c(T, H) = \begin{cases} 
0, & \text{if } H \text{ is type I} \\
1, & \text{if } H \text{ is type II} \\
-1, & \text{if } H \text{ is type III}.
\end{cases}$$

Then $(T, v) \in X_{N,n}$ is GIT semistable relative to $\mathcal{L}$ if and only if, for every type I, II, or III flag $H$,

$$\Omega(v, H) \leq qc(T, H). \quad (7)$$

A point $(T, v) \in X_{N,n}$ is GIT stable relative to $\mathcal{L}$ if and only if, for every type I, II, or III flag $H$, the inequality (7) is strict.

**Proof.** Given a basis $B$ of $k^{N+1}$, let $\Pi_+(T, v)$ denote the corner polyhedron of $(T, v)$. By Proposition 3.3 the point $(T, v)$ is $B$-semistable if and only if, in the $B$-aligned basis $B'$ of $\mathcal{L}$ obtained by Segre and Veronese maps, we have

$$0 \in \Pi_+(T, v).$$

Let $M$ be the matrix of $T$ in basis $B$, and let $\Pi_+(M)$ be the associated corner polyhedron of type $A_N$, which is by definition the corner polyhedron of $M$ relative to $\mathcal{O}(1)$. Let $\Pi_+(v)$ be the corner polyhedron of $v$ relative to $\mathcal{O}(m)$. By Lemma 2.7 and 2.8

$$\Pi_+(T, v) = \Pi_+(v) + q\Pi_+(M).$$

By Proposition 3.5, the corner polyhedron $\Pi_+(v)$ has just one vertex $\eta(v)$. Thus $B$-semistability is equivalent to

$$0 \in q\Pi_+(M) + \eta(v).$$

Equivalently,

$$-\eta(v) \in q\Pi_+(M).$$

By Proposition 3.16 the polyhedron $\Pi_+(M)$ is an intersection of halfspaces of the form $
\{s_I \geq c\}$, for various nonempty sets $I \subseteq [N]$ and values $c \in \{0, 1, -1\}$.

Say $(T, v)$ is semistable relative to $\mathcal{L}$. Then, by the preceding discussion, $(T, v)$ satisfies some list of conditions of the form

$$\Omega(v, \mathcal{H}) \leq c_0(T, \mathcal{H})q,$$

where $\mathcal{H}$ is a flag and $c_0(T, \mathcal{H}) \in \{0, 1, -1\}$.

We now show that the conditions described in the theorem statement appear in this way.

Let $\mathcal{H}$ be type I. Let the single element of $\mathcal{H}$ be $H$. We claim there exists a flag completion $\mathcal{H}'$ of $\mathcal{H}$ such that the completed flag pair $(\mathcal{H}, \mathcal{H}')$ is of type (P-1A). Indeed, let $\mathcal{H}''$ be any flag completion of $\mathcal{H}$, with some associated basis $B''$. Since $0 \neq TH_1$ or $T(k^{N+1}) \subset H$, there
is a permutation $B'$ of the basis $B''$ that fixes $H$, such that the matrix of $T$ is not strictly-upper-triangular. Let $\mathcal{H}'$ be the flag associated to $B'$. Since $TH_1 \subseteq H_1$, the pair $(\mathcal{H}, \mathcal{H}')$ is type (P-1A). Let $\rho \in [N]$ be the value such that $H = \mathcal{H}'_{\rho}$. By Proposition [3.16] in the basis $B'$, there is a facet of $\Pi_+(M)$ with supporting halfspace $\{s_\rho \geq 0\}$. Thus $s_\rho(z)(-\eta) \geq 0$, so by [6], we have $\Omega(v, H) \leq 0$.

Let $\mathcal{H}$ be type II. There exists a flag completion $\mathcal{H}'$ of $\mathcal{H}$ such that the completed flag pair $(\mathcal{H}, \mathcal{H}')$ is of type (P-1B). Let $I \subseteq [N]$ be the subset of indices corresponding to the inclusion of $\mathcal{H}$ in $\mathcal{H}'$. By Proposition [3.16] writing $M$ for the matrix of $T$ in basis $B$, there is a facet of $\Pi_+(M)$ with supporting halfspace $\{s_I \geq -1\}$. Thus $s_I(z)(-\eta) \geq -q$, so by [6], we have $\Omega(v, H) \leq q$.

Let $\mathcal{H}$ be type III. There exists a flag completion $\mathcal{H}'$ of $\mathcal{H}$ such that the completed flag pair $(\mathcal{H}, \mathcal{H}')$ is of type (P-2B); namely, let $\mathcal{H}'$ be any completion of $T^{-1}(0) \subseteq T^{-1}(H_1) \ldots \subseteq T^{-1}(H_{\nu-1})$.

Let $I \subseteq [N]$ be the subset of indices corresponding to the inclusion of $\mathcal{H}$ in $\mathcal{H}'$. By Proposition [3.16] writing $M$ for the matrix of $T$ in basis $B$, there is a facet of $\Pi_+(M)$ with supporting halfspace $\{s_I \geq 1\}$. Thus $\Omega(v, H) \leq -q$.

We have proved one direction of the theorem; now we prove the other.

For every complete flag $\mathcal{H}'$, and every subflag $\mathcal{H}$ of $\mathcal{H}'$ such that the completed flag pair $(\mathcal{H}, \mathcal{H}')$ is type (P-1A), (P-1B), (P-2A), or (P-2B), we define a quantity $c(T, \mathcal{H}, \mathcal{H}')$ by

$$c(T, \mathcal{H}, \mathcal{H}') = \begin{cases} 0, & (\mathcal{H}, \mathcal{H}') \text{ is type (P-1A) for } T, \\ -1, & (\mathcal{H}, \mathcal{H}') \text{ is type (P-1B) for } T, \\ 0, & (\mathcal{H}, \mathcal{H}') \text{ is type (P-2A) for } T, \\ 1, & (\mathcal{H}, \mathcal{H}') \text{ is type (P-2B) for } T. \end{cases}$$

We claim that, if [7] holds for all flags $\mathcal{H}$ of type I, II, and III, then for all completed flag pairs $(\mathcal{H}, \mathcal{H}')$ of type (P-1A), (P-1B), (P-2A), or (P-2B),

$$\Omega(v, H) \leq c(T, \mathcal{H}, \mathcal{H}')q. \quad (8)$$

Indeed, assuming [8], by Proposition [3.16] for every basis $B$ of $k^{N+1}$, writing $M$ for the matrix of $T$, we have $-\eta(v) \in q\Pi_+(M)$ by [6]. Hence $0 \in \Pi_+(T, v)$ for every basis $B$, proving semistability.

Finally, we check that [7] implies [8]:

- If $(\mathcal{H}, \mathcal{H}')$ is type (P-1A) or (P-2A), then $\mathcal{H}$ is type I and $c(T, \mathcal{H}, \mathcal{H}') = c(T, \mathcal{H})$.
- If $(\mathcal{H}, \mathcal{H}')$ is type (P-1B), then $\mathcal{H}$ is type II and $c(T, \mathcal{H}, \mathcal{H}') = c(T, \mathcal{H})$.
- If $(\mathcal{H}, \mathcal{H}')$ is type (P-2B), then $\mathcal{H}$ is type III and $c(T, \mathcal{H}, \mathcal{H}') = c(T, \mathcal{H})$.

For stability, the same argument works using strict inequalities.

Our main theorem follows:

**Proof of Theorem [7].** In Theorem [4.2], take $m_1 = \ldots = m_n = 1$. \(\square\)

**Remark 4.3.** Our proof of Theorem [11] could be adapted to study the action of $\text{SL}_{N+1}$ on

$$(\mathbb{P}^N)^n \times (\mathbb{P}(\text{Mat}_{N+1}))^{n''},$$

for any $n, n' \in \mathbb{N}$, where the action is the usual left action on each $\mathbb{P}^N$ and conjugation on each $\mathbb{P}(\text{Mat}_{N+1})$. The facets of the corner polyhedra seem to be more difficult to compute in
this case, and we have not tried to compute them in general. However, when \( n = 1 \) or \( n = 2 \), the corner polyhedra are not too complicated, and we expect that our methods would lead to a nice description of stability.

Finally, we prove two useful facts about the structure of the quotient: that it is nonempty (Corollary 1.3), and that it is rational (Theorem 1.4).

Proof of Corollary 1.3. Let \( T \neq 1 \) be invertible. There exists a point \( v \) that is not in any \( T \)-invariant proper linear subspace. Let \( v_1 = \ldots = v_n = v \). Let us check that the stability conditions in Theorem 1.1 hold. Since \( T \) is invertible, it is not nilpotent, so there are no type III flags relative to \( T \). The conditions for the type II flags are met since \( q \geq n \). The type I flags are simply the invariant linear subspaces for \( T \), but these do not contain \( v \), so the type I conditions are all met. □

Proof of Theorem 1.4. The existence and dimension count follow immediately from Corollary 1.3. The claim is independent of \( L \) because varying the sheaf \( L \) does not change the birational type of the quotient. Let \( S_{N+1} \) denote the symmetric group on \( N + 1 \) letters. Given a generic point \((T, v_1, \ldots, v_n) \in \mathcal{X}_{N,n}\), consider the \( N+1 \) fixed points of \( T \) as an element of \((\mathbb{P}^N)^n/S_{N+1}\). There exists a projective transformation that diagonalizes \( T \) to some matrix \( \text{diag} [\lambda_1, \ldots, \lambda_{N+1}] \) of eigenvalues and takes \( v_1 \) to \([1 : \ldots : 1]\). For each \( i \) in the range \( 1 < i \leq n \), let \( v'_i \) be the image of \( v_i \). Since there is no ordering on the eigenvectors, a projective transformation with this property is unique up to the action of \( S_{N+1} \). Thus the multivalued map 

\[
(T, v_1, \ldots, v_n) \rightarrow ([\lambda_1 : \ldots : \lambda_{N+1}], v'_2, \ldots, v'_n)
\]

descends to a well-defined rational map 

\[
\mathcal{X}_{N,n}/\text{SL}_{N+1} \rightarrow (\mathbb{P}^N)^n/S_{N+1},
\]

where \( S_{N+1} \) acts diagonally on each factor by permuting coordinates. Then, to prove rationality, it suffices to show that each factor \( \mathbb{P}^N/S_{N+1} \) is rational. The theorem on symmetric functions states that \( \mathbb{A}^{N+1}/S_{N+1} \cong \mathbb{A}^{N+1} \), so \( \mathbb{P}^N/S_{N+1} \) is a weighted projective space, and these are all rational because they are toric varieties. □
