Dirac-Source Diode with Sub-unity Ideality Factor

Gyuho Myeong^{1†}, Wongil Shin^{1†}, Seungho Kim¹, Hongsik Lim¹, Boram Kim¹, Taehyeok Jin¹, Kyunghwan Sung¹, Jihoon Park¹, Michael S. Fuhrer², Kenji Watanabe³, Takashi Taniguchi³, Fei Liu^{4**}, Sungjae Cho^{1*}

An increase in power consumption necessitates a low-power circuit technology to extend Moore's law. Low-power transistors, such as tunnel field-effect transistors (TFETs)¹⁻⁵, negative-capacitance field-effect transistors (NC-FETs)⁶, and Dirac-source field-effect transistors (DS-FETs)⁷⁻¹⁰, have been realised to break the thermionic limit of the subthreshold swing (SS). However, a low-power diode rectifier, which breaks the thermionic limit of an ideality factor (η) of 1 at room temperature, has not been proposed yet. In this study, we have realised a DS Schottky diode, which exhibits a steep-slope characteristic curve, by utilising the linear density of states (DOSs) of graphene⁷. For the developed DS Schottky diode, $\eta < 1$ for more than two decades of drain current with a minimum value of 0.8, and the rectifying ratio is large (> 10⁵). The realisation of a DS Schottky diode paves the way for the development of low-power electronic circuits.

Power consumption of integrated digital devices sets the ultimate limit to downscaling and Moore's Law¹¹. Reducing power consumption has been thwarted by fundamental limits on the operating voltage set by thermionic emission¹². For an ideal thermionic device the dependence of current *I* on voltage *V* is expressed through the subthreshold swing $SS = [dlog(I)/dV]^{-1} = (k_BT/q)log(10) \approx 60 \text{ mV/dec}$ at room temperature, where k_BT is the thermal energy and q is the elemental charge.

Two-dimensional (2D) van der Waals (vdW) materials^{13,14} have been proposed for various schemes to overcome the thermionic limit (SS = 60 mV/dec) of metal-oxide semiconductor field-effect transistors (MOSFETs) in nonconventional transistors such as TFETs, NC-FETs, and DS-FETs¹⁻¹⁰. In particular, DS-FETs use the linear energy dispersion relationship of graphene, producing a super-exponential change in the DOS with energy¹⁵. As a result, DS-FETs have achieved a smaller SS than that of a MOSFET, with a large drive current⁷⁻¹⁰.

Integration of heterogeneous electronic components on a single low power-consumption platform is highly desirable to enable application such as the Internet of Things. Schottky diodes are important electronic components with low operation voltage and high current¹⁶, and have many useful applications such as rectifiers, mixers, selectors, switches, photo detectors and solar cells¹⁶. Although there has been considerable development of low-power transistors, steep slope diode (or diode) rectifiers that overcome the thermionic limit ($\eta < 1$) of conventional diodes have not been proposed yet, but will be necessary for device integration with low-power transistors. Herein, we propose a DS Schottky diode as an essential element for low-power circuits. The DS injects cold electrons without a long thermal tail above the potential barrier in the channel (Fig S1). Our proposed DS Schottky diode consists of a graphene/MoS₂/graphite heterojunction, where graphene acts as a cold electron injector, whereas the graphite/MoS₂ interface provides a Schottky barrier for rectification. The MoS₂ channel was chosen because of its high-gate tunability and mobility¹⁷. The minimum and average values of η for the DS Schottky diode are 0.76 and less than 1 over more than two decades of current at room temperature, respectively, with a high rectifying ratio (> 10⁵).

The proposed DS Schottky diode device (Fig. 1a) consists of four components: (i) an n-type monolayer MoS₂ channel, (ii) a graphene DS neutral at a zero gate-voltage, (iii) a graphite drain-contact to form a Schottky barrier between the graphite and monolayer MoS₂ for electrical rectification with a bias voltage, and (iv) metal (back and top) gate electrodes to tune the Fermi levels of 2D materials. Two-dimensional van der Waals epitaxy was performed inside an Ar-filled glovebox until the heterostructure was encapsulated by hexagonal boron nitride (hBN) to avoid any contamination through air exposure or chemicals (Fig. S2). Unlike a metal contact, a graphite contact with the monolayer MoS₂ forms a non-reactive clean interface¹⁸, preventing Fermi-level pinning¹⁹ (Fig. S3 and Fig. S4). The diode has a local top-gate and a global back-gate. The top gate only modulates the channel of the monolayer MoS₂ band, whereas the global back gate affects the graphene/MoS₂/graphite heterostructure. The gate-dependent electrical measurements (Fig. S5) indicate that the Dirac point of hBN-encapsulated graphene not on MoS₂ is located at $V_{BG} \approx -18$ V because of the n-doping caused by the monolayer MoS₂²⁰.

Fig. 1b presents the characteristic drain current (I_D) versus bias voltage (V_{bias}) curve for the DS Schottky diode at $V_{BG} = -30$ V. At $V_{BG} = -30$ V, the G1 and G2 regions of graphene are p-type. When a bias voltage is applied to the graphene, electrons are injected from the p-type graphene source to the graphite drain. The electrical measurements reveal a nearly Ohmic graphene/MoS₂ contact and a Schottky barrier of the graphite/MoS₂ contact (Fig. S6). When a negative back-gate voltage is applied, the Schottky barrier height increases, and the device current is mainly modulated by the Schottky barrier at the interface between the graphite and monolayer MoS₂.

The performance of a Schottky diode is mainly characterised by two figures of merit. One is the rectifying ratio, which refers to the ratio between the on and off currents ($R = \frac{I_{on}}{I_{off}}$), whereas the other is η , which is the slope representing the change in drain current with a bias voltage and can be obtained from the

following Schottky diode equation:

$$I_{\rm D} = I_{\rm S} \left(1 - e^{qV_{\rm bias}/\eta k_{\rm B}T} \right),\tag{1}$$

where q is the elementary charge, V_{bias} is the applied bias voltage, η is the ideality factor, k_B is the Boltzmann constant, T is the temperature, and I_D and I_S are the drain and leakage currents, respectively. Eqn (1) corresponds to SS = $(\eta k_B T/e)\log(10)$ hence values $\eta < 1$ correspond to SS below the thermionic limit. The characteristic curve at a negative gate voltage in Fig. 1b exhibits rectification behaviour with $\eta < 1$ observed over more than two decades of drain current, a minimum η of 0.76, and a large rectifying ratio (> 10⁵).

To explore the switching mechanism of DS Schottky diode, we developed analytical formula for ideality factor and performed numerical device simulations (See supplementary materials 7). Both the two methods show that the ideality factor less than 1 is obtained in DS diode due to the linear density of states of graphene. The switching slope of a diode is determined by the energy-dependent current density injected from an electrode, which is related to DOS and the distribution function. Graphene has a linear energy-dependent electronic DOS near the Dirac point, which is different from conventional metals with a constant DOS around the Fermi level. Therefore, the thermal tail of the Boltzmann distribution function is suppressed by the Dirac point tuned to the off-state region by doping. Namely, as the bias voltage is decreased on the graphene electrode as shown in Fig. 1c, the part of current density related to the distribution function is increased exponentially similar as conventional metals, which results in the ideal factor limit of 1. While, the injected DOS over the top of channel barrier is also increased linearly from off-state to on-state, as shown in Fig. 1c. Therefore, current is increased super-exponentially and the ideal factor below 1 is obtained in the diode with graphene electrode as the injection source.

Therefore, the switching slope of a diode, i.e., $\eta < 1$, is obtained in the diode with a graphene electrode as the cold electron injection source because of the linear DOS of the DS. Detailed simulation results are presented in Fig. S7. Quantum transport simulations show that DS diode has promising device performance. The ideality factor as small as 0.69 is obtained in the simulated DS diode and is less in 1 in more than five decades of current at room temperature.

The on-state current is larger than $10^3 \,\mu A/\mu m$ and the rectifying ratio is over 10^7 .

Fig. 2a presents the I_D-V_{bias} characteristic curve of the DS Schottky diode at different back-gate voltages. For the proposed DS Schottky diode to work as a diode, an asymmetric Schottky barrier height between the source and drain is necessary²¹⁻²⁴. To satisfy this condition, we placed asymmetric graphene and graphite contacts with the monolayer MoS₂ channel with gates. Without gate modulation, graphene has a work function of 4.3–4.7 eV from a monolayer to a few layers²⁵⁻²⁷. Because the work function of graphene (~4.3 eV) does not differ significantly from the electron affinity of MoS₂ (~4.2 eV)²⁸⁻³¹, the Schottky barrier height at the graphene/MoS₂ interface is negligible, compared to the Schottky barrier height at the graphite/MoS₂ interface that the Dirac point of pristine graphene is located near the conduction band edge of MoS₂. Fig. S6 indicates that the graphene/MoS₂ device shows an almost Ohmic IV curve, whereas graphite/MoS₂ does not show an Ohmic IV curve at room temperature. Fig. 2a shows that as the gate voltage

decreases, the rectification behaviour becomes dominant at negative gate voltages. As the back-gate voltage exceeds $V_{BG} > 0$, non-diode I_D - V_{bias} characteristic curves appear.

To clarify the origin of the gate-dependent modulation of the I_D -V_{bias} characteristic curves, we measured the modulation of the Schottky barrier height with back-gate voltages from the activation energy in the reverse bias regime. The Schottky diode equation (Eq. 1) can be rewritten as

$$I_D = AA^* T^{\alpha} e^{-q\Phi_B/k_B T} \left(1 - e^{\frac{qV_{bias}}{\eta k_B T}}\right), \quad (2)$$

where *A* is the area of the Schottky junction, A^* is the Richardson constant, $\alpha = 3/2$ is an exponent for a twodimensional semiconducting system³², k_B is the Boltzmann constant, q is the elementary charge, T is the temperature, and Φ_B is the Schottky barrier height. When a large negative bias in absolute value is applied, i.e., $e^{qV_{bias}/k_BT} \approx 0$, the saturated drain current is proportional to $T^{3/2}e^{-q\Phi_B/k_BT}$. The inset of Fig. S4a shows a plot of $\ln(I_{sat}/T^{3/2})$ versus $1/k_BT$ in the reverse bias saturation regime ($V_{bias} = +1 V$). We extract Φ_B for a given V_{BG} from the slope of each curve. Fig. S4a shows the Schottky barrier height obtained from the slope of each curve in the inset of Fig. S4a. As shown in Fig. S4b, in the highly positive V_{BG} regime, the device shows an almost linear I_D - V_{bias} curve, exhibiting nearly Ohmic contact behaviour (negligible Schottky barriers on both sides of the contacts, graphene and graphite with MoS₂). The adjustable Schottky barrier height with gate voltage indicates that Fermi-level pinning does not exist at the interface between graphite and monolayer MoS₂. This absence of Fermi-level pinning is owing to the defect- and disorder-free interface between twodimensional materials, graphite and monolayer MoS₂^{18,19}.

To prove that the proposed diode is operated via cold carrier injection from a graphene DS at negative back-gate voltages, we measured the SS to determine if it showed sub-thermionic values. Fig. S8a shows the characteristic I_D versus top-gate voltage (V_{TG}) transfer curve under the working conditions of the DS-FET, i.e., $V_{BG} < -18$ V, where both the G1 and G2 regions of graphene are p-type. When we apply $V_{BG} = -20$ V, graphene regions G1 and G2 become heavy and slightly p-type, respectively. When the top gate placed on the MoS₂ channel is swept from the off state to the on state, the DOS of the graphene increases according to the band diagram presented in Fig. S8c, thereby operating as a DS-FET. As shown in Fig. S8b, the SS value of the device is less than 60 mV/dec, which indicates that the proposed diode acts as a DS-FET owing to the linear energy dispersion relationship of the graphene-source electrode, resulting in a super-exponential change in the DOS. Both DS-FET and DS Schottky diode have the same origin for SS < 60 mV/dec and $\eta < 1$. Fig. 3 shows the I_D-V_{bias} characteristic curve in the steep-slope diode regime at V_{BG} = -15, -30, and -45 V, where the graphene is p-doped. At V_{BG} = -15 V, region G1 is p-type and region G2 is slightly n-type doped. However, as the negative bias voltage is applied, the top of the Schottky barrier is located at a valence band of graphene region G2. At V_{BG} < -15 V, both regions G1 and G2 are p-type. In all the regimes at V_{BG} = -15,

-30, and -45 V, where the top of the Schottky barrier is located below the Dirac point of graphene regions G1 and G2, η of the device is less than 1 in more than two decades of current owing to the cold charge injection from the DS at a forward bias (V_{bias} < 0). The minimum η that we measured in one decade of current is 0.76.

The red dotted line in Fig. 3 is an ideal diode curve ($\eta = 1$) in the forward bias direction. The DS diodes in these gate-voltage regions show rectification ratios exceeding 10⁵ at V_{BG} = -15 V (more than 10⁴ when V_{BG} = -30 V and more than 10³ when V_{BG} = -45 V). We note that the device leakage current level is limited by the leakage currents (~ 50 pA) from the measurement equipment (Fig. S9b). Therefore, the reverse bias leakage current level from the diode should be lower than the measured values.

In conclusion, we successfully demonstrated the first DS Schottky diode that operates based on cold charge injection from a graphene source owing to the linear DOS and a Schottky barrier at the interface between graphite and monolayer MoS₂. As the linear DOS of the injected charges from p-type graphene over the top of the Schottky barrier between graphite and n-type monolayer MoS₂ increases linearly from reverse to forward bias, an ideal factor below 1 is obtained in the diode with a graphene electrode as the injection source. Using gate modulation of the Schottky barrier height of the graphite/MoS₂ junction, gradual switching between the diode and non-diode behaviours was also observed. The fabricated DS Schottky diode presents a minimum η as low as 0.76 in one decade of current, and it remains less than 1 for more than two decades of current at room temperature, with a high rectifying ratio exceeding 10⁵. Additionally, the device shows SS < 60 mV/dec for the same origin as that for $\eta < 1$. The realisation of a steep-slope DS Schottky diode paves the way for the development of low-power circuit elements and energy-efficient circuit technology.

Methods

Device fabrication

We first prepared monolayer MoS₂, graphene, graphite, and hBN flakes on a 90 nm Si/SiO₂ wafer via mechanical exfoliation from bulk crystals in an Ar-filled glove box (< 0.1 ppm of H₂O and O₂) to maintain clean surfaces and prevent contamination from air exposure. Monolayer MoS₂ and graphene were identified using the optical contrast and Raman spectroscopy. Each piece was picked up using a standard dry transfer method with a polydimethylsiloxane (PDMS) stamp covered with a polycarbonate (PC) film and transferred onto a 285-nm wafer. The PC film was washed with chloroform, acetone, and isopropyl alcohol (IPA). Then, standard e-beam lithography and CF₄/O₂ plasma etching, followed by e-beam deposition, were used to place electrical contacts on the vdW layers. Additional e-beam lithography and deposition were performed to place the gate electrode (Fig. S2).

Measurement

To obtain a transfer curve, we performed DC measurements from room temperature to high temperatures in a home-built measurement vacuum chamber. Yokogawa 7651 and Keithley 2400 were used to bias the DC voltages to the source and gate electrodes. A DDPCA-300 preamplifier was used to amplify the drain current $(\times 10^6)$ and convert it to a voltage, and this signal was measured using a Keithley 2182a nanovoltmeter (Fig. S9a).

Figure 1. a Schematic image of graphene/MoS₂/graphite heterojunction diode. We used graphene as a source and graphite as a drain. The graphene source can be divided into two regions, G1, which is outside MoS₂, and G2, which is on MoS₂. **b** Characteristic I_D-V_{bias} curve in our device, which exhibits $\eta = 0.76$ in 1 decade of current and an average $\eta < 1$ in more than two decades of current. The rectifying ratio of our device is larger than 10^5 . **c** Band diagram of DS Schottky diode, which explains the working principle of cold electron injection from graphene.

Figure 2. Characteristic I_D-V_{bias} curve for various V_{BG} and its band diagram. a Characteristic I_D-V_{bias} curve in the range of $V_{BG} = -45 \sim +45$ V. As V_{BG} decreases, change from non-diode to diode behaviour is observed. b Band diagram when V_{BG} < 0 (diode regime). Owing to the larger work function of graphite than that of graphene, the device becomes a graphite/MoS₂-interface Schottky barrier-dominant Schottky diode. c Band diagram when V_{BG} > 0 (non-diode regime). Owing to the weak Fermi-level pinning between the 2D metal and MoS₂, the Schottky barrier height of the graphite/MoS₂ interface can be modulated. As V_{BG} increases, the work function of graphite decreases, and the Schottky barrier height of the graphite/MoS₂ interface decreases.

Figure 3. Slopes of DS Schottky diode versus ideal diode and recorded ideality factor in 2D vdW material-based diode. Comparison of slopes between the proposed DS Schottky diode and an ideal diode. Black and red dotted data represent those of the DS Schottky diode and an ideal diode, respectively. The DS Schottky diode exhibits an average η of 1 for 2.2, 2.6, and 2.5 decades when $V_{BG} = -15$, -30, and -45 V, respectively.

Supplementary Texts

1. Electron density distribution of normal metallic and Dirac sources

The continuous density of states (DOS) of a normal metallic source exhibits the Boltzmann distributed electron density given by $n(E) \approx \exp((E_F - E)/k_BT)$. For a Dirac source, the linearly varied DOS produces a super-exponentially decreasing electron density (given by $n(E) \approx (E_{Dirac} - E) \exp((E_F - E)/k_BT))$ with decreasing energy. Fig. S1 compares the electron densities of the normal metallic and Dirac sources. The green dotted curve in Fig. S1(b) indicates the electron density of the normal metallic source to facilitate its comparison against that of the Dirac source.

2. Device Fabrication

Fig. S2 illustrates the fabrication of the Dirac-source (DS) Schottky triode. As can be seen, the first step involves the preparation of a polydimethylsiloxane (PDMS) stamp covered with a polycarbonate (PC) film on a glass slide. Subsequently, MoS₂ flakes are mechanically exfoliated on a Si/SiO₂ wafer. In this study, the MoS₂ exfoliation was performed in an Ar-filled glove box to prevent contamination. Using the standard drytransfer method, each flake is picked up in the order—top hexagonal boron nitride (hBN), graphite, graphene, MoS₂, and bottom hBN. After fabrication of the PC film and confirming sufficient adherence of the prepared flakes, the wafer was slowly heated to 90 °C, during which time, the slide glass is slowly raised. During the pick-up process, owing to the large area of the top hBN, graphene, graphite, and MoS₂ do not directly touch the PC film. After fabrication of the heterostructure on the PC film, the latter is slowly placed onto a prepared 285-nm-thick Si/SiO₂ wafer. Subsequently, the wafer is heated to 180 °C, thereby melting the PC film. Thereafter, the PC film is successively washed using chloroform, acetone, and isopropyl alcohol (IPA). After transfer of the heterojunction to a new wafer, the device is exposed to chemicals to erase the released PC film. However, graphene, graphite, and MoS₂ layers are encapsulated within large areas of the top and bottom hBN layers, which the chemicals cannot percolate. After fabricating the heterostructure on a 285-nm Si/SiO₂ wafer, the standard e-beam lithography and plasma etching procedures are performed via e-beam deposition (Cr/Au= 5/60 nm) to place electrical contacts in the graphene and graphite layers. The hBN and graphite layers are etched using CF₄/O₂ and Ar/O₂, respectively. Additional e-beam lithography and deposition processes are performed to facilitate top-gate placement.

3. Contact quality between normal and two-dimensional (2D) metals

With regard to the fabrication of electronic devices using transition metal dichalcogenides (TMD) materials, several recent studies have reported the improvement of the metal-semiconductor interface as a means for enhancing device performance. For example, the use of the 2D-semimetal, pre-patterned metal contacts, as well as the method of releasing evaporated metal on a TMD substrate have been suggested as ways to improve the metal-semiconductor interface¹⁻³. These methods are intended to prevent the damage caused to the TMD material during the direct metal deposition. Fig. S3 illustrates the schematic process of establishing the metal-evaporation and 2D-metal contacts. The metal-deposition process comprises three steps: (1) coating polymethyl methacrylate (PMMA) resist, pattern lithography and development, (2) metal deposition, and (3) lift-off. Each step is influenced by a factor that limits the realizable contact and device quality. During lithography pattern development, the region of metal deposition is exposed to various chemicals (resistive coating, developer, and stopper) and air. During metal deposition, hot metal vapor adheres to the contact region, thereby causing structural deformations within the TMD material¹. During lift-off, the channel region of the device is exposed to a solvent. Thus, electronic devices fabricated using direct metal deposition are subjected to the occurrence of chemical contamination and structural deformation in both the metal-contact and channel regions. This severely impacts the device performance. Contrastingly, in devices that incorporate 2D van der Waals (vdW) metal contacts, it is possible to maintain an ultraclean interface between the TMD material and metal.

4. Schottky barrier measurement

Owing to the weak Fermi-level pinning between the 2D metal and MoS_2^4 , the Schottky barrier height can be altered by modifying the applied gate voltage. Fig. S4(a) depicts the measured Schottky barrier heights. Owing to limitations of the measurement system used in this study, measurements could only be performed in the voltage range of $V_{BG} = -12$ V to 16 V. At the positive end of the applied V_{BG} values, the proposed device exhibits a linear I–V characteristic, thereby indicating a near-Ohmic contact. Accordingly, an increase in V_{BG} causes a reduction in the graphite and graphene work functions⁵. This decreases the Schottky barrier heights of the graphene–MoS₂ and graphite–MoS₂ interfaces.

5. Electron doping of graphene on MoS₂

A previous study has explained the doping mechanism of graphene on MoS_2^6 . The placement of graphene on n-type MoS_2 , causes the former's Fermi level to become n-doped. To estimate the Fermi level of the G2

graphene region, we performed appropriate measurements over several layers. Figs. S5(a) and S5(b) depict the actual image and schematic of the test device, which was fabricated by aligning MoS₂ and graphene such that they overlapped. Therefore, the resulting transfer curves differ when measurements are performed on the "graphene side" and "across MoS₂." Figs. S5(c) and S5(d) reveal that when measurements are performed on the "graphene side," graphene exhibits a single Dirac point around $V_{BG} = 0$ V. In contrast, when measurements are performed "across MoS₂" a Dirac point is observed around $V_{BG} = 0$ V and a shoulder peak is observed around $V_{BG} = -18$ V. This shoulder peak indicates that the graphene on MoS₂ is n-doped. The electron doping of graphene on MoS₂ was confirmed by performing the "across MoS₂" measurements by sweeping the top gate placed atop the MoS₂–graphene overlap. As observed, graphene exhibits a Dirac point around $V_{TG} = -0.8$ V, which nearly equals the location of the shoulder peak depicted in Fig. S5(c).

6. Ohmic and non-Ohmic contact behaviors of graphene and graphite electrodes on MoS₂

Fig. S6 illustrates the contact behaviors of the graphene–MoS₂–graphene and graphite–MoS₂–graphite heterostructures. As reported previously⁷, the graphene contact demonstrates a nearly linear I–V curve, which represents Ohmic behavior. In contrast, the graphite contact demonstrates a nonlinear I–V curve and non-Ohmic behavior.

7. Theoretical backgrounds of DS diode

7. 1 Analytical formula for ideality factor less than one of DS diode

The Dirac point of graphene is above the conduction band edge of MoS_2 as show in Fig. 1c, and the doping of graphene is p-type at a negative gate voltage. When the bias voltage applied to graphene decreased, the injected current density increased differently from that in the case of normal metals. The current is described using Landauer approach, as follows:

$$I = \frac{2q}{h} \int_{-\infty}^{\infty} dET(E) M(E) [f(E - E_{F,S}) - f(E - E_{F,D})], \qquad (1)$$

where T(E) is the transmission at energy E, M(E) is the number of channels at energy E, f(E) is the Fermi distribution function of the contact, and $E_{F,S}$ and $E_{F,D}$ are the Fermi levels of the source and drain, respectively. In this case, $E_{F,S} = 0$, $E_{F,D} = E_{F,S} - qV_{bias} = -qV_{bias}$. Because graphene has a linear density of state, $M(E) = M_0 |E - E_D|$, where E_D is the Dirac point of the graphene source. The thermionic current has a transmission, T(E) = 1. Applying the above conditions to Equation 1, we obtain:

$$I = \frac{2qM_0}{h} \int_{-\infty}^{\infty} dE |E - E_{Dirac}| [f(E) - F(E + qV_{bias})].$$
(2)

When the Dirac point of graphene is above the top of barrier of MoS₂, the energy between the Dirac point of graphene and the top of barrier of MoS₂ is larger than a few k_BT .

$$I = \frac{2qM_0}{h} \left(1 - e^{-\frac{qV_{bias}}{k_B T}} \right) \left\{ \int_{E_{top}}^{E_D} dE(E_D - E) e^{-\frac{E}{k_B T}} + \int_{E_D}^{\infty} dE(E - E_D) e^{-\frac{E}{k_B T}} \right\}$$
$$= \frac{2qM_0k_B T}{h} \left(1 - e^{-\frac{qV_{bias}}{k_B T}} \right) \left[2k_B T e^{-\frac{E_D}{k_B T}} - (E_{top} + k_B T - E_D) e^{-\frac{E_c}{k_B T}} \right]$$
$$\sim \frac{2qM_0k_B T}{h} \left(1 - e^{-\frac{qV_{bias}}{k_B T}} \right) \left[E_D - E_{top} - k_B T \right] e^{-\frac{E_c}{k_B T}}$$
$$= J_0 \left(1 - e^{-\frac{qV_{bias}}{k_B T}} \right) \left[E_D - E_{top} - k_B T \right], \tag{3}$$

where E_{top} is the top of barrier of MoS_2 .

From Equation 4, η can be defined as

$$\eta = -\frac{q\partial V_{bias}}{k_B T \partial log I_D} = \frac{1}{1 + \frac{k_B T}{E_D - E_{top} - k_B T}}$$
(4)

and when $E_D - E_{top} = nk_B T$,

$$=\frac{1}{1+\frac{1}{n-1}}=\frac{n-1}{n}<1,$$
(5)

i.e., η becomes less than 1.

7. 2 Theoretical calculations and simulations of DS diode

Quantum transport simulations are performed to explore switching properties of DS Schottky diode. The DS diode consists of graphene, monolayer (ML) MoS_2 and graphite vdW heterojunction with graphene as a cold electron source. Both graphene and ML MoS_2 are described by a Dirac Hamiltonian⁸:

$$\widehat{H}_{0} = at \left(\tau k_{x} \,\widehat{\sigma}_{x} + k_{y} \,\widehat{\sigma}_{y}\right) + \frac{\lambda}{2} \,\widehat{\sigma}_{z} \tag{6}$$

Where, a is the lattice constant, t is the intralayer hopping energy and Δ is the band gap which is 0 eV for graphene and 1.65 eV for ML MoS₂⁸. $\hat{\sigma}$ denotes Pauli metrics on the Pseudo spin basis. The van der Waals coupling parameters between graphene and ML MoS₂ are obtained by fitting the band structure of graphene-MoS₂ heterojunction calculated by using density functional theory (DFT). Graphite is modeled by n-type bilayer graphene Hamiltonian to simplify calculations⁹. The ballistic transport properties of DS diode are calculated by solving the Schrodinger equation within the non-equilibrium Green's function (NEGF) and Poisson's equation self-consistently⁸.

Fig. S7 shows the device structure and transport properties of the simulated DS diode. The device consists of 10 nm graphite, 32 nm MoS₂ and 8 nm graphene. An Ohmic contact is used between p-type graphene and 7 nm n-type MoS₂ as shown in Fig, S7(a). The Schottky barrier between graphite and MoS₂ is set at 0.48 eV. The contact types are consistent with the fabricated DS diode. The top gate length is 20 nm and bias voltage is applied on p-type graphene. MoS₂ under the gate has a flat band at $V_G= 0$ V. It is shown that a steep slope switching is realized in DS diode at $V_G = 0.1$ V in Fig. S7(b) and the ideality factor can be as small as 0.69 at -0.15 V < V_{bias} < -0.10 V, which breaks the switching limit of conventional Schottky diode. At $V_{\text{bias}} = -0.05$ V, the Dirac point of graphene is below the top of barrier of MoS₂ as shown in Fig. S7(c). As bias voltage is decreased to -0.15 V, the Dirac point of graphene gets larger than the Schottky barrier at graphite-MoS₂ interface as shown in Fig. S7(d). The injected carrier around the Dirac point is effectively filtered as calculated current density in Fig. S7(d). Due to the linear density of states of graphene, the current is increased super-exponentially and ideality factor is less than 1 as expected. The current is increased by over 5 orders of magnitude with the average ideality factor about 0.88 as bias voltage is decreased from -0.10 V to -0.40 V. Besides promising steep slope switching, DS diode also have high on-state current over 10³ μ A/µm and large rectifying ratio over 10⁷.

8. Dirac-Source FET measurement

Fig. S8 shows the Dirac-source FET measurement to prove that the cold electron injection from the graphene source is operating mechanism of proposed DS diode.

9. Device dimensions, measurement setup, and system leakage level

Fig. S9 depicts the device dimensions, measurement setup schematic, and system leakage level. The contact areas of the graphene–MoS₂ and graphite–MoS₂ interfaces equal $21.9 \,\mu m^2$ and $19.7 \,\mu m^2$, respectively. The length of the channel between graphene and graphite equals $3.35 \,\mu$ m. The graphene and graphite contacts were used as the source and drain electrodes, respectively. Using the Yokogawa 7651 DC source, a bias voltage was applied to the graphene electrode, and the current signal from the graphite electrode was amplified to 10^6 times in the DDPCA-300 pre-amplifier and the corresponding voltage was extracted. The current value was measured by monitoring the signal changes between DDPCA-300 pre-amplifier and its conversion to voltage using the Keithley 2182A Nanovoltmeter. The leakage level of the proposed system approximately equals 50 pA.

10. Thickness characterization of MoS2 and graphene via Raman spectra analysis

17

Fig. S10 depicts the Raman spectra of MoS₂ and graphene used in the proposed DS triode. As can be seen, the MoS₂ spectra are characterized by the E^{1}_{2g} (in-plane) and A_{1g} (out-of-plane) peaks. In this study, the thickness characterization of MoS₂ was performed by comparing the peak-to-peak distance between the E^{1}_{2g} and A_{1g} modes¹⁰. In the MoS₂ case, this distance equaled approximately 18.8 cm⁻¹, thereby indicating the use of an MoS₂ monolayer in the device. Meanwhile, the Raman spectra of graphene are characterized by the G and 2D peaks, and the graphene-layer thickness can be determined by evaluating the intensity ratio of the G and 2D modes, i.e., I_{2D}/I_{G}^{11} . As observed, the graphene monolayer yields an I_{2D}/I_{G} value that exceeds unity. This result is consistent with $I_{2D}/I_{G} \approx 3$.

11. Non-zero threshold voltage in diode behavior regime

Fig. S11 depicts the mechanism of non-zero threshold voltage in diode regime. A conventional Schottky diode consisting of n-type semiconductor and metal, where Fermi level of the semiconductor is fixed near the conduction band, should have sign change of the IV curve at zero bias voltage. However, the Fermi level of the monolayer MoS₂ in our triode can change with the gate voltage. At $V_{BG} = 0V$, where the Fermi level of MoS₂ lies near the conduction band, the IV curve of our triode shows sign change at zero bias voltage. However, At $V_{BG} \leq -15$ V, where the Fermi level of MoS₂ moves away from the conduction band with decreasing gate voltage, the sign change of the IV curves no longer occurs at zero bias voltage. We believe this is an artifact of a small (positive) offset current in the measurement setup, which overwhelms the extremely low forward-bias (negative) current over a range of negative bias voltages, as explained below.

When the Fermi level of MoS₂ is near the conduction band edge at $V_{BG} = 0$ V, small negative (forward) bias applied to graphene can activate carriers that can pass over the Schottky barrier formed at the interface between graphite and MoS₂. However, When the Fermi level is located deep inside the bandgap, large negative bias voltage should be applied for the thermally activated electrons to pass over the Schottky barrier as in Fig. S11. The triode thus remains in the off-state (where we observe only the leakage current level of the equipment ≈ 50 pA) not only in the reverse bias regime, but also in the low forward bias regime where large enough bias is not applied so that the carriers cannot pass over the Schottky barrier.
