ABSTRACT

In this paper, we present the tool Fast Box Analysis of Two-Level Lattice Neural Networks (Fast BATLLNN) as a fast verifier of box-like output constraints for Two-Level Lattice (TLL) Neural Networks (NNs). In particular, Fast BATLLNN can verify whether the output of a given TLL NN always lies within a specified hyper-rectangle whenever its input is constrained to a specified convex polytope (not necessarily a hyper-rectangle). Fast BATLLNN uses the unique semantics of the TLL architecture and the decoupled nature of box-like output constraints to dramatically improve verification performance relative to known polynomial-time verification algorithms for TLLs with generic polytopic output constraints. In this paper, we evaluate the performance and scalability of Fast BATLLNN, both in its own right and compared to state-of-the-art NN verifiers applied to TLL NNs. Fast BATLLNN compares very favorably to even the fastest NN verifiers, completing our synthetic TLL test bench more than 400x faster than its nearest competitor.

1 INTRODUCTION

Neural Networks (NNs) increasingly play vital roles within safety-critical cyber-physical systems (CPSs), where they either make safety-critical decisions directly (as in the case of low-level controllers) or influence high-level supervisory decision making (e.g., through vision networks). Ensuring the safety of such systems thus demands algorithms capable of formally verifying the safety of their NN components. However, since CPS safety is characterized by closed-loop behavior, it is not enough to pragmatically verify the input/output behavior of a NN component once. Such a verifier must additionally be as fast as possible, so that it can feasibly be invoked many times during the course of verifying a closed-loop property (as in [30, 34] for example).

In this paper, we propose Fast BATLLNN as an input/output verifier for Rectified Linear Unit (ReLU) NNs with a special emphasis on execution time. In particular, Fast BATLLNN takes a relatively uncommon approach among verifiers in that it explicitly trades off generality for execution time: whereas most NN verifiers are designed to work for arbitrary deep NNs and arbitrary half-space output properties (or the intersections thereof) [2], Fast BATLLNN instead forgoes this generality in network and properties to reduce verification time. That is, Fast BATLLNN is only able to verify a very specific subset of deep NNs: those characterized by a particular architecture, the Two-Level Lattice (TLL) NN architecture introduced in [14]; see also Figure 1 and Section 2.3. Similarly, Fast BATLLNN is restricted to verifying only box-like output constraints (formally, hyper-rectangles). Through extensive experiments, Fast BATLLNN exemplifies that sacrificing generality in both of these senses can lead to dramatically faster verification times. Compared to state-of-the-art general NN verifiers, Fast BATLLNN is 400–1900x faster verifying the same TLL NNs and properties.

In this sense, Fast BATLLNN is primarily inspired by the recent result [15], which showed that verifying a Two-Level Lattice (TLL) NN is an “easier” problem than verifying a general deep NN. Specifically, [15] exhibits a polynomial time algorithm to verify a TLL with respect to an arbitrary half-space output property.

Figure 1: Illustration of TLL NN architecture for a function $\mathbb{R}^n \to \mathbb{R}_1$ reproduced from [14]. More details in Section 2.3.
perform layer-by-layer reachability analysis to compute the reachable set [5, 13, 19, 20, 29, 32, 36, 37]; and (iv) convex relaxations methods [10, 23, 31, 35]. Methods in categories (i) - (iii) tend to suffer from poor scalability, especially relative to convex relaxation methods. In this paper, we perform comparisons with state-of-the-art examples from category (iv) [25, 33] and category (iii) [5], as perform well overall in the standard verifier competition [2].

2 PRELIMINARIES

2.1 Notation

We will denote the real numbers by $\mathbb{R}$. For an $(n \times m)$ matrix (or vector), $A$, we will use the notation $[A]_{[i,j]}$ to denote the element in the $j^{th}$ row and $i^{th}$ column of $A$. Analogously, the notation $[A]_{[i,:]}$ will denote the $i^{th}$ row of $A$, and $[A]_{:,j:}$ will denote the $j^{th}$ column of $A$; when $A$ is a vector instead of a matrix, both notations will return a scalar corresponding to the corresponding element in the vector. We will use bold parenthesis $(\cdot)$ to delineate the arguments to a function that returns a function. We use two special forms of this notation: for an $(m \times n)$ matrix, $W$, and an $(m \times 1)$ vector, $b$:

$$\mathcal{L}(W, b) : x \mapsto Wx + b$$  \hspace{1cm} (1)

$$\mathcal{L}(W, b) : x \mapsto \max \{Wx + b, 0\}$$  \hspace{1cm} (2)

We also use the functions First and Last to return the first and last elements of an ordered list (or by overloading, a vector in $\mathbb{R}^n$). The function Concat concatenates two ordered lists, or by overloading, concatenates two vectors in $\mathbb{R}^n$ and $\mathbb{R}^m$ along their (common) non-trivial dimension to get a third vector in $\mathbb{R}^{n+m}$. Finally, an over-bar indicates (topological) closure of a set: i.e. $\bar{A}$ is the closure of $A$.

2.2 Neural Networks

We will exclusively consider Rectified Linear Unit Neural Networks (ReLU NNs). A $K$-layer ReLU NN is specified by $K$ layer functions, $\{L_{gi} : i = 1, \ldots, K\}$, of which we allow two kinds: linear and nonlinear. A nonlinear layer is a function:

$$L_{gi} : \mathbb{R}^k \rightarrow \mathbb{R}^n, \quad L_{gi} : z \mapsto \max \{Wz + b, 0\}$$  \hspace{1cm} (3)

where the max function is taken element-wise, $W_{gi}$ and $b_{gi}$ are matrices of appropriate dimensions, and $\Theta_{gi} = (W_{gi}, b_{gi})$. A linear layer is the same as a nonlinear layer, except it omits the nonlinearity $\max(\cdot, 0)$ in its layer function; a linear layer will be indicated with a superscript lin e.g. $L_{gi}^{\text{lin}}$. Thus, a $K$-layer ReLU NN function is specified by functionally composing $K$ such layer functions whose input and output dimensions satisfy $l_1 = o_{K-1} = i : 2, \ldots, K$. We always consider the final layer to be a linear layer, so we may define:

$$\mathcal{N} = L_{gK}^{\text{lin}} \circ L_{gK-1} \circ \cdots \circ L_{g1}$$  \hspace{1cm} (4)

To make the dependence on parameters explicit, we will index a ReLU function $\mathcal{N}$ by a list of matrices $\Theta = (\Theta_1, \ldots, \Theta_K)$:2 in this respect, we will often use $\mathcal{N} = \mathcal{N}(\Theta)$.

1Recall that any ReLU NN implements a CPWA: i.e., a function that continuously switches between finitely many affine functions.

2That is $\Theta$ is not the concatenation of the $\Theta_i$ into a single large matrix, so it preserves information about the sizes of the constituent $\Theta_i$. 
2.3 Two-Level-Lattice (TLL) Neural Networks

In this paper, we are exclusively concerned Two-Level Lattice (TLL) ReLU NNs as noted above. In this subsection, we formally define NNs with the TLL architecture using the succinct method exhibited in [15]; the material in this subsection is derived from [14, 15].

The most efficient way to characterize a TLL NN is by way of three generic NN composition operators. Hence, we have the following three definitions, which serve as auxiliary results in order to eventually define a TLL NN in Definition 4.

Definition 1 (Sequential (Functional) Composition). Let $\mathcal{M}(\Theta_1) : \mathbb{R}^1 \rightarrow \mathbb{R}^5$ and $\mathcal{M}(\Theta_2) : \mathbb{R}^5 \rightarrow \mathbb{R}^6$ be two NNs. Then the sequential (or functional) composition of $\mathcal{M}(\Theta_1)$ and $\mathcal{M}(\Theta_2)$, i.e., $\mathcal{M}(\Theta_1) \circ \mathcal{M}(\Theta_2)$, is a well-defined NN, and can be represented by the parameter list $\Theta_1 \circ \Theta_2 \triangleq \text{concat}(\Theta_1, \Theta_2)$.

Definition 2. Let $\mathcal{M}(\Theta_1)$ and $\mathcal{M}(\Theta_2)$ be two $K$-layer NNs with parameter lists:

$$\Theta_1 = (\{W_1^i, b_1^i\}, \ldots, \{W_K^i, b_K^i\}), \quad i = 1, 2.$$  \hspace{1cm} (5)

Then the parallel composition of $\mathcal{M}(\Theta_1)$ and $\mathcal{M}(\Theta_2)$ is a NN given by the parameter list

$$\Theta_1 \parallel \Theta_2 \triangleq \{[W_1^1, b_1^1], \ldots, [W_K^1, b_K^1]\}.$$  \hspace{1cm} (6)

That is, $\Theta_1 \parallel \Theta_2$ accepts an input of the same size as (both) $\Theta_1$ and $\Theta_2$, but has as many outputs as $\Theta_1$ and $\Theta_2$ combined.

Definition 3 (n-element min/max NNs). An $n$-element min network is denoted by the parameter list $\Theta_{\text{min}} : \mathcal{M}(\Theta_{\text{min}}) : \mathbb{R}^n \rightarrow \mathbb{R}$ such that $\mathcal{M}(\Theta_{\text{min}})(x) = \min_j x_j$. An $n$-element max network is denoted by $\Theta_{\text{max}}$, and functions analogously. These networks are defined in [14].

With Definition 1 through Definition 3 in hand, it is now possible for us to define TLL NNs in just the same way as [15]. We likewise proceed to first define a scalar (or real-valued) TLL NN; the structure of such a TLL NN is illustrated in Figure 1. Then we extend this notion to a multi-output (or vector-valued) TLL NN.

Definition 4 (Scalar TLL NN [15]). A NN that maps $\mathbb{R}^n \rightarrow \mathbb{R}$ is said to be a TLL NN of size $(N, M)$ if the size of its parameter list $\Sigma_{N,M}$ can be characterized entirely by integers $N$ and $M$ as follows.

$$\Sigma_{N,M} \triangleq \underbrace{\Theta_{\text{max}} \circ (\Theta_{\text{min}} \circ \Theta_{S_1}) \cdots \circ (\Theta_{\text{min}} \circ \Theta_{S_M}) \circ \Theta_t}_{(7)}$$

where

- $\Theta_t \triangleq (\{W_t, b_t\})$;
- each $\Theta_{S_j}$ has the form $\Theta_{S_j} = (S_j, \Theta_{N,1})$; and
- $S_j = [I_N | I_{[0]} | \cdots | I_{[0]} | I_{[0]} | \cdots | I_{[0]}]^{T}$ for some length-$N$ sequence $(u_j) \subseteq \{1, \ldots, N\}$ where $I_N$ is the $(N \times N)$ identity matrix.

The linear functions implemented by the mapping $\mathbb{L}(W_t, b_t)$ for $i = 1, \ldots, N$ will be referred to as the local linear functions of $\Sigma_{N,M}$; we assume for simplicity that these linear functions are unique. The matrices $(S_j)_{j = 1, \ldots, M}$ will be referred to as the selector matrices of $\Sigma_{N,M}$. Each set $S_j \subseteq (1, \ldots, N)$ is said to be the selector set of $S_j$.

Definition 5 (Multi-output TLL NN [15]). A NN that maps $\mathbb{R}^n \rightarrow \mathbb{R}^m$ is said to be a multi-output TLL NN of size $(N, M)$ if its parameter list $\Sigma_{N,M}^{(m)}$ can be written as

$$\Sigma_{N,M}^{(m)} = \Sigma_{N,M}^1 \cdots \Sigma_{N,M}^m$$  \hspace{1cm} (8)

for $m$ equally-sized scalar TLL NNs, $\Sigma_{N,M}^1, \ldots, \Sigma_{N,M}^m$; these scalar TLLs will be referred to as the (output) components of $\Sigma_{N,M}^{(m)}$.

2.4 Hyperplanes and Hyperplane Arrangements

Here we review notation for hyperplanes and hyperplane arrangements; these results will be important in the development of Fast BATLLNN. [25] is the main reference for this section.

Definition 6 (Hyperplanes and Half-spaces). Let $f : \mathbb{R}^n \rightarrow \mathbb{R}$ be an affine map. Then define:

$$H^0_f \triangleq \{x \mid f(x) < 0\} \quad q = -1$$

$$H^1_f \triangleq \{x \mid f(x) > 0\} \quad q = +1$$

$$H^1_f \triangleq \{x \mid f(x) = 0\} \quad q = 0.$$

We say that $H^0_f$ is the hyperplane defined by $f$ in dimension $n$, and $H^1_f$ are the negative and positive half-spaces defined by $f$, respectively.

Definition 7 (Hyperplane Arrangement). Let $\mathcal{L}$ be a set of affine functions where each $f \in \mathcal{L} : \mathbb{R}^n \rightarrow \mathbb{R}$. Then $\{H^0_f \mid f \in \mathcal{L}\}$ is an arrangement of hyperplanes in dimension $n$.

Definition 8 (Region of a Hyperplane Arrangement). Let $\mathcal{H}$ be an arrangement of $N$ hyperplanes in dimension $n$ defined by a set of affine functions, $\mathcal{L}$. Then a non-empty open subset $R \subseteq \mathbb{R}^n$ is said to be a region of $\mathcal{H}$ if there is an indexing function $s : \mathcal{L} \rightarrow \{-1, 0, +1\}$ such that $R = \bigcap_{f \in \mathcal{L}} H^{s(f)}_f$; $R$ is said to be $n$-dimensional or full-dimensional if it is non-empty and described by an indexing function $s(t) \in \{-1, +1\}$ for all $f \in \mathcal{L}$.

Theorem 1 ([25]). Let $\mathcal{H}$ be an arrangement of $N$ hyperplanes in dimension $n$. Then $|\mathcal{H}|$ is at most $\sum_{k=0}^{n} \binom{N}{k}$.

Remark 1. Note that for a fixed dimension, $n$, the bound $\sum_{k=0}^{n} \binom{N}{k}$ grows like $O(N^n/n!)$, i.e. sub-exponentially in $N$.

3 PROBLEM FORMULATION

The essence of Fast BATLLNN is its focus on verifying TLL NNs with respect to box-like output constraints. Formally, Fast BATLLNN considers only verification problems of the following form (stated using notation from Section 2).

Problem 1. Let $\mathcal{M}(\Sigma_{N,M}^{(m)}) : \mathbb{R}^n \rightarrow \mathbb{R}^m$ be a multi-output TLL NN. Also, let:

- $P_X \subseteq \mathbb{R}^n$ be a closed, convex polytope specified by the intersection of $N_X$ half-spaces, i.e. $P_X \triangleq \cap_{X \subseteq \mathcal{L}} \{x \mid H^X_f(x) \leq 0\}$ where each $H^X_f : \mathbb{R}^n \rightarrow \mathbb{R}$ is affine; and
- $P_Y \subseteq \mathbb{R}^m$ be closed hyper-rectangle, i.e. $P_Y \triangleq \prod_{k=0}^{m} [a_k, b_k]$ with $-\infty \leq a_k \leq b_k \leq \infty$ for each $k$. 

Then the verification problem is to decide whether the following formula is true:

$$\forall x \in P_X \subseteq \mathbb{R}^n : \{\mathcal{M}(\Xi_{N,M})y(x) \in P_Y \subseteq \mathbb{R}^m\}.$$ 

(10)

If (10) is true, the problem is SAT; otherwise, it is UNSAT.

Note that the properties (and their interpretations) in Problem 1 are dual to the usual convention; it is more typical in the literature to associate “unsafe” outputs with a closed, convex polytope, and then the existence of such unsafe outputs is denoted by UNSAT (see [28] for example). However, we chose this formulation for Problem 1 because it is the one adopted by [15], and because it is more suited to NN reachability computations, one of the motivating applications of Fast BATLLNN. Indeed, to verify a property like (10), the typical dual formulation of Problem 1 would require $2 \cdot m$ verifier calls, assuming unbounded polytopes are verifiable (and the formula has the same truth value as (10):

instances of Problem 1A and Problem 1B. That is, the following convex polytope as in Problem 1.

become clear in Section 4.

is specified for a sequel to consider the following two verification problems; each of Fast BATLLNN. To this end, we will find it convenient in the treatment of Problem 1 greatly facilitates the development and operation (see also Definition 5). As a result, a component-wise treatment

property $P$ to consider the stated formulation of Problem 1: both the output directly solves Problem 1, requires adaptation to verify the dual

Of course this choice comes with a trade-off: Fast BATLLNN, which are more suited to NN reachability computations, one of the motivating

problems; each of these forms; at the end of this section, we will show how to combine these results into a verification algorithm

for Problem 1, and then we will analyze the overall computational complexity of Fast BATLLNN.

4 FAST BATLLNN: THEORY

In this section, we develop the theoretical underpinnings of Fast BATLLNN. As noted in Section 3, the essential insight of our algorithm is captured by our solutions to problems Problem 1A and Problem 1B. Thus, this section is organized primarily around solving sub-problems of these forms; at the end of this section, we will

4.1 Verifying Problem 1A

Problem 1A, as stated above, regards the TLL NN to be verified merely as a map from inputs to outputs; this is the behavior that we wish to verify, after all. However, this point of view obscures the considerable semantic structure intrinsic to the neurons in a TLL NN. In particular, recall that $\mathcal{M}(\Xi_{N,M})$ implements the following function, which was derived from the Two-Level Lattice representation of CPWAs – see Section 2.3 and [14, 26]:

$$\mathcal{M}(\Xi_{N,M})y(x) = \max_{1 \leq j \leq M} \min_{1 \leq i \leq L} \mathcal{L}(W_i, b_j)(x).$$

(14)

In (14), the sets $s_j$ are the selector sets of $\mathcal{M}(\Xi_{N,M})$ and the $\mathcal{L}(W_i, b_j)$ are the local linear functions of $\mathcal{M}(\Xi_{N,M})$; both terminologies are formally defined in Definition 4. Upon substituting (14) into (11), we obtain the following, far more helpful representation of the property expressed in Problem 1A:

$$\exists x \in P_X \subseteq \mathbb{R}^n : \max_{1 \leq j \leq M} \min_{1 \leq i \leq L} \mathcal{L}(W_i, b_j)(x) > b.$$  

(15)

Literally, (15) compares the output property of interest, $b \in \mathbb{R}$, with a combination of real-valued max/min operations applied to scalar affine functions. Crucially, that comparison is made using the usual order relation on $\mathbb{R}$, $\geq$, which is exactly the same order relation upon which the max and min operations are based.

Thus, it is possible to simplify (15) as follows. First note that the result of the max operation in (15) can exceed $b$ on $P_X$ if and only if:

$$\exists x \in P_X \exists j \in \{1, \ldots, M\} : \min_{1 \leq i \leq L} \mathcal{L}(W_i, b_j)(x) > b.$$  

(16)

In turn, the result of any one of the min operations in (15) can exceed $b$ on $P_X$, and hence make (16) true, if and only if:

$$\exists x \in P_X : \forall i \in s_j : \mathcal{L}(W_i, b_j)(x) > b.$$  

(17)

In particular, (17) is actually an intersection of half spaces, some open and some closed: the open half spaces come from local linear functions that violate the property; and the closed half-spaces come from the input property, $P_X$ (see Problem 1). Moreover, there are at most $M$ such intersections of relevance to Problem 1A: one for each of the $j = 1, \ldots, M$ such min operations present in (15). Finally, note that linear feasibility problems consisting entirely of non-strict inequality constraints are easy to solve: this suggests that we should first amend the $> b$ inequality with $\geq b$ before proceeding.
Formally, these ideas are captured in the following proposition.

**Proposition 1.** Consider an instance of Problem 1A. Then that instance is **UNSAT** if and only if the set:

\[
\bigcup_{j=1,\ldots,M} \left( \bigcap_{i \in s_j} \{ x : L_i(W_i, b_i)(x) > b \} \bigcap_{i=1}^{N_X} \{ x : f_{X,i}(x) \leq 0 \} \right) \neq \emptyset.
\]  

(18)

Or equivalently, if for at least one of the \( j = 1, \ldots, M \), the linear feasibility problem specified by the constraints

\[
F_j = \left\{ \begin{array}{l}
L_i(W_i, b_i)(x) \geq b \\
L_j(W_j, b_j)(x) \geq b
\end{array} \right. \bigcap_{i=1}^{N_X} \{ x : f_{X,N_X}(x) \leq 0 \}
\]  

is feasible, and one of the following conditions is true:

- it has non-empty interior;
- or there is a feasible point that lies only on some subset of the \( \{ f_{X,i} : i = 1, \ldots, N_X \} \).

**Proof.** The first claim follows immediately from the manipulations described in (16) and (17). The second claim merely exhausts the possibilities for how the constraints \( L_i(W_i, b_i)(x) > b \) can participate in a feasible set for the linear program given by \( F_j \). □

**Remark 2.** The conclusion of Proposition 1 also has the following important interpretation: the \( 2x \cdot (\ldots > b) \) property can be seen to “distribute across” the max/min operations in (15), and upon doing so, it converts the lattice operation max into set union and the lattice operation min into set intersection. Furthermore, since a TLL NN is constructed from two levels of lattice operations applied to affine functions, the innermost lattice operation of min is converted into a set intersection of half-spaces — i.e., a linear feasibility problem.

Of course Proposition 1 also suggests a natural and obvious algorithm to verify an instance of Problem 1A. The pseudocode for this algorithm appears as the function `verifyScalarUB` in Algorithm 1, and its correctness follows directly from Proposition 1. In particular, `verifyScalarUB` simply evaluates the feasibility of each set of constraints \( F_j, j = 1, \ldots, M \) in turn, until either a feasible problem is found or the list is exhausted. Then for each such feasible \( F_j \), `verifyScalarUB` attempts to find an interior point of the feasible set to reconcile it with the desired inequalities in (18); failing that, it searches for a vertex of the feasible set where no output property constraints are active. In practice, these operations can be combined by operating on the feasible point returned by the original feasibility program: an LP can be used to maximize the value of each constraint activate in order to explore adjacent vertices. Note further that `verifyScalarUB` may not need to execute all \( M \) possible linear programs for properties that are **UNSAT**: it can terminate early on the first “satisfied” linear program found.

### 4.2 Verifying Problem 1B

Naturally, we start our consideration of Problem 1B in very much the same way as Problem 1A. However, given that Problem 1B and Problem 1A are in some sense *dual*, the result is not nearly as convenient. In particular, substituting (14) into (12), and attempting carry out the same sequence of manipulations that led to Proposition 1 results in the following formula:

\[
\bigcap_{j=1,\ldots,M} \left( \bigcup_{i \in s_j} \{ x : L_i(W_i, b_i)(x) < a \} \bigcap_{i=1}^{N_X} \{ x : f_{X,i}(x) \leq 0 \} \right) \neq \emptyset,
\]  

(20)

which has the same truth value as formula (12). Unfortunately, (20) is not nearly as useful as the result in Proposition 1: under the “dual” output constraint \( \leq a \), set intersection and set union are switched relative to Proposition 1. As a consequence, (20) is not itself a direct formulation in terms of intersections of half-spaces — i.e., linear feasibility problems.

Nevertheless, rearranging (20) into the union-of-half-space-intersections form of Proposition 1 is possible and profitable. Using basic set operations, it is possible to rewrite (20) in a union-of-intersections form as follows (the set intersection \( P_X = \bigcap_{i=1}^{N_X} \{ x : f_{X,i}(x) \leq 0 \} \) is moved outside the outer union for convenience):

\[
P_X \cap \bigcup_{i=1}^{M} \bigcap_{j \in s_j} \{ x : L_i(W_i, b_i)(x) < a \} \neq \emptyset.
\]  

(21)

By construction, (21) again has the same truth value as (12), but it is now in the desired form. In particular, it is verifiable by evaluating a finite number of half-space intersections much like Proposition 1.

Unfortunately, as a result of this rearrangement, the total number of mutual half-space intersections — or intersection “terms” — has grown from \( M \) to \( \prod_{j=1}^{M} |s_j| \), where \( |s_j| \) is the cardinality of the selector set, \( s_j \). In particular, this number can easily exceed \( M \): for example, if each of the \( s_j \) has exactly two elements, then there are \( 2^M \) total mutual intersection terms. Thus, verifying (21) in its current form would appear to require (in the worst case) exponentially more linear feasibility programs than the verifier we proposed for Problem 1A. This situation is not only non-ideal in terms of

### Input

- \( b \in \mathbb{R} \), a upper bound to verify
- \( \Xi_{N,M} \), parameters of a TLL NN to verify
- \( L_X = \{ f_X, \ldots, f_X, f_X \} \), affine functions specifying an input constraint polytope, \( P_X \)

### Output

- Boolean (True = SAT; False = **UNSAT**)

### Algorithm 1: verifyScalarUB

```plaintext
1 function verifyScalarUB(b, \Xi_{N,M}, L_X)  
2 for j = 1, \ldots, M do  
3     constraints \( \left( [L_i(W_i, b_i)(x) \geq b] \text{ for } i \in s_j \right) \)  
4     constraints.append(\( \{ f_X,i(x) \leq 0 \} \) \( \ldots, f_X,N_X(x) \leq 0 \})  
5     (sol, status) \( \leftarrow \) SolveLinFeas(constraints)  
6     if status == Feasible then  
7         if all([L_i(W_i, b_i)](sol) > b for i = 1 \ldots N])  
8             return False  
9         FindInt(constraints) \( \leftarrow \) True  
10 end  
11 end  
12 return True
```

2021, USA.
run-time: it would also seem to contradict [15], which describes an algorithm with polynomial-time complexity in N and M — and that algorithm is after all applicable to more general output properties.

Fortunately, however, there is one aspect not emphasized in this analysis so far: these intersection terms consist of half-spaces, and moreover, each of the half-spaces therein is specified by a hyperplane chosen from among a single, common group of N hyperplanes. This will ultimately allow us to identify each non-empty intersection term in (21) with a full, n-dimensional region from this hyperplane arrangement, and by Theorem 1 in Section 2.4, there are at most O(N^n/n!) such regions. Effectively, then, the geometry of this hyperplane arrangement (with N hyperplanes in dimension n) prevents exponential growth in the number intersection terms relevant to the truth of (21): indeed, the polynomial growth, O(N^n/n!), means that many of those intersection terms cannot correspond to valid regions in the arrangement 3.

In particular, consider the following set of affine functions, which in turn defines an arrangement of hyperplanes in \( \mathbb{R}^n \):

\[
I^n_k = L_k(W_{k}, b_{k}) - a. \tag{22}
\]

Let \( h_a \triangleq \bigcup_{i=1}^N I^n_k \) denote the corresponding arrangement. Now, consider any index \((i_1, \ldots, i_M) \in s_1 \times \cdots \times s_M \) specifying an intersection term in (21), and suppose without loss of generality that \( i_1, \ldots, i_K \) are the only unique indices therein (an assumption we carry forward). Then using the notation \( H^{-1} \) introduced in Definition 6, it is straightforward to write:

\[
\bigcap_{k=1,\ldots,M} \{ x : L_k(W_{k}, b_{k}) (x) < a \} = \bigcap_{i=1}^K H^{-1}_{i}, \tag{23}
\]

and where \( I^n_k \) is as defined in (22). As a consequence, we conclude:

\[
\bigcap_{k=1,\ldots,M} \{ x : L_k(W_{k}, b_{k}) (x) < a \} \neq \emptyset \quad \Leftrightarrow \quad \exists (s' : \{ I^n_k : i = 1, \ldots, K \} \rightarrow \{-1,0,+1\}) \left( \bigcap_{i=1}^K H^{-1}_{i} (s') \neq \emptyset \right). \tag{24}
\]

Although it seems unnecessary to introduce the function \( s' \), this notation directly connects (23) to full-dimensional regions of the arrangement \( h_a \). Indeed, it states that the intersection term of interest is non-empty if and only if there is a full-dimensional region in the hyperplane arrangement whose index function \( s : \{ I^n_k : i = 1, \ldots, N \} \rightarrow \{-1,+1\} \) agrees with one of the partial indexing functions \( s' \) described in (24). More simply, said intersection term is non-empty if and only if it contains a full-dimensional region from the arrangement \( h_a \); such a region can be said to “witness” the non-emptiness of the intersection term. This idea is illustrated in Figure 2.

Formally, we have the following proposition.

**Proposition 2.** Consider an instance of Problem 1B. Then that instance is UNSAT if and only if the set:

\[
\bigcap_{(i_1,\ldots,i_M) \in s_1 \times \cdots \times s_M} \bigcap_{k=1,\ldots,M} \{ x : L_k(W_{k}, b_{k}) (x) < a \} \neq \emptyset. \tag{25}
\]

\footnote{Of course these results apply when \( n \) is fixed, see also [15], and the comments therein pertaining to NN verification encodings of 3-SAT problems [21].}

**Figure 2:** Illustration of identifying a non-empty intersection term from (21) with a full-dimensional region from the hyperplane arrangement \( h_a \), positive half-spaces are indicated with blue arrows. Intersection term and defining half-spaces shown in red; “witness” region from \( h_a \) shown in blue. Input constraints, \( P_X \), omitted for clarity.

And this is the case if and only if there exists an index \((i_1, \ldots, i_M) \in s_1 \times \cdots \times s_M \) with distinct elements denoted by \( j_1, \ldots, j_K \in \{1, \ldots, M\} \) such that the following holds:

- there exists a region \( R \) in \( h_a \), specified by \( s_R : \{ I^n_i : i = 1, \ldots, N \} \rightarrow \{-1,0,+1\} \), such that:

\[
s_R(I^n_i) = -1 \quad \text{for all} \quad k = 1, \ldots, K \tag{26}
\]

and

\[
R \cap P_X \neq \emptyset. \tag{27}
\]

If such a region \( R \) exists, then it is said to witness the non-emptiness of the corresponding intersection term with the index \((i_1, \ldots, i_M) \).

**Proof.** The proof follows from the above manipulations. \( \square \)

Proposition 2 establishes a crucial identification between full-dimensional regions in a hyperplane arrangement and the non-empty intersection terms in (21), a verification formula equivalent to the satisfiability of Problem 1B. However, it is still framed in terms of individual indices of the form \((i_1, \ldots, i_M) \), which are too numerous to enumerate for reasons noted above. Thus, converting Proposition 2 into a practical and fast algorithm to solve Problem 1B entails one final step: efficiently evaluating a full-dimensional region in \( h_a \) to determine if it matches any index of the form \((i_1, \ldots, i_M) \in s_1 \times \cdots \times s_M \). This will finally lead to Fast BATLNN’s algorithm to verify an instance Problem 1B by enumerating the regions of \( h_a \) instead of enumerating all of the indices in \( s_1 \times \cdots \times s_M \).

Predictably, Fast BATLNN essentially takes a greedy approach to this problem. In particular, consider a full-dimensional region, \( R \subset \mathbb{R}^n \), of the hyperplane arrangement \( h_a \), and suppose that \( R \) is specified by the index function (see Definition 8):

\[
s_R : \{ I^n_i : i = 1, \ldots, N \} \rightarrow \{-1,+1\}. \tag{28}
\]

According to Proposition 2, \( s_R \) will be a witness to a violation of Problem 1B if each of its negative hyperplanes (those assigned \(-1 \) by \( s_R \)) can be matched to any element of one of the selector sets, \( s_j \). Thus, to establish whether \( s_R \) corresponds...
The pseudocode for this algorithm, with an outer loop to iterate verifyScalarUB in Algorithm 1 is straightforward. There are \( M \) total min (or intersection) terms, and each of these requires: one LP to check for \( \geq b \) feasibility (line 5 of Algorithm 1); followed by at most \( N \) LPs to find an interior point (line 8 of Algorithm 1). Thus, the complexity of verifyScalarUB is bounded by the following:

\[
O(M \cdot N \cdot \text{LP}(N + N_X, n))
\]

4.3.2 Complexity of Problem 1B. Analyzing the runtime complexity of verifyScalarLB in Algorithm 2 is also more or less straightforward, given an algorithm that enumerates the regions of a hyperplane arrangement. Fast BATLLNN uses an algorithm very similar to the reverse search algorithm described in [4] and improved slightly in [17]. For a hyperplane arrangement consisting of \( N \) hyperplanes in dimension \( n \), that reverse search algorithm has a per-region complexity bounded by:

\[
O(N \cdot \text{LP}(N, n)).
\]

By Theorem 1 in Section 2, there are at most \( O(N^n/n!) \) such regions. Indeed, the per-region complexity of the loops in verifyScalarLB is easily seen to be bounded by \( M \cdot N^2 \) operations per region. Thus, it remains to evaluate the complexity of checking the intersection \( \text{reg} \cap P_X = \emptyset \) (see line 4 of Algorithm 2); however, this only appears as a separate operation for pedagogical simplicity. Fast BATLLNN actually follows the technique in [15] to achieve the same assertion: the hyperplanes describing \( P_X \) are added to the arrangement \( h_a \), and any region for which one of those hyperplanes satisfies \( s(X_i) = +1 \) is ignored. This can be done with the additional per-region complexity associated with the size of the larger arrangement, but without increasing the number of regions evaluated beyond \( O(N^n/n!) \). Thus, we claim the complexity of Algorithm 2 is bounded by:

\[
O\left(M \cdot N^2 \cdot \text{LP}(N + N_X, n) \cdot (N^n/n!)\right) = O(M \cdot N^{n+3} \cdot \text{LP}(N + N_X, n)/n!).
\]

4.3.3 Complexity of Fast BATLLNN Compared to [15]. We begin by adapting the TTL verification complexity reported in [15, Theorem 3] to the scalar TLLs and single output properties of Problem 1A and Problem 1B. In the notation of this paper, it is as follows:

\[
O(n \cdot M \cdot N^{2n+3} \cdot \text{LP}(N^2 + N_X, n)/n!).
\]

It is immediately clear that Fast BATLLNN has a significant complexity advantage for either type of property. Even the more expensive verifyScalarLB has a runtime complexity of \( \approx O(N^n) \) compared to \( \approx O(N^2n) \) for [15, Theorem 3], and that doesn’t even count the larger LPs used in [15, Theorem 3].

5 IMPLEMENTATION

5.1 General Implementation

The core algorithms of Fast BATLLNN, Algorithm 1 and Algorithm 2, are amenable to considerable parallelism. Thus, in order to make Fast BATLLNN as fast as possible, its implementation is focused on parallelism and concurrency as much as possible. With this in mind, Fast BATLLNN is implemented using a high-performance concurrency abstraction library for Python called charm4py [1]. charm4py uses an actor model to facilitate concurrent programming, and it provides a number of helpful features to achieve good performance with relatively little programming effort. For example, it employs a cooperative scheduler to eliminate race-conditions, and it transparently offers the standard Python
pass-by-reference semantics for function calls on the same Processing Element (PE). Moreover, it can be compiled to run on top of Message Passing Interface (MPI), which allows a single code base to scale from an individual multi-core computer to a multi-computer cluster. Fast BATLLNN was written with the intention of being deployed this way: it offers flexibility in how its core algorithms are assigned PEs, so as to take better take advantage of both compute and memory resources that are spread across multiple computers.

5.2 Implementation Details for Algorithm 2

Between the two core algorithms of Fast BATLLNN, Algorithm 2 is the more challenging to parallelize. Indeed, Algorithm 1 has a trivial parallel implementation, since it consists primarily of a for loop over a known index set. In Algorithm 2, it is the for loop over regions of a hyperplane that makes parallelization non-trivial. Hence, this section describes how Fast BATLLNN parallelizes the region enumeration of a hyperplane arrangement for Algorithm 2.

To describe the architecture of Fast BATLLNN’s implementation of hyperplane region enumeration, we first briefly introduce the well-known reverse search algorithm for the same task [17], and the algorithm on which Fast BATLLNN’s implementation is loosely based. As its name suggests, it is a search algorithm: that is, it starts from a known region of the arrangement and searches for regions adjacent to it, and then regions adjacent to those, and so on. In particular, though, the reverse search algorithm is fundamentally a depth-first search, and it uses a minimum-index rule to ensure that regions are not visited multiple times (i.e., functioning much as Bland’s rule in simplex solvers) [4, 17]. This type of search algorithm has the great benefit that it is memory efficient, since it tracks the current state of the search using only the memory required to track adjacency indices; even the information required to back-track over the current branch is computed rather than being stored [17, pp. 10]. However, the memory efficiency of [17] comes at the expense of parallelizability, precisely because the search state is stored using variables that are incremented with each descent down a branch.

The natural way to parallelize such a search is to allow multiple concurrent search workers, but have them enter their independent search results into a common, synchronized hash table. Assuming an amortized $O(1)$ hash complexity, this solution doesn’t affect the overall computational complexity; on the other hand, it comes with a steep memory penalty, since it could require storing all $O(N^2)$ regions in the worst case. However, there is nevertheless a way to efficiently enable and coordinate multiple search processes, while avoiding this excessive memory requirement.

To this end, Fast BATLLNN leverages a special property of the region adjacency structure in a hyperplane arrangement. In particular, the regions of a hyperplane arrangement can be organized into a leveled adjacency poset [11]. That is, relative to any initial base region, all of the regions in the arrangement can be grouped according to the number of hyperplanes that were “crossed” in the process discovering them; the same idea is also implicit in [4, 17]. This leveled property of the adjacency poset is illustrated in Figure 3: the top pane shows a hyperplane arrangement with its regions labeled; the bottom pane depicts the region adjacency poset for this arrangement, with levels indicated relative to a base region, $B$. For example, a search starting from $B$ will find region $R_1$ by crossing only $ℓ_4$ and region $R_2$ by crossing $ℓ_4$ and $ℓ_3$.

Thus, Fast BATLLNN still approaches the region enumeration problem as search, but instead it proceeds level-wise. All of the regions in the current level can be easily divided among the available processing elements, which then search in parallel for their immediately adjacent regions; the result of this search is a list of regions comprising the entire next level in the adjacency poset, which then becomes the current level and the process repeats. From an implementation standpoint, searching the region adjacency structure level-wise offers a useful way of reducing Fast BATLLNN’s memory footprint. In particular, once a level is fully explored, the regions it contains will never be seen again. Thus, Fast BATLLNN need only maintain a hash of regions from one level at a time: the hash tables from previous levels can be safely discarded. In this way, Fast BATLLNN achieves a parallel region search but without resorting to hashing the entire list of discovered regions.

Finally, we note that a search-type algorithm for region enumeration has a further advantage for solving a problem like Problem 1b, though. In particular, a search algorithm reveals each new region with a relatively low computational cost — see (30); this is in contrast to some other enumeration algorithms, which must run to completion before even one region is available. Since Algorithm 2 is structured such that it can terminate on the first violating region found, this has a considerable advantage for UNSAT problems, as a violating region may be found very early in the search.

6 EXPERIMENTS

We conducted a series of experiments to evaluate the performance and scalability of Fast BATLLNN as a TLL verifier, both in its own right and relative to general NN verifiers applied to TLL NNs. In particular, we conducted the following three experiments:

Exp. 1) Scalability of Fast BATLLNN as a function of TLL input dimension, $n$; the number of local linear functions, $N$, and the number of selector sets, $M$, remained fixed.

Exp. 2) Scalability of Fast BATLLNN as a function of the number of local linear functions, $N$, with $N = M$; the input dimension, $n$, remained fixed.
Exp. 3) Comparison with general NN verifiers: mnenum [5], PeregriNN [23] and Alpha-Beta-Crown [33].

All experiments were run within a VMWare Workstation Pro virtual machine (VM) running on a Linux host with 48 hyper-threaded cores and 256 GB of memory. All instances of the VM were given 64 GB of memory, and a core count that is specified within each experiment. A timeout of 300 seconds was used in all cases.

6.1 Experimental Setup: Networks and Properties

6.1.1 TLL NNs Verified. Given that Problem 1 can be decomposed into instances of Problem 1A and Problem 1B, all of these experiments were conducted on scalar-output TLL NNs using real-valued properties of the form in either Problem 1A or Problem 1B.

In Experiments 1 and 2, TLL NNs of the desired $n$, $N$ and $M$ were generated randomly according to the following procedure, which was designed to ensure that they are unlikely to be degenerate on (roughly) the input set $\mathcal{P}$ for Experiment 3, since some of the general NN verifiers accept only 

Section 6.1.1. However, using a hyper-rectangle $P_X$ was necessary for Experiment 3, since some of the general NN verifiers accept only hyper-rectangle input constraints. Thus, we made the universal choice $P_X = [-2, 2]^n$ for consistency between experiments.

6.1.3 Output Properties Verified. For a scalar TLL, only two parameters are required to specify an output property: a real-valued scalar and the direction of the inequality. In all cases, the direction of the inequality was determined by the outcome of Bernoulli random variable. And in all cases except one (noted in Experiment 2), the random real-valued property was generated by the following procedure. First, the TLL network was evaluated at 10,000 samples collected from the set $P_X$; any property between the min and max of these output samples is guaranteed to be UNSAT. Then, to get a mixture of SAT/UNSAT properties, we select a random property from this interval symmetrically extended to twice its original size.

6.2 Experiment 1: Input Dimension Scalability

In this experiment, we evaluated the scalability of Fast BATLLNN as a function of input dimension of the TLL to be verified. To that end, we generated a suite of TLL NNs with input sizes varying from $n = 1$ to $n = 30$, using the procedure described in Section 6.1.1. We generated 20 instances for each size, and for all TLLs, we kept $N = M = 64$ constant. We then verified each of these TLLs with respect to its own, randomly generated property (as described in Section 6.1.3). For this experiment, Fast BATLLNN was run in a VM with 32 cores.

Figure 4 summarizes the results of this experiment with a box-and-whisker plot of verification times: each box-and-whisker summarizes the verification times for the twenty networks of the corresponding input dimension; no properties/networks resulted in a timeout. The data in the figure shows a clear trend of increasing median, as expected for progressively harder problems (recall the runtime complexities indicated in Section 4.3). By contrast, note that the minimum and maximum runtimes grow very slowly with dimension: given the complexity analysis of Section 4.3, we speculate that these results are likely due to the characteristics of the generated TLLs. That is, the generation procedure appears to “saturate” the sense that it eventually produces networks which require, on average, a constant number of loop iterations to verify.

As usual, the boxes denote the first and third quartiles; the orange horizontal line denotes the median, and the whiskers show the maximum and minimum.
6.3 Experiment 2: Network Size Scalability

In this experiment, we evaluated the scalability of Fast BATLLNN as a function of the number of local linear functions, \( N \), in the TLL to be verified. To that end, we generated a suite of TLL NNs local linear functions ranging in number from \( N = 16 \) to \( N = 512 \), again using the procedure described in Section 6.1.1. We generated 20 instances for each value of \( N \), and for all networks we set \( M = N \) and \( n = 15 \). We then verified each of these networks with respect to its own, randomly generated property. The properties for network sizes \( N = 16 \) through \( N = 256 \) were generated as described in Section 6.1.3; however, our TensorFlow implementation occupied too much memory to generate samples for TLLs of size \( N = 512 \), so the properties for these networks were generated using the bounds for the \( N = 256 \) TLLs. For this experiment, Fast BATLLNN was run in a VM with 32 cores.

Figure 5 summarized the results of this experiment with a box-and-whisker plot of verification times: each box-and-whisker summarizes the verification times for the twenty test cases of the corresponding size, much as in Section 6.2. However, since some verification problems timed out in this experiment, those time outs were excluded from the box-and-whisker; they are instead indicated by a superimposed bar graph, which displays a count of the number of timeouts obtained from each group of equally-sized TLLs. The data in this figure shows the expected trend of increasingly difficult verification as \( N \) increases; this is especially captured by the trend of experiencing more timeouts for larger networks. The outlier to this trend is the size \( N = 512 \), but this is most likely due to different method of generating properties for these networks (see above). Finally, note that the minimum verification times exhibit a much slower growth trend, as in Experiment 1.

6.4 Experiment 3: General NN Verifiers

In this experiment, we compared the verification performance of Fast BATLLNN with state-of-the-art (SOTA) NN verifiers designed to work on general deep NNs. For this experiment, we compared against generic verifiers Alpha-Beta-Crown [33], nnenum [5] and PeregriniNN [23], as a representative sample of SOTA NN verifiers. Moreover, we conducted this experiment on the same 240 networks used in [15], and described in Section 6.1.1; this further facilitates a limited comparison with that algorithm, subject to the caveats described in Section 6.1.1 and Section 6.1.3.

In order to make this test suite of TLLs available to the generic verifiers, each network was first implemented as a TensorFlow model using a custom implementation tool. The intent was to export these TensorFlow models to the ONNX format, which each of the generic verifiers can read. However, most of the generic verifiers do not support implementing multiple feed-forward paths by tensor reshaping operations, as in the most straightforward implementation of a TLL; see Figure 1 and Section 2.3. Thus, we had to first "flatten" our TensorFlow implementation into an equivalent network where each min network accepts the outputs of all of the selector matrices, only to null the irrelevant ones with additional kernel zeros in the first layer. This is highly sub-optimal, since it results in neurons receiving many more inputs than are really required. However, we could not devise another method to circumvent this limitation present in most of the tools.

With all of the tools able to read the same NNs in our (borrowed) test suite, we randomly generated verification properties for each of the networks, as in the previous experiments. However, recall that the generic NN verifiers have a slightly different interpretation of properties compared with Fast BATLLNN. For scalar-output networks, this amounts to verifying the properties in Problem 1A and Problem 1B with the same interpretations, but with non-strict inequalities instead of strict inequalities. Since this will only generate divergent results when a property happens to be exactly equal to the maximum or minimum value on \( P_x \), we elide this issue.

Thus, we ran each of the tools, Fast BATLLNN, Alpha-Beta-Crown, nnenum and PeregriniNN on this test suite of TLLs and properties. PeregriniNN was configured with \( \text{SPLIT\_RES} = 0 \); \( \text{nnenum} \) was configured with \( \text{TRY\_QUICK\_APPROX} = \text{True} \) and all other parameters set to default values; and Alpha-Beta-Crown was configured with input space splitting, \( \text{share\_slopes} = \text{True} \), \( \text{no\_solve\_slopes} = \text{True} \), \( \text{lr\_alpha} = 0.01 \), and \( \text{branching\_method} = \text{sb} \). All the solvers used float64 computations. Furthermore, we ran two versions of this experiment, one where the VM had 4 cores and one where the VM had 24 cores.

Figure 6 summarizes the results of this experiment in the form of a cactus plot: a point on any one of the curves indicates the timeout that would be required to obtain the corresponding number of proved cases for that tool (from among of the test suite described above). As noted, each tool was run separately in two VMs, one with 4 cores and one with 24 cores; thus, each tool has two curves in Figure 6. The data shows that Fast BATLLNN is on average \( 960 \times 435 \times \) faster than nnenum, \( 1800 \times 1370 \times \) faster than Alpha-Beta-Crown, and \( 1000 \times 500 \times \) faster than PeregriniNN using 4 and 24 cores.
cores respectively. Fast BATLLNN also proved all 240 properties in just 17 seconds (4 cores), whereas nnenum proved 193, Alpha-Beta-Crown proved 153, and PeregrNN proved 186. Note that unlike the other tools, Fast BATLLNN doesn’t exhibit exponential growth in execution time on this test suite, which is consistent with the complexity analysis in Section 4.3. Despite the caveats noted above, Fast BATLLNN also compares favorably with the execution times shown in [15, Figure 1(b)], which end up in the 100’s or 1000’s of seconds for $N = 64$. Finally, note that although Fast BATLLNN suffered from slightly worse measured performance with 24 cores, the rate at which its timeouts increased was significantly slower than with 4 cores; this suggests the data is reflecting constants, rather than inefficient use of parallelism. Of similar note, Alpha-Beta-Crown seems to suffer from the overhead of using more CPU cores. Based on our understanding, the algorithm doesn’t benefit from multiple cores except for solving MIP problem.
