Abstract

Regularization can mitigate the generalization gap between training and inference by introducing inductive bias. Existing works have already proposed various inductive biases from diverse perspectives. However, to the best of our knowledge, none of them explores inductive bias from the perspective of class-dependent response distribution of individual neurons. In this paper, we conduct a substantial analysis of the characteristics of such distribution. Based on the analysis results, we articulate the Neuron Steadiness Hypothesis: the neuron with similar responses to instances of the same class leads to better generalization. Accordingly, we propose a new regularization method called Neuron Steadiness Regularization to reduce neuron intra-class response variance. We conduct extensive experiments on Multilayer Perceptron, Convolutional Neural Network, and Graph Neural Network with popular benchmark datasets of diverse domains, which show that our Neuron Steadiness Regularization consistently outperforms the vanilla version of models with significant gain and low additional overhead.

Introduction

Deep Neural Network (DNN) achieves state-of-the-art results in a wide range of areas and has various applications across industries, including self driving cars [Rao and Fr-tunik\textsuperscript{1} 2018], virtual assistants [Rawassizadeh et al.\textsuperscript{1} 2019], intelligent healthcare [Miotto et al.\textsuperscript{1} 2018], personalized recommendation [Naumov et al.\textsuperscript{1} 2019], etc. DNN’s success usually relies on a plenty amount of training data. However, DNN’s generalization is often hampered in many domains where training data is insufficient because data annotation is labor-intensive and expensive.

Regularization is a popular method which helps to improve generalization via introducing inductive bias. Regularization is one of the key elements of machine learning, particularly of deep learning [Goodfellow, Bengio, and Courville\textsuperscript{1} 2016]. Specifically, inductive bias represents assumptions about the model properties other than the consistency of outputs with targets. There have been tremendous efforts in identifying such desired properties, which results in a series of widely used regularization methods. For example, L2 Regularization [Plaut et al.\textsuperscript{1} 1986] [Lang and Hinton\textsuperscript{1} 1990] penalizes large norms of model weights, which puts constraints on "parameter scale". L1 regularization improves "sparseness" by rewarding zero weight or neuron response. Jacobian regularization [Sokolić et al.\textsuperscript{1} 2017] [Hoffman, Roberts, and Yaida\textsuperscript{1} 2019] minimizes the norm of the input-output Jacobian matrix to improve "smoothness" of the learned mapping function. Orthogonal regularization [Cui et al.\textsuperscript{1} 2020] [Brock et al.\textsuperscript{1} 2017] enlarges "weight diversity" to reduce the feature redundancy. Batch Normalization [Ioffe and Szegedy\textsuperscript{1} 2015] promotes "training dynamics stability" by reducing the internal covariate shift.

Although the existing works have already proposed various inductive biases from diverse perspectives, including aforementioned "parameter scale", "sparseness", "smoothness", "weight diversity", "training dynamics stability", to the best of our knowledge, there is no work to explore inductive bias from the perspective regarding the characteristics of neuron response distribution on each class. From another point of view, the existing works leverage the information related to weights (parameter scale regularization), weight correlations (orthogonal regularization), derivatives of mapping function (smoothness regularization), collective neurons responses (sparseness regularization, Batch Normalization), but none of them considers the intra-class response distribution of individual neurons.

In this paper, we study the characteristics of the intra-class response distribution of each individual neuron to identify the new regularization method. In more detail, for each individual neuron, we analyze the variance of its response to samples of the same class, which is called neuron intra-class response.

\textsuperscript{*}These authors contributed equally to the work.

variance. We find that such intra-class response variance has an obvious correlation with classification correctness. As shown in Figure 1, we find the correctly classified samples usually have smaller intra-class response variance compared to the misclassified samples. Besides, it can be observed that the vanilla model with cross entropy as the optimization target usually could not control intra-class response variance well, as shown in Figure 2, which leaves a potential improvement space for the regularization. The details of experiments and observations are explained in section.

Based on these observations, we articulate the Neuron Steadiness Hypothesis, neuron with similar responses to instances of the same class, i.e., smaller neuron intra-class response variance, can lead to better generalization. Accordingly, we propose the regularization method called Neuron Steadiness Regularization to improve generalization by penalizing large neuron intra-class response variance.

Our regularization method shows significant improvement on various network architectures, including Graph Neural Network (GNN), Convolution Neural Network (CNN), and Multilayer Perceptron (MLP).

To sum up, our contributions are as follows:

• We articulate the Neuron Steadiness Hypothesis and demonstrate its validity, which provides a new regularization perspective based on the neuron-level class-dependent response distribution.
• We propose a new regularization method called Neuron Steadiness Regularization that improves generalization ability. The proposed method is computationally efficient and adaptive to various architectures and tasks.
• Extensive experiments are conducted on multiple kinds of datasets, like images, citation graphs, and product graphs, with various network architectures, including GNN, CNN, and MLP. The significant accuracy improvement evidently verifies the effectiveness of the proposed Neuron Steadiness Regularization.

Observations
In this section, we verify the validity of our proposed Neuron Steadiness Hypothesis by experiments with the following identified observations.

Correlation between neuron intra-class response variance and classification correctness
The neuron intra-class response variance is derived from neuron response distribution. For any neuron in a given neural network, its response distribution could be obtained by
We investigate the tendency of neuron intra-class response with our proposed neuron steadiness regularization. We perform the analysis on the vanilla model and the model variance, which results in higher testing accuracy. From Figure 2, we could also see that regulating neuron intra-class distribution, and the training procedure of the model trained with our proposed regularization, the neuron intra-class response variance is growing larger because cross entropy only important, the learned model with well-controlled intra-class response variance of correctly classified samples are averaged and the entire training set after each training epoch. Then, for each neuron, we calculate the intra-class response variance corresponding to the correctly classified samples and misclassified samples, respectively. Finally, we aggregate such two respective variances of all neurons in the penultimate layer separately and present them in Figure 1.

Figure 1 shows that, for different networks, the average intra-class response variance of correctly classified samples is smaller than that of misclassified ones on arbitrary class. It illustrates that there is a strong correlation between classification correctness and neuron intra-class response variance.

**Dynamics of neuron intra-class response variance during training procedure**

We investigate the tendency of neuron intra-class response variance along with the training procedure. For comparison, we perform the analysis on the vanilla model and the model with our proposed neuron steadiness regularization. We calculate the intra-class response variance of each neuron on the entire training set after each training epoch. Then, the intra-class response variance of all neurons are averaged and denoted as average variance in Figure 2(c). We also show the testing accuracy and the training cross entropy loss in Figure 2(a) and (b), respectively. Other architectures demonstrate similar tendencies and can be found in Appendix.

From Figure 2, we could see that the cross entropy objective keeps being optimized during the training procedure which leads to increasing classification accuracy for both models. However, for the vanilla version, the average neuron intra-class response variance is growing larger because the model training does not impose constraints on neuron intra-class response variance. For the model trained with our proposed regularization, the neuron intra-class response variance is controlled and decreases after a few epochs. More importantly, the learned model with well-controlled intra-class response variance has higher testing accuracy than the vanilla version although its corresponding cross entropy loss is even larger. One potential reason is that cross entropy only increases the distance among different classes while ignoring the intra-class distribution, and the training procedure of the model with our regularization gradually enforces decision boundary distance by reducing neuron intra-class response variance, which results in higher testing accuracy. From Figure 2, we could also see that regulating neuron intra-class response variance may also help the optimization procedure to achieve higher accuracy in earlier epochs.

To conclude all above observations, it is reasonable to design the regularization based on the neuron steadiness hypothesis, i.e., reducing neuron intra-class response variance, for better generalization.

**Method**

In this section, we first describe the proposed Neuron Steadiness Regularization. Then we further introduce several techniques for computational efficiency with mini-batch.

**Definition of Neuron Steadiness Regularization**

Neuron Steadiness Regularization (NSR) for a specific neuron is defined as the summation of intra-class response variances of different classes. The NSR for the \( n_{th} \) neuron can be formulated as:

\[
\sigma_n = \sum_{j=1}^{J} \alpha_j \cdot \text{Var} (X_{n,j}) = \sum_{j=1}^{J} \alpha_j \cdot E [(X_{n,j} - E[X_{n,j}])^2]
\]

where \( X_{n,j} \) is a random variable denoting the \( n_{th} \) neuron’s response for a sample belonging to the \( j_{th} \) class. \( J \) is the number of classes. \( \alpha_j = \frac{z_j}{\sum_z} \) is the prior probability of the \( j_{th} \) class where \( z_j \) is the sample amount of \( j_{th} \) class. Notice that \( \alpha_j \) is not a hyper-parameter, and it only presents the importance of different classes. With the NSR term defined for each individual neuron, the overall regularization is derived by applying NSR term on all neurons in the network as follows:

\[
\mathcal{L}_S = \sum_{n=1}^{N} \lambda_n \sigma_n
\]

where \( \mathcal{L}_S \) represents the NSR term for the entire network, \( N \) is the number of neurons in the network. \( \lambda_n \) is the hyper-parameter to present the significance of the \( n_{th} \) neuron. In this paper, for practical simplicity, \( \lambda \) is set as the same value for all neurons in the same layer. Adding the overall regularization term to the main training target, i.e., the cross entropy loss, the final regularized loss function can be written as:

\[
\mathcal{L} = \mathcal{L}_C + \mathcal{L}_S,
\]

where \( \mathcal{L}_C \) represents cross entropy loss.

**Practical Implementation**

**Mini-batch Training** In order to use mini-batch training, we adapt our NSR method to allow forward and backward propagation for mini-batches of samples. To be specific, we first transform Eq. (1) as:

\[
\sigma_n = \sum_{j=1}^{J} \alpha_j \left( E \left[ X_{n,j}^2 \right] - E^2 [X_{n,j}] \right)
= E \left[ \sum_{j=1}^{J} \alpha_j X_{n,j}^2 \right] - \sum_{j=1}^{J} \alpha_j E^2 [X_{n,j}]
\]

The first term has the same form as typical loss functions, i.e., an expectation of the function of data samples, which
can be easily generalized to a mini-batch training setting via estimating the expectation with a batch of samples. Although the second term can be estimated in the same way, the square operation magnifies the estimation error, especially when the batch size is not large enough.

To alleviate the problem while not introduce much computing overhead, we propose a memory queue based estimation method that allows us to leverage more history samples for estimation without additional sampling and forward/backward computation. For each class, we record the number of samples and the summation values of the neurons’ response within each batch. To further reduce the storage overhead, we only maintain these values of the latest $M$ batches by two $M$-length queues.

More specifically, an element $c_{m,j}$ in the first memory queue is the count number of $j_{th}$ class instances in the $m_{th}$ batch, represented as:

$$c_{m,j} = \sum_{y_i \in Y_m} \delta(y_i = j),$$

where $Y_m$ is the set of labels in the $m_{th}$ batch, $y_i$ is the label of $i_{th}$ sample, and $\delta$ is a characteristic function, i.e., $\delta(\text{condition}) = 1$ if condition is satisfied, otherwise $\delta(\text{condition}) = 0$. An element $s_{m,j}^{(n)}$ in the second memory queue is the summation value of $n_{th}$ neuron’s response for the samples belonging to the $j_{th}$ class within the $m_{th}$ batch, represented as:

$$s_{m,j}^{(n)} = \sum_{x_i^{(n)} \in X_m^{(n)}} \delta(y_i = j) \cdot x_i^{(n)},$$

where $X_m^{(n)}$ is the set of the $n_{th}$ neuron’s response within the $m_{th}$ batch and $x_i^{(n)}$ is the $n_{th}$ neuron’s response of the $i_{th}$ sample. When a new batch is fed, the estimation of expectation $E[X_{n,j}]$ can be updated by the following steps:

$$C_j := C_j - c_{0,j} + c_{s,j}, \quad S_j^{(n)} := S_j^{(n)} - s_{0,j}^{(n)} + s_{s,j}^{(n)}$$

$$E[X_{n,j}] := \frac{S_j^{(n)}}{C_j},$$

where $E[X_{n,j}]$ is the estimation of expectation $E[X_{n,j}]$, $C_j = \sum_m c_{m,j}$, $S_j^{(n)} = \sum_m s_{m,j}^{(n)}$, and $c_{s,j}$, $s_{s,j}$, as new elements appended to the queues, represent the count number and the summation for the new batch. Based on this dynamic update method, the additional memory overhead is negligible, and we give a space complexity analysis in Appendix.

**Steadiness Redundancy among Neurons** Considering the trade-off between performance gain and computational overhead, it may not be necessary to apply NSR on all neurons. The experiment results in Figure 3 show that every layer’s variance ratio decreases even only one specific layer is applied with NSR. It indicates the correlation or redundancy among the steadiness constraints of different layers, meaning that applying NSR on different layers of neurons has an overlapping effect on neuron steadiness control. More detailed experiment results in show that only applying NSR on a particular layer, i.e., the last layer of MLP or CNN and the first layer of GNN, could achieve comparable accuracy with the best result obtained by applying NSR on multiple layers.

**Experiment**

In this section, we conduct experiments over a variety of datasets to examine the performance of our neuron steadiness regularization on three extensively used neural network architectures. We design a series of experiments to answer the following research questions:

- **RQ1**: How does NSR perform on various datasets and different neural architectures?
- **RQ2**: Does NSR outperform other classical regularization methods?
- **RQ3**: What is the effect of combining NSR with other popular methods like Batch Normalization or Dropout?
- **RQ4**: How to decide the layer(s) to be applied with NSR?

**Experiment Setup**

**Network Architectures and Datasets** The three architectures utilized in experiments are Multilayer Perceptron (MLP), Convolutional Neural Network (CNN) and Graph Neural Network (GNN). For vanilla models used as our baselines in different architectures, we adopt ResNet-18 (He et al. 2016), VGG-19 (Liu et al. 2018) and ResNet-50 for CNN, GCN (Kipf and Welling 2017) and GraphSAGE (Hamilton, Ying, and Leskovec 2017) for GNN. We run five MLP models with different layers and MLP with L layers (including input layer) is denoted by MLP-L. We elaborate on the details of these vanilla models in the Appendix. As for benchmark datasets used in our experiments, MLP and CNN are applied to image recognition task on MNIST (LeCun 1998), CIFAR-10 (Krizhevsky, Hinton et al. 2009) and ImageNet (Deng et al. 2009) datasets, respectively, while GNN is applied to node classification on four real-world graph datasets: WikICS (Mernyei and Cangea 2020), PubMed (Yang, Cohen, and Salakhudinov 2016), Amazon-Photo and Amazon-Computers (Shchur et al. 2018). Notice that ImageNet is a large benchmark dataset with 1000 classes. We describe the details of these datasets in Appendix.

Experiment Settings  We divide 60000 training images of MNIST into the training set with 50000 samples and the validation set with the remaining 10000 samples. For each of four graph datasets, it is randomly split into training, validation, and testing sets with ratio 6:2:2. The implementation settings of GraphSAGE and GCN are followed by (Ma et al. 2021). For ResNet-18 and VGG-19 on CIFAR-10, we follow the implementation setting details of Zhang et al. 2019 and Gouk et al. 2018 correspondingly. For ResNet-50 on ImageNet, we follow the official implementation provided by torchvision library. To be specific, SGD (Ruder 2016) is used to optimize MLP, and Adam (Kingma and Ba 2015) for other models except for ResNet-18 that is optimized by Momentum (Ruder 2016) according to the implementation of Zhang et al. 2019. We use the typical setting of batch size as 100 for all experiments. To ensure the model convergence, training epochs are set as 100 for both MLP and GNN, and 200 for ResNet and 500 for VGG.

For practical simplicity, we use the same \( \lambda_l \) for neurons at the \( l \)-th layer which is denoted as \( \lambda_l \), and we apply NSR to only one particular layer in our experiments except for RQ4. We tune this hyper-parameter \( \lambda \) like most of the regularization methods. We apply random search strategy to find the proper \( \lambda_l \) from 1e-2 to 100. The error rate is the metric and each result is averaged over 5 runs with different random seeds. The hardware environment is detailed in Appendix.

Experiment Results

RQ1: Performance of Neuron Steadiness Regularization (NSR)  It is worth mentioning that for the experiments presented under this RQ, we apply NSR to only one specific layer instead of the entire network. One reason is to reduce the number of hyper-parameters \( \lambda \). Another reason comes from the steadiness redundancy among neurons. We find that adding NSR in one specific layer could usually achieve results comparable to the best results obtained by adding it into multiple layers. The detailed comparison results and the criteria for determining the layer index for applying NSR are discussed in RQ4.

Here, we discuss the performance of NSR over different models and present the results on Tab. 1~Tab. 3 “Gain” is the percentage of relative reduction in the error rate. Tab. 1 demonstrates that NSR can improve the performance of MLP with different layers: the relative error rate is reduced by 9.39% at least and 43.79% at most. Besides, as the number of network layers increases, the gain of NSR shows a roughly upward trend. The four-layer MLP achieves the lowest classification error rate among all vanilla version baselines, and the accuracy becomes worse as the networks grow deeper. It indicates that deep MLP encounters a severe overfitting problem. The success of our regularization in addressing such a problem reveals the importance of stabilizing the response of each individual neuron to instances from the same class.

For the CNN models, Tab. 2 demonstrates that NSR can reduce the relative error rate for CIFAR-10 by 11.97% on VGG-19 and 9.00% on ResNet-18, and reduce the relative error rate (top-5) for ImageNet by 9.34% on ResNet-50. Considering that VGG-19, ResNet-18 and ResNet-50 have already adopted Batch Normalization, Dropout regularization and Weight Decay in the vanilla model, the accuracy gain of our method reveals that NSR can have extra benefits to ulteriorly enhance generalization ability when combining with Batch Normalization, Dropout and Weight Decay. We will show more evidence about this in RQ3.

For the two GNN models, the number of layers varies from 2 to 4. This setting follows the empirical experience as nodes will capture similar information from neighbors and result in over smoothness when GNNs grow deeper. Tab 3 shows that GraphSAGE and GCN applied with NSR outperform the vanilla model with different layer depths on all datasets. Specifically, GraphSAGE and GCN achieve an average improvement of 8.6% and 5.8%, respectively, and 17.0% improvement at most.

RQ2: Comparison with Other Regularization  We first compare our NSR method with several classical regularization methods shown in Tab. 4 Notice that, the same as the setting in RQ1, our NSR have only one hyper-parameter \( \lambda \) to tune. Also, we utilize the same hyper-parameter searching strategy to select the best hyper-parameter values for both our NSR and the other regularization methods. As shown in Tab. 4, our NSR performs best among these regularization methods on all three models with different architectures, i.e., MLP-4 (MLP), ResNet-18 (CNN), GraphSAGE (GNN). The results indicate that our NSR has remarkable improvement and is general for various architectures.

RQ3: Combination with Other Regularization We further investigate the effect of combining our NSR with other popular methods like Batch Normalization and Dropout. We conduct the experiments on MLP-4 and the result are organized in Table 5. From Table 5, we can find that both Batch Normalization and Dropout can reduce error rate compared with vanilla baseline, and adding our NSR on the top of them can further promote the performance significantly. It indicates that NSR can provide complementary regularization benefits with Batch Normalization and Dropout.

RQ4: Layer selection for applying NSR In this section, we shed light on how to decide which layer to apply NSR. As our NSR is used to reduce neuron intra-class response variance, naturally, the intuitive criteria is to apply NSR to the layer with the largest aggregated neuron intra-class response variance. According to the experiments, such criteria works...
well.

Taking MLP-4 on MNIST and GraphSAGE-2 on Amazon-Computers as two examples, we apply NSR to different layer(s), and their corresponding error rates are listed in Tab. 6. By applying NSR to each layer of the model, we notice that, except the first layer of MLP-4 which is the input layer, the second and last layer of MLP-4, their neuron intra-class response variance are 409, 510, and 1660, respectively. For GraphSAGE-2, its neuron intra-class response variance are 4.15 and 2.68, for the first and last layer, respectively. The variance of MLP-4 and GraphSAGE-2 are quite different because of the data characteristic difference between MNIST and Amazon-Computers.

The results in Tab. 6 show that, no matter which layer(s) is applied with NSR, it could always improve the accuracy compared with the vanilla baseline for both MLP-4 and GraphSAGE-2. In addition, applying NSR to the layer with the biggest variance, i.e., the last layer for MLP-4 and the first layer for GraphSAGE-2, could achieve the most significant gain compared with applying NSR to other individual layers. Also, it could achieve similar accuracy compared with the best one obtained by applying NSR to multiple layers. Furthermore, we summarize an empirical guidance based on more experiments: By simply applying NSR to the last layer of MLP and CNN, and the first layer of GNN, we could usually obtain significant accuracy improvement.

**Related Work**

Regularization improves generalization ability by introducing the inductive bias based on prior knowledge. According to the type of prior knowledge, existing works can be roughly categorized into Domain Specific Regularization and Model Generic Regularization. Domain Specific Regularization usually encodes the domain specific requirements or preferences based on the domain background knowledge, and usually has a nice gain for the target problems or domains. While, Model Generic Regularization is usually based on the reasonable hypothesis about general properties of DNN, learning dynamics, etc. They could be helpful to a wide range of domains and scenarios.

**Domain Specific Regularization** shows success in various domains including Face Recognition [Wen et al. 2016], Liu et al. [2017a], Liu et al. (2017b), Knowledge Graph Completion [Zhang, Cai, and Wang 2020], Lacroix, Usunier, and Obozinski [2018], Minervini et al. [2017], Graph Neural Network [Chen et al. 2018], Hou et al. [2019], Kong et al. [2020], Yang et al. [2020], Long et al. [2019], and so on. [Du et al. 2021]. In Face Recognition, [Cai et al. 2018] points out the existence of external factors, such as different situations of environmental illumination, head poses, facial expressions, which brings the challenge that face images from the same person may have even larger differences than face images from different persons. To address specific challenges in face recognition, [Liu et al. 2017a] imposes the careful-designed regularization method which enforces the representations of face instances from the same person to be similar. In Knowledge Graph Completion, learning the embedding of entities and relations is usually a key step of performing statistical analysis. [Minervini et al. 2017] regularizes the training of neural knowledge graph embedding by imposing a set of soft model-dependent constraints on the predicate embedding. Those constraints encode the background knowledge of equivalence and inversion axioms. In Graph Neural Network, the popular used model usually suffers from the over-smoothing problem due to the six degrees of separation [Kleinfeld 2002], [Chen et al. 2020] statistically analyzes the high correlation between smoothness and the mean average distance (MAD) among node representation. Then a regularization called MADGap is proposed which punishes over smoothness by minimizing MAD.

**Model Generic Regularization** can be categorized into network-wise Regularization, layer-wise Regulation, and neuron-wise Regularization, according to the granularity of the studied properties. Network-wise Regularization encodes the desired property of the entire network, like the sparseness of the network, the smoothness of the mapping function between input and output. For example, L2 Regularization [Plaut et al. 1986], [Lang and Hinton 1999] is the most well-known regularization term which encourages small sum squared magnitude of model weights. L1 Regularization is widely used to improve the sparseness of the network. Recently, [Hoffman, Roberts, and Yaida 2019] introduces an efficient framework to minimize the norm of input-out Jacobian matrix for noise robustness. Layer regularization becomes popular due to the success achieved by Batch Normalization [Ioffe and Szegedy 2015] and a series of layer-wise normalization methods [Ulyanov, Vedaldi, and Lempitsky 2016], [Plaut et al. 1986]. It should be pointed out that, some methods could work well at network level while producing issues at layer-wise level. For example, [Gu and Rigazio 2015] imposes a layer-wise Jacobian penalty to ensure the smoothness of each mapping function corresponding to individual layers. Although it operates in finer granularity with the similar motivation of traditional Jacobian based regularization, it was claimed with the degradation on noiseless data by [Goodfellow, Shlens, and Szegedy 2015]. Neuron-wise Regularization is the method with the most fine-grained granularity. Dropout [Hinton et al. 2012], [Srivastava et al. 2014] is the typical example belonging to this category. It randomly removes neurons with a certain probability to avoid strong co-adaptation between neurons. Our proposed Neuron Steadiness Regularization belongs to the neuron-wise regularization which leverages the information of individual neuron response distribution.

**Conclusion and Future Work**

We explore the inductive bias from the new perspective of class-dependent response distribution of individual neurons. Based on our experimental observations, we articulate the Neuron Steadiness Hypothesis and propose the Neuron Steadiness Regularization that penalizes large intra-class response variance of neurons. Extensive evaluations conducted on diverse datasets with various network architectures demonstrate its effectiveness of the proposed method. Especially, we show its effectiveness on the classification task with a large model, i.e., ResNet-50, and a big dataset with many classes, i.e., ImageNet with 1000 classes. We also carefully consider the border impact from various perspectives such as fairness, security, harm to people and so on, we do not find
any apparent risk related with our work.

One future direction is to explore other statistics based on such neuron-level class-dependent response distribution. There may be better statistics for regularization other than the intra-class response variance. Another direction is to explore hyper-parameter setting strategies. In this paper, for the simplicity of hyper-parameter setting, we use the same value of $\lambda$ for all neurons in the same layer. While, as NSR is about individual neuron, $\lambda$ of different neurons is not necessarily the same. One intuitive idea is to set $\lambda$ according to neuron importance like (Dhamdhere, Sundararajan, and Yan 2019).
