(Dated: 1 December 2021)

Secure operation of electric power grids fundamentally relies on their dynamical stability properties. For the third order model, a paradigmatic model that captures voltage dynamics, three routes to instability are established in the literature, a pure rotor angle instability, a pure voltage instability and one instability induced by the interplay of both. Here we demonstrate that one of these routes, the pure voltage instability, is inconsistent with Kirchhoff's nodal law and thus nonphysical. We show that voltage collapse dynamics nevertheless exist in the absence of any voltage instabilities.

nonlinear dynamics, network dynamics, power system stability, susceptance and admittance matrix, synchronization

Most aspects of our daily life essentially depend on a reliable supply of electrical power, thereby imposing severe challenges for stable operation of power grids that consist of many generators (producers of electric power) and loads (consumers of power) connected with transmission lines. From a perspective of network dynamical systems, these challenges translate to requiring steady states that are (asymptotically) stable against sufficiently small dynamical perturbations, such that all dynamical variables relax back to their steady synchronous (phase-locked) state with fixed phase differences, constant overall grid frequency as well as fixed voltage amplitudes. In contrast, instabilities may cause growth or fluctuations of phase differences, deviating and changing frequencies and non-constant voltage levels, all undesired in power grid operation. For the most basic model class of power system dynamics that covers voltage dynamics, three routes to instabilities have been established in the literature. Here we demonstrate that only two of these three remain in the physically relevant regime, while the third is excluded due to Kirchhoff's nodal law of current conservation.

I. INTRODUCTION

Electric power supply substantially relies on the stable power grid dynamics. Two classes of system variables are especially important for reliable grid operation: grid frequency and terminal voltage amplitudes^{1–3}. Instabilities to fluctuations and collapse of terminal voltages have been identified as key contributing factors for large-scale blackouts, for instance, in the northeastern United States (2003) and Athens/Greece (2004)^{2,3}. The phenomena of voltage collapse and voltage instability in power system models have been extensively studied in the literature, see, e.g., $^{4-6}$.

Since more than a decade ago, beginning with the derivation of a dynamic network model from the physics of coupled synchronous machines⁷ and its collective dynamical phenomena such as phase-locking and synchronization in larger networks⁸, the self-organized nonlinear dynamics of entire power grid networks have drawn vast attention among research communities. The collective dynamics of such systems were studied with respect to global asymptotic stability $^{6-9}$, real world statistical properties of fluctuations 10,11 and induced response dynamics¹² up to dynamically induced cascading failures^{13,14}. All of such works have contributed to a conceptual understanding of the stability properties and in particular various types of instabilities in power grid dynamics on the system's level. In one of the most fundamental dynamic models, a power grid network consists of nodes that are synchronous machines modeling electrical motors or generators. A range of models of this class with various degrees of detail have been studied in the literature^{2,15}. A most commonly studied model consists of coupled swing equations, employing the second order model of synchronous machines⁷. Here, the independent variables describing the state of each machine iare given by the deviation of the power angle $\Theta_i(t)$ from an operating point and its time derivative $\dot{\Theta}_i(t)$ quantifying the local deviation from the grid frequency, with a nominal value of $2\pi \times 50$ Hz in Europe and $2\pi \times 60$ Hz in the US^{16} . Grid frequency constitutes an important quantity for grid operators to control the dynamical state of power grids^{1,2}. The second order model of synchronous machines takes the terminal voltage amplitudes E_i to be constant and therefore cannot address any instabilities resulting from the dynamics of voltages. The third order model constitutes the next higher order model and enables a dynamical description of terminal voltage amplitudes^{2,6,9}. In particular, three routes to instability are established in the literature 6,9 for the third order model: one pure rotor angle instability, one pure voltage instability as well as an instability related to the interplay of rotor angle and voltage dynamics. In this work we

differentiate between linear (asymptotic) stability of the voltage subsystem, known as the pure voltage instability in the literature, and alterations of voltage variables upon parameter changes that are not related to a change of the linear stability of the voltage subsystem. We refer to the first one as *voltage instability* or instability of the voltage subsystem, and the latter as *voltage collapse*.

In this article, we demonstrate that the pure voltage instability in the third order model is inconsistent with Kirchhoff's nodal law (also known as Kirchhoff's current law) and thus physically impossible. It emerges as an artifact of extending the parameter regime of the model to nonphysical configurations that violate Kirchhoff's nodal law. Without the constraint of Kirchhoff's nodal law, voltage instability may or may not emerge in the third order model, depending on the choice of system parameters. Employing Gershgorin's circle theorem, we analytically show that the relevant eigenvalues of the local Jacobian stay negative and bounded away from zero if Kirchhoff's law is respected. Thus, instabilities of the voltage subsystem are not captured by the third order model in the regime that is physically relevant. Moreover, we numerically demonstrate that voltage collapse is still observable in the third order model within the physically relevant parameter regime if reactive power demand cannot be met due to limitations in the dynamic transmission capacities.

II. NECESSARY CONDITIONS FOR PURE VOLTAGE INSTABILITIES IN THE THIRD ORDER MODEL

The loss of acceptable voltage levels has been observed in different forms in real world power systems¹. Mathematical models of power systems predict the existence of both, voltage collapse and instabilities and capture transitions from normal operation to dysfunctional states by bifurcations induced by varying parameters across specific critical values.

Let us consider the third-order model, a dynamical systems model of a power grid that consists of N generators and consumers modeled as synchronous machines which are interconnected by alternating current (AC) transmission lines. The third-order model captures three dynamical variables per node i, a phase angle $\Theta_i(t)$, its instantaneous rotation frequency $\omega_i(t) = d\Theta_i/dt(t)$ and a voltage amplitude $E_i(t)$. The dynamics of one synchronous machine i reads^{2,6}

$$\Theta_{i} = \omega_{i}$$

$$\dot{\omega}_{i} = P_{i} - \alpha_{i}\omega_{i} - P_{i}^{\text{el}}(\boldsymbol{\Theta}, \boldsymbol{E}),$$

$$\dot{E}_{i} = E_{i}^{f} - E_{i} + X_{i}I_{i}(\boldsymbol{\Theta}, \boldsymbol{E}).$$
 (1)

where the dot denotes differentiation with respect to time t. Here $\boldsymbol{\Theta} \in \mathbb{R}^N$ denotes the vector of the power angles, $\boldsymbol{\omega} = \dot{\boldsymbol{\Theta}}$ the angular frequency, both with respect to the grid reference frame (rotating at e.g., $\Omega = 2\pi \times 50$ Hz in Europe), and $\boldsymbol{E} \in \mathbb{R}^N_+$ the vector of terminal voltage

amplitudes. Here, \mathbb{R}_+ denotes the set of non-negative real numbers such that each component $E_i \geq 0$. The remaining machine parameters are the power input or output $P_i \in \mathbb{R}$ (negative for consumers and positive for generators), the mechanical damping $\alpha_i > 0$, the voltage set point $E_i^f > 0$, and the reactance $X_i \geq 0$ of the synchronous machine *i*. The coupling functions $P_i^{\text{ell}} : \mathbb{R}^N \times \mathbb{R}^N \to \mathbb{R}$ and $I_i : \mathbb{R}^N \times \mathbb{R}^N \to \mathbb{R}$ represent respectively the electrical powers and the currents exchanged between the *N* synchronous machines through the transmission lines.

An alternating current (AC) transmission line (i, j) between adjacent nodes i and j is modelled by its admittance $Y_{ij} = G_{ij} + iB_{ij} \in \mathbb{C}$, where G_{ij} is the conductance and B_{ij} the susceptance. In general, B_{ij} can be positive or negative. However, Ohm's law for amplitudes, such as E_i , involves the absolute value of the admittances

$$|Y_{ij}| = \sqrt{G_{ij}^2 + B_{ij}^2}.$$
 (2)

For our application it is therefore sufficient to consider the absolute values of the susceptances $|B_{ij}| \ge 0$ and for simplicity we just assume $B_{ij} \ge 0$ for $i \ne j$. Lossless transmission, i.e., neglecting Ohmic losses $(G_{ij} = 0)$, is taken as a reasonable assumption in high voltage power grid modelling², such that the exchanged powers and currents read^{2,9}

$$P_i^{\text{el}}(\boldsymbol{\Theta}, \boldsymbol{E}) = \sum_{j=1}^N B_{ij} E_i E_j \sin(\Theta_i - \Theta_j)$$
$$I_i(\boldsymbol{\Theta}, \boldsymbol{E}) = \sum_{j=1}^N B_{ij} E_j \cos(\Theta_j - \Theta_i).$$
(3)

Here symmetric susceptances $(B_{ij} = B_{ji})$ constitute a symmetric susceptance matrix $B = B^{\mathsf{T}} \in \mathbb{R}^{N \times N}$, with the diagonal elements $B_{ii} < 0$ being self-susceptances. For the moment we describe the self-susceptances B_{ii} in relation to the off-diagonal elements according to

$$B_{ii} = \Gamma_i - \sum_{j=1, j \neq i}^N B_{ij} < 0 \tag{4}$$

with an additional shunt susceptance parameter $\Gamma_i \in \mathbb{R}$. First, we consider the parameters Γ_i as free model parameters and study their implications on the system's stability. Later we will discuss the physically relevant choice of Γ_i . The system Eq. (1) with substituted coupling functions Eq. (3) reads

$$\dot{\Theta}_i = \omega_i$$
 (5a)

λī

$$\dot{\omega}_i = P_i - \alpha_i \omega_i + \sum_{j=1}^N B_{ij} E_i E_j \sin(\Theta_j - \Theta_i)$$
(5b)

$$\dot{E}_i = E_i^f + (X_i \Gamma_i - 1) E_i + X_i \sum_{j=1, j \neq i}^N B_{ij} (E_j \cos(\Theta_j - \Theta_i) - E_i).$$
(5c)

Power grids are operated near an equilibrium state which for the third-order model is a fixed point

$$(\Theta^*, \omega^*, E^*),$$
 (6)

given by a simultaneous solution to Eq. (5a)-(5c) at zero rates of change,

$$\dot{\Theta}_i = \dot{\omega}_i = \dot{E}_i = 0 \text{ for all } i \in \{1, 2, ..., N\}.$$
 (7)

The existence of equilibria depends on the specific choices of the nodal parameters E_i^f, P_i, X_i , the line susceptances B_{ij} and Γ_i . For instance, an equilibrium only exist if the powers P_i are in balance

$$0 = \sum_{i=1}^{N} P_i. \tag{8}$$

Furthermore, from the paradigmatic Kuramoto model¹⁷ it is well known that the coupling strengths have to be sufficiently large to compensate the powers P_i in order to allow the system to settle into an equilibrium. Since for the third order model (5c) the equilibrium coupling strengths

$$K_{ij} \coloneqq B_{ij} E_i^* E_j^* \tag{9}$$

are bound by

$$K_{ij} \le B_{ij} (E_l^f + X_l \mu)^2 \le B_{ij} (E_l^f)^2,$$
 (10)

with the index l denoting the largest equilibrium voltage amplitude $E_l^* \geq E_i^*$ for all $i \in \{1, 2, ..., N\}$ and $\mu \leq 0$, we conclude that E_i^f and the susceptances B_{ij} with $i \neq j$ have to be sufficiently large. Furthermore, the reactances X_i have to be sufficiently small. We derive necessary conditions for the existence of a fixed point in the appendix.

Fixed voltages E_i^* and fixed frequencies ω_i^* are desired in power grid operations, as well as that the system relaxes back to equilibrium when exposed to small perturbations.

Whether the system relaxes back towards the equilibrium, is characterized by the linear stability of the corresponding fixed point of the system¹⁸. At a fixed point (Θ^* , **0**, E^*), the evolution of the linear response (ϑ, ν, ϵ) of the system [(5a)-(5c)] is governed by

$$\begin{pmatrix} \dot{\vartheta} \\ \dot{\nu} \\ \dot{\epsilon} \end{pmatrix} = \begin{pmatrix} 0 & I_N & 0 \\ \Lambda & -\alpha I_N & A \\ A^{\mathsf{T}} & 0 & C \end{pmatrix} \begin{pmatrix} \vartheta \\ \nu \\ \epsilon \end{pmatrix} =: J \begin{pmatrix} \vartheta \\ \nu \\ \epsilon \end{pmatrix}, \quad (11)$$

where $I_N \in \mathbb{R}^{N \times N}$ denotes an identity matrix and $\Lambda, A, C \in \mathbb{R}^{N \times N}$ are submatrices of the Jacobian matrix J. The submatrices are defined via their matrix elements

$$\begin{split} \Lambda_{ij} &= \begin{cases} B_{ij}E_i^*E_j^*\cos(\Theta_j^* - \Theta_i^*) & \text{for } i \neq j \\ -\sum_{k\neq i}B_{ik}E_i^*E_k^*\cos(\Theta_k^* - \Theta_i^*) & \text{for } i = j \end{cases} \\ A_{ij} &= \begin{cases} B_{ij}E_i^*\sin(\Theta_j^* - \Theta_i^*) & \text{for } i \neq j \\ \sum_kB_{ik}E_k^*\sin(\Theta_k^* - \Theta_i^*) & \text{for } i = j \end{cases} \\ C_{ij} &= \begin{cases} X_iB_{ij}\cos(\Theta_j^* - \Theta_i^*) & \text{for } i \neq j \\ X_i\Gamma_i - 1 - X_i\sum_{k\neq i}B_{ik} & \text{for } i = j \end{cases} . \end{split}$$

The matrix J has one eigenvalue $\lambda_0 = 0$ corresponding to the eigenvector $v_0 = (1, 0, 0)^{\mathsf{T}}$, indicating that the system is marginally stable along $v_0^{6,8,9}$. Nevertheless, since a shift along v_0 does not change the physical state of the system, we thus only consider the system's linear stability in the orthogonal space⁶

$$\mathcal{D}^{\perp} = \left\{ \boldsymbol{x} \in \mathbb{R}^{3N} | \boldsymbol{x} \boldsymbol{v}_{0} = 0 \right\}.$$
(13)

As shown by Sharafutdinov et al.⁶, the asymptotic stability of the system in \mathcal{D}^{\perp} (a negative definite J) implies that both submatrices Λ , the rotor angle subsystem, and C, the voltage subsystem, are negative definite themselves, i.e.,

$$J$$
 is negative definite $\Rightarrow \Lambda$ and C are negative definite.
(14)

In this way, three routes to instability in the third order model of synchronous machines are established⁶: One pure rotor angle instability, where Λ loses negative definiteness; one pure voltage instability, where *C* loses negative definiteness; and a third route resulting from an interplay between both subsystems where a fixed point for both voltage and rotor angle equation cannot be determined simultaneously.

In particular, if the real parts of any eigenvalue of either one of the two submatrices C or Λ crosses zero from below (excluding $\lambda_0 = 0$ for Λ), the entire systems' equilibrium becomes linearly unstable. Related earlier work has shown that one condition for Λ to be negative definite is^{2,19}

$$|\Theta_j - \Theta_i| \le \frac{\pi}{2} \tag{15}$$

for all adjacent synchronous machines i and j, i.e., those directly connected by a transmission line. We now focus on the analysis of the voltage subsystem characterized by the matrix C by applying the Gershgorin disk theorem²⁰. The broadly applicable theorem states^{20–24} that for any square matrix $M \in \mathbb{C}^{N \times N}$ all the eigenvalues λ_j^M for all $j \in \{1, 2, ..., N\}$ are in the union

$$\lambda_j^M \in \bigcup_{i=1}^N \mathcal{G}_i,\tag{16}$$

of ${\cal N}$ disks

(12)

$$\mathcal{G}_i \coloneqq \left\{ z \in \mathbb{C} \mid |z - M_{ii}| \le \sum_{j \ne i} |M_{ij}| \right\}.$$
(17)

The diagonal elements M_{ii} define the center of the disk, while the sum across the absolute values of the offdiagonal elements of the same row defines its radius. Since linear stability of the voltage subsystem alone is ensured if all eigenvalues λ_i^C of the matrix C have a negative real part, we evaluate under which conditions all the Gershgorin disks are entirely on the left-hand side of the imaginary axis. To this end, we define the directed margin d_i

$$d_i \coloneqq \sup \left\{ \operatorname{Re}(q) \, | \, q \in \mathcal{G}_i \right\},\tag{18}$$

between the imaginary axis and the Gershgorin disk. A negative margin for all i ensures linear stability of the voltage subsystem characterized by C. Thus, for parameters where all $d_i < 0$, voltage instabilities do not occur. For general setups of the network and machine parame

FIG. 1. Negative margins d_i ensure linear stability of the voltage subsystem: The voltage subsystem of N =2 coupled third-order synchronous machines is evaluated in terms of the margin d_i . The two Gershgorin disks coincide, and the true positions of the eigenvalues are precisely on the borders of the disks. The parameters are $P_1 = -P_2 = 1.5$, $B_{12} = B_{21} = 2$, $E^f = 2$, 1.0 and $\Gamma_1 = \Gamma_2 = 0$.

ters, the margins d_i of the symmetric matrix C satisfy

$$d_{i} = C_{ii} + \sum_{j \neq i}^{N} |C_{ij}|$$

$$= -1 + X_{i}\Gamma_{i} - X_{i} \sum_{j=1, j \neq i}^{N} B_{ij}$$

$$+ X_{i} \sum_{j=1, j \neq i}^{N} |B_{ij} \cos(\Theta_{j}^{*} - \Theta_{i}^{*})|$$

$$= -1 + X_{i}\Gamma_{i} + X_{i} \sum_{j \neq i}^{N} B_{ij}(|\cos(\Theta_{j}^{*} - \Theta_{i}^{*})| - 1)$$

$$\leq -1 + X_{i}\Gamma_{i}.$$
(19)

In the first step, we apply the definition of the Gershgorin disk \mathcal{G}_i to the matrix M = C. In the second step, we

substitute the matrix elements of C according to Eq. (12), exploiting that $X_i > 0$. In the third step, as $B_{ij} > 0$ for $i \neq j$, we factor it out and regroup the terms. Finally, bounding the cosine function by its upper bound $1 = \max\{\cos(x) \mid x \in \mathbb{R}\}$ provides an upper bound for d_i . We set the upper bound $X_i\Gamma_i - 1 = 0$ of d_i and obtain

$$X_{\rm crit}(\Gamma) = \frac{1}{\Gamma},\tag{20}$$

a lower bound for the critical parameter $X_{\rm crit}$ with $\Gamma = \max\{\Gamma_i \mid i \in \{1, 2, ..., N\}\}$. For all $0 \leq X \leq X_{\rm crit}(\Gamma)$ the matrix C is negative definite as shown via the Gershgorin disk theorem. For $X > X_{\rm crit}$ the matrix may have positive eigenvalues $\lambda_i^C > 0$ but due to the upper bound approximation in Eq. (19) this is not guaranteed, hence referred to as potentially unstable region in Fig. 2. For our further analysis, we will rely on the stable regime and do not need further knowledge about the potentially unstable region. We have derived a bound $X_{\rm crit}(\Gamma)$ for, which

$$X < X_{\rm crit}(\Gamma) \iff$$
 voltage stability
 $X \ge X_{\rm crit}(\Gamma) \iff$ potential voltage instability, (21)

holds.

FIG. 2. The minimal stable region of the voltage subsystem depends on the parameter Γ : The matrix of the voltage subsystem is negative definite in the purple region, such that no pure voltage instability occurs here. In particular, for $\Gamma \leq 0$ the voltage subsystem alone is linearly stable for all $X \in \mathbb{R}^+$. This analysis holds for arbitrary system sizes N, parameter settings and thus network topologies.

III. ABSENCE OF PURE VOLTAGE INSTABILITIES

The above analysis proves for $X_i \leq X_{\text{crit}}(\Gamma)$ the linear stability of the voltage subsystem. However, it does not take into account whether fixed points exist in the potentially unstable region at all. Hence, we do not know at this point whether a transition to an unstable voltage subsystem at all is possible or not. For instance, in the simplest system of N = 2 coupled third-order synchronous machines, one can show that all fixed points are found in the stable region of the voltage subsystem for arbitrary choices of Γ . The equilibrium of this system configuration is explicitly given via the set of equations,

$$0 = \omega_1^*$$

$$0 = \omega_2^*$$

$$0 = P_1 - \alpha_1 \omega_1^* + B_{12} E_1^* E_2^* \sin(\Theta_2^* - \Theta_1^*)$$

$$0 = P_2 - \alpha_2 \omega_2^* + B_{12} E_1^* E_2^* \sin(\Theta_1^* - \Theta_2^*)$$

$$0 = E^f - E_1^* + X\Gamma E_1^* + XB_{12}(E_2^* \cos(\Theta_2^* - \Theta_1) - E_1^*)$$

$$0 = E^f - E_2^* + X\Gamma E_2^* + XB_{12}(E_1^* \cos(\Theta_2^* - \Theta_1) - E_2^*),$$

(22)

which effectively reduces to

$$0 = P + B_{12}E^*E^*\sin(\Delta\Theta^*)$$
(23a)

$$0 = E^f - E^* + X\Gamma E^* + XB_{12}(E^*\cos(\Delta\Theta^*) - E^*),$$
(23b)

with $E_1 = E_2 = E^*$ (which follows from subtracting the voltage equations from one another) and $\Delta \Theta^* = \Theta_2^* - \Theta_1^*$. In this configuration, C reads

$$C = \begin{pmatrix} -X(B_{12} - \Gamma) - 1 & XB_{12}\cos(\Delta\Theta) \\ XB_{12}\cos(\Delta\Theta) & -X(B_{12} - \Gamma) - 1 \end{pmatrix}$$
(24)

and has the two real eigenvalues

$$\lambda_{\pm}^{C} = -X(B_{12} - \Gamma) - 1 \pm XB_{12}\cos(\Delta\Theta).$$
 (25)

To investigate where the voltage subsystem changes its linear stability, we analyze the point where its largest eigenvalue $\lambda_{+}^{C} = 0$ such that

$$XB_{12}\cos(\Delta\Theta) = X(B_{12} - \Gamma) + 1.$$
 (26)

We substitute the latter into Eq. (23b) and find

$$0 = E^{f} - E^{*} + X\Gamma E^{*} + E^{*}(XB_{12} - X\Gamma + 1) - XB_{12}E^{*}$$

$$0 = E^{f}.$$
(27)

Given that E^f is a strictly positive machine parameter, we conclude that for N = 2, no transition from a stable equilibrium towards an unstable equilibrium of the voltage subsystem exists, under any configuration of all parameters of the model system. This finding constitutes a contradiction to previously published statements in the literature about an instability of the 2-node third-order model of synchronous machines⁶, where for a positive Γ a transition towards an unstable voltage subsystem has been demonstrated numerically. The estimator $X_{\rm crit}(\Gamma)$ shows no options for pure voltage instabilities for general system configurations if Γ_i for all *i* are set to negative values. But what are physically possible choices for Γ ?

IV. KIRCHHOFF'S NODAL LAW REQUIRES $\Gamma < 0$

In this section we motivate the physically relevant parameter ranges for the shunt susceptances Γ starting with a sample grid and deriving the form of the nodal susceptance matrix based on Kirchhoff's nodal law (also known as Kirchhoff's current law). Let us consider a network of electric transmission lines as depicted in Fig 3. The nodes $i \in \{1, 2, 3\}$, simply intersections of transmission lines, connect the synchronous machines (as indicated by the dashed boxes) with the transmission lines of the power grid. Kirchhoff's nodal law states that the currents flowing into any such intersection nodes have to balance the current flowing out of the node. In other words, charge is a conserved quantity. Kichhoff's nodal law is closely interlinked with a specific choice of the shunt susceptance parameter Γ . For illustration, we apply the current law to the network configuration displayed in Fig. 3. We know, for instance, that the sum across all currents at the node i = 1 has to be zero

$$0 = \tilde{I}_1 + \tilde{I}_{21} + \tilde{I}_{31} + \tilde{I}_{1a} + \tilde{I}_{1b}, \qquad (28)$$

with the current \tilde{I}_1 to be the one flowing into the synchronous machine 1 indicated by the left dashed box in Fig. 3. The currents \tilde{I}_{xy} refer to the currents flowing across the susceptance B_{xy} . The tilde $\tilde{\cdot}$ indicates that the quantity is described in the grid reference frame rather than in the reference frame of the synchronous machine. Essentially, voltages on two perpendicular rotor axes (of which one is assumed to be identically zero in the third order model) of the synchronous machine are rotated by the power angle Θ_i to the grid reference frame. More details are provided in, e.g., Schmietendorf et al.⁹. In order to compute the current, \tilde{I}_1 we resolve Eq. (28) and obtain

$$\tilde{I}_1 = -\tilde{I}_{21} - \tilde{I}_{31} - \tilde{I}_{1a} - \tilde{I}_{1b}.$$
(29)

Furthermore, applying Ohm's law $I = B\Delta E$ to both lines, we find

$$\tilde{I}_1 = B_{12}(\tilde{E}_2 - \tilde{E}_1) + B_{13}(\tilde{E}_3 - \tilde{E}_1) - B_{1a}\tilde{E}_1 - B_{1b}\tilde{E}_1,$$
(30)

where we set the ground node's voltage amplitude to zero, $E_0 = 0$. We can write Eq. (30) in vector form and find

$$\tilde{I}_{1} = \begin{pmatrix} -B_{12} - B_{13} - B_{1a} - B_{1b} & B_{12} & B_{13} \end{pmatrix} \begin{pmatrix} \dot{E}_{1} \\ \tilde{E}_{2} \\ \tilde{E}_{3} \end{pmatrix}$$
(31)

This is the first component of the generalized Ohm's law for the network in Fig. 3 that in general reads

$$\tilde{I} = B\tilde{E},\tag{32}$$

with the susceptance matrix $B \in \mathbb{R}^{3 \times 3}$, from which we identify the first diagonal element

$$B_{11} = -B_{12} - B_{13} - B_{1\alpha} - B_{1\beta}.$$
 (33)

We thereby identify the parameter Γ_1 for this system

$$\Gamma_1 = -B_{1b} - B_{1a} \le 0. \tag{34}$$

This generalizes to the overall form Eq. (4) for the self susceptance

$$B_{ii} = \Gamma_i - \sum_{j \neq i} B_{ij}, \qquad (35)$$

for arbitrary network topologies with the shunt susceptance $\Gamma_i \leq 0$ corresponding to the negative of the line susceptances connecting the node to the ground node. According to the upper bound of d_i in Eq. (19) visualized in Fig. 2, a negative shunt susceptance Γ automatically ensures linear stability of the voltage subsystem. We thus showed that the voltage subsystem at an equilibrium is **always** asymptotically stable if the parameters, in particular the shunt susceptance Γ_i , reflect Kirchhoff's nodal law.

FIG. 3. Sample grid to explain the properties of the nodal susceptance matrix B: The sample grid consists of three interconnected machines. The variables \tilde{E}_i stand for the voltage at the respective node. The variables \tilde{I}_i represent the current that flows from each node to the attached dashed box.

By setting the shunt susceptance $\Gamma_i > 0$ in recent literature^{6,9} linearly unstable voltage subsystems were uncovered, which have to be considered nonphysical as violating Kirchhoff's nodal law.

V. VOLTAGE COLLAPSE IN THIRD ORDER SYNCHRONOUS MACHINE DYNAMICS.

FIG. 4. Voltage collapse without pure voltage insta**bility.** (a) Equilibrium voltage amplitude E^* changes with the reactive power P in a N = 2 node system. The system exhibits two relatively large voltage equilibria, one stable (solid line) and one unstable (dashed line) that annihilate in a saddle-node bifurcation (near P = 2.5), beyond which no real solution for Eq. (23a,23b) exists. (b) Consistently negative eigenvalues indicate that the voltage subsystem is linearly stable for the whole range of P and the stable and unstable branch of the entire third order dynamics where the fixed point exists. (c,d) Time evolution of the voltage amplitude E(t) upon temporally changing power P(t). At t = 10, the power demand P increases (instantaneously) from 2.25 to 3, overloading the line in the current equilibrium. As a consequence, the voltage amplitudes of the system drop substantially, a phenomenon known as voltage collapse^{2,3}. Even after lowering P again all the way to 2 at t = 30, the voltage amplitudes remain low. Only sufficiently small P allow the system to relax back to the stable equilibrium as shown for t > 70 where the power P = 0.1. Network parameters are $\Gamma_1 = \Gamma_2 = 0, B_{12} = B_{21} = 2, X = 1.0, \alpha = 0.1$ and $E^f = 2$.

Despite the fact that the physical third-order model

of synchronous machines does not exhibit pure voltage instabilities, i.e., linearly unstable voltage subsystems, we emphasize that it still captures the phenomenon of voltage collapse, i.e., substantial voltage changes upon parameter changes. Voltage collapse has been discussed as one of the root causes of various real world power $outages^{2,3}$. In this section, we illustrate numerically that the third order model of synchronous machines has the capability to undergo voltage collapse. The underlying cause, instead of a linear instability of the voltage subsystem, is a saddle-node bifurcation at which the existence of two equilibria is lost, including the stable one. The saddle-node bifurcation occurs when transmission line capacities at the respective voltage levels are not sufficient to meet the power demand P of the consumer. We investigate this (see Figure 4) for a simple system of N = 2nodes and one transmission line, as in section II.

Figure 4 displays the loss of existence of two equilibria upon parameter changes of the reactive power P and a possible way of restoring higher voltage levels. Beyond the critical value of the power $P_{\text{max}} = B_{12}(E^*)^2$, see Eq. (23a) where P_{max} has to compensate for the power Pthat needs to be transported across a transmission line, the stable equilibrium is lost and the third order dynamics causes the voltage amplitudes to drop significantly. The third order model thus captures the phenomenon of voltage collapse. However, the root cause is not the loss of the stability of the voltage subsystem but a power overload of the transmission line and the related loss of equilibria. Even at P below the previously valid critical value of the power P_{max} , the system does *not* relax back to the stable equilibrium. Significantly smaller power values $P < B_{12}(E(t))^2$ are needed to stabilize the power transmission. See Figure 4 for details of the example.

VI. CONCLUSION

In this article we have analyzed the possibility of pure voltage instabilities in the third order model and explained why, due to violating Kirchhoff's nodal law, they cannot occur at physically consistent parameters. These findings contrast previously published work^{6,9} that, however, correctly derived necessary conditions for and numerically exemplified linear stability. Interestingly, real world power outages have indeed been tied to effects described as voltage instabilities. However, this terminology referred to voltage drops^{1,2}, which we have observed numerically in the third order model upon changes of parameters without changes in stability of any operating state. The power overload of transmission lines is the root cause for the voltage collapse. We thus emphasize that the term voltage collapse is to be carefully separated from the term voltage instability, which relies on the linear stability of the voltage subsystem. These two phenomena are mathematically not connected. Another class of power system models, given by algebraic differential equations, were studied extensively in the

literature^{4,5} in terms of voltage collapse. The fundamental difference of that model class is that consumers are assumed to have fixed power angles, Θ as well as fixed reactive and active power demand. Thus, they represent algebraic constraints to the dynamics of the generators. In such a setup, linearly stable, low voltage equilibria may be identified. It is particularly difficult to operate a system that is trapped at such an equilibrium, and bring it back to a high voltage fixed state^{4,5}. A detailed analysis of a three bus system is given in²⁵. In contrast to the third order model of power grids, these extended models exhibit changes of local stability properties upon parameter changes.

For the third order model, it is sufficient to ensure that line capacity constraints are satisfied to ensure stable, high voltage operation. Given the results presented above, two research paths open up to further study voltage stability properties in power system models. First, one could factor in Ohmic losses, i.e., $G_{ij} > 0$ and analyze whether local stability properties of the voltage subsystem undergo a bifurcation. Second, one could investigate non-local stability properties in the third order model by numerically analyzing basin stability²⁶ for voltage and rotor angle perturbations. The basin size may depend strongly on the line load. Furthermore, it would be of interest to extend the basin stability argument to the extended model of differential algebraic equations^{4,5}.

VII. ACKNOWLEDGEMENTS

We thank Malte Schröder and Philip Marszal for valuable comments on the manuscript. We gratefully acknowledge support the Bundesministerium für Bildung und Forschung (BMBF, Federal Ministry of Education and Research) under Grant. No. 03EK3055F.

VIII. CONFLICT OF INTEREST

The authors have no conflicts to disclose.

IX. APPENDIX

Here we motivate our statement in the main text about parameter configurations under which fixed points of Eq. (4a)-(4c), i.e., points where $\dot{\Theta}_i = \dot{\omega}_i = \dot{E}_i = 0$ for all *i*, exist.

Corollary 1 The powers P_i across the network of third order synchronous machines have to be in balance

$$0 = \sum_{i=1}^{N} P_i,$$
 (36)

to allow the entire system to settle to an equilibrium.

a. Proof: To show that such balance is a necessary condition for the existence of a fixed point, we take the sum over all N nodes^{2,6} of the rotor angle equation Eq. (4b), yielding

$$0 = \sum_{i=1}^{N} (P_i - \alpha_i \omega_i^*) + \sum_{i=1}^{N} \sum_{j=1}^{N} B_{ij} E_i^* E_j^* \sin(\Theta_j^* - \Theta_i^*).$$
(37)

The sine functions are antisymmetric, while B is symmetric against an exchange of indices such that the double sum equals zero. Furthermore, Eq. (4a) implies that $\omega_i^* = 0$ for all i and therefore

$$0 = \sum_{i=1}^{N} P_i.$$
 (38)

The second assertion is that the voltage set points E_i^f have to be sufficiently large for a fixed point to exist. We identify the effective coupling strengths K_{ij} in Eq. (4b)

$$K_{ij} = B_{ij} E_i^* E_j^*. (39)$$

From the paradigmatic Kuramoto model¹⁷ it is known that the coupling strength needs to be sufficiently large in order to compensate the parameters P_i for all *i* to allow the system to settle in a phase locked state. Due to the first condition, Eq. (36) a phase locked state is also an equilibrium.

Corollary 2 The equilibrium coupling strength $K_{ij} = B_{ij}E_i^*E_j^*$ of the rotor angle dynamics is bound by

$$K_{ij} \le B_{ij} (E^f + X_i \mu)^2 \le B_{ij} (E^f)^2,$$
 (40)

with $\mu \leq 0$ for networks of N third order synchronous machines with $E_i^f = E^f$ for all $i \in \{1, 2, ..., N\}$.

b. Proof: We prove that relation Eq. (40) holds for every synchronous machine individually. We assume an

equilibrium of the entire system $\Theta^* \in \mathbb{R}^N, E^* \in \mathbb{R}^N$ exists. We exploit the following properties

$$E_i^f = E^f > 0$$

$$E_i^* > 0$$

$$X_i > 0$$

$$B_{ij} \ge 0$$

$$\Gamma_i \le 0$$

$$\cos(x) \le 1 \text{ for all } x \in \mathbb{R}$$
(41)

for all $i \in \{1, 2, ..., N\}$. Among the finite number of equilibrium voltage amplitudes, E_i^* we pick the largest E_i^* such that for all $j \neq i$

$$E_i^* \ge E_j^* \tag{42}$$

holds. For the synchronous machine i the voltage amplitude equilibrium defining equations reads

$$0 = E^{f} + (X_{i}\Gamma_{i} - 1)E_{i}^{*} + X_{i}\sum_{j=1, j\neq i}^{N} B_{ij}(E_{j}^{*}\cos(\Theta_{j}^{*} - \Theta_{i}^{*}) - E_{i}^{*}).$$
(43)

We exploit that B_{ij} , E_j^* , X_i are nonnegativ, as well as the upper bound of $\cos(x)$ to evaluate

$$0 \leq E^{f} + (X_{i}\Gamma_{i} - 1)E_{i}^{*} + X_{i}\sum_{j=1, j\neq i}^{N} B_{ij}(E_{j}^{*} - E_{i}^{*})$$

= $E^{f} + (X_{i}\Gamma_{i} - 1)E_{i}^{*} + X_{i}\mu$ (44)

with $\mu \leq 0$ due to the fact that we have chosen the largest voltage amplitude E_i^* . We conclude

$$0 \leq E^{f} + (X_{i}\Gamma_{i} - 1)E_{i}^{*} + X_{i}\mu$$

$$\leq E^{f} + (X_{i}\Gamma_{i} - 1)E_{i}^{*}$$

$$\leq E^{f} - E_{i}^{*}$$
(45)

by exploiting that $\Gamma_i X_i \leq 0$. The latter is equivalent to

$$E_i^* \le E^f, \tag{46}$$

and as $E_i^* \ge E_j^*$ for all $j \in \{1, 2, ..., N\}$ we have shown that relation Eq. (46) holds for all $i \in \{1, 2, ..., N\}$. The coupling strength K_{ij} is bounded by

$$K_{ij} = B_{ij} E_i^* E_j^* \le B_{ij} (E^f)^2.$$
 (47)

From this, we conclude that the parameter E^f has to be set sufficiently large in order to provide sufficient coupling strength for the system to settle into an equilibrium. Furthermore, we show that X_i has to be sufficiently small to guarantee the existence of an equilibrium. For this we start with Eq. (45)

$$0 \leq E^{f} + (X_{i}\Gamma_{i} - 1)E_{i}^{*} + X_{i}\mu$$

$$\leq E^{f} - E_{i}^{*} + X_{i}\mu \qquad (48)$$

which is equivalent to

$$E_i^* \le E^f + X_i \mu \tag{49}$$

with negative μ as E_i^* is again the largest voltage amplitude in the network. Increasing X_i thus lowers the upper bound for the largest voltage amplitude and the upper bound for all coupling strengths K_{ij} can be refined to

$$K_{ij} = B_{ij} E_i^* E_j^* \le B_{ij} (E^f + X_i \mu)^2$$
 (50)
