Abstract

Modeling semantic information is helpful for scene text recognition. In this work, we propose to model semantic and visual information jointly with a Visual-Semantic Transformer (VST). The VST first explicitly extracts primary semantic information from visual feature maps with a transformer module and a primary visual-semantic alignment module. The semantic information is then joined with the visual feature maps (viewed as a sequence) to form a pseudo multi-domain sequence combining visual and semantic information, which is subsequently fed into a transformer-based interaction module to enable learning of interactions between visual and semantic features. In this way, the visual features can be enhanced by the semantic information and vice versa. The enhanced version of visual features are further decoded by a secondary visual-semantic alignment module which shares weights with the primary one. Finally, the decoded visual features and the enhanced semantic features are jointly processed by the third transformer module obtaining the final text prediction. Experiments on seven public benchmarks including regular/irregular text recognition datasets verify the effectiveness our proposed model, reaching state of the art on four of the seven benchmarks.

Introduction

Scene text recognition (STR) is the task of recognizing text from images taken in complex scenes such as street view. It is an inherently difficult task due to the variance of shape, color, scale and appearance of the embedded text. Clutter background, large perspective distortion, lighting condition, degraded image quality due to motion/out-of-focus blur also impose severe challenges to the successfully solving the task, resulting severe miss-predictions.

Despite its difficulty, STR has many real-world applications ranging from self-driving cars (Yu et al. 2019), street image understanding to applications such as instant translation and intelligent text reading in smart-phones (Wu et al. 2019). For decades, STR has been an active research direction (Baek et al. 2019; Li et al. 2019; Shi et al. 2018; Wan et al. 2020; Long, He, and Yao 2021), attracting many efforts in designing new models and creating new datasets in order to solve the problem.

A complete approach to recognizing text from scene images usually involves text detection and text recognition. In this paper, we assume that text detection is done and only focus on the recognition part. That is, we assume the input to our model is a cropped image with regular or irregular characters lying in it. A large portion of the previous work and many open-source datasets (Karatzas et al. 2013, 2015) follow from this assumption. In this work, we will refer to STR as just recognizing text from cropped images.

The approaches to solving STR problem can be roughly divided into two categories: linguistic-based and linguistic-free. Linguistic-based methods refer to those which incorporate vocabulary (dictionary) or lexicon (parts of words), while linguistic-free methods use only the images themselves without relying on explicit language modeling, whether from internal or external, pretrained or from-scratch.

The motivation of this work is multi-fold. Firstly, to deal with the cases when visual information alone is inadequate, semantic or linguistic features has been introduced in various effects, among which (Qiao et al. 2020) propose a semantic enhanced encoder-decoder framework to recognize low-quality scene texts. A semantic module is designed to directly produce semantic features that are consistent with the word embedding learned from a pretrained language model. Inspired by their efforts in exploiting semantic features, we also explicitly model semantic information. But unlike their approach, we achieve semantic modeling without relying on external language models but instead using an alignment module.

On the other hand, our work is also partially inspired from wav2vec (Baevski et al. 2020) in audio community. The wav2vec model first extract primary audio features from waveform using 1D convolution. The features are processed by a succeeding transformer module, resulting in secondary contextualized audio features. The secondary audio features interact with the primary features by predicting them back at the next few time steps. Similarly, we extract semantic and visual features at different stages, making them interact with each other so that the overall recognition performance is improved.

Apart from the aforementioned work, we have also noted that many efforts have been devoted to modeling visual-semantic relation. We argue that extracting semantic fea-
The architecture of Visual-Semantic Transformer (VST). The VST consists of several key modules, namely ConvNet (C), Visual module (V), Interaction module (I), Semantic module (S) and two weight-sharing Visual-Semantic Alignment (A, or vs-align) modules. Best view in color.

Figure 1: The architecture of Visual-Semantic Transformer (VST). The VST consists of several key modules, namely ConvNet (C), Visual module (V), Interaction module (I), Semantic module (S) and two weight-sharing Visual-Semantic Alignment (A, or vs-align) modules. Best view in color.

features from appearance and then enforce interaction with visual features is one key to successfully solving STR. To this end, we propose a novel transformer model for scene text recognition. Our model is a unified end-to-end text recognizer which converts image patches into text in parallel (i.e., non-autoregressively), without using complex decoder such as CTC (Graves et al. 2006). The model, which we coin Visual-Semantic Transformer (VST), is able to learn semantic features from appearance and combine them back with visual features to enable visual-semantic interaction using multi-head self-attentions (MHSA).

The overall architecture of VST is shown in Fig. 1. The VST first explicitly extracts primary semantic information from visual feature maps with a transformer module and a primary visual-semantic alignment module (vs-align). The semantic information is then joined with the visual feature maps (viewed as a sequence) to form a pseudo multi-domain sequence combining visual and semantic information, which is subsequently fed into the second transformer module to enable learning of interactions between visual and semantic features. In this way, the visual features can be enhanced by the semantic information and vice versa. The visual features are further decoded with a secondary vs-align module which shares weights with the primary one. Finally, the decoded visual features and the semantic features can be jointly processed by the third transform module and the final softmax layer to obtain the resulting text. Overall, our approach is end-to-end and conceptually simple. Experiments on public benchmarks on regular/irregular text recognition tasks demonstrate the effectiveness of our proposed model. The main contributions of this paper are as follows,

- We propose a novel visual-semantic transformer to effectively solve STR problem, surpassing or on par with state-of-the-art in most STR datasets.
- We design weight-sharing visual-semantic alignment modules to explicitly enforce the learning of semantic information without external language models.
- We introduce an interaction module that allows visual and semantic information to globally interact with and enhance from each other.

In this work, semantic information refers to the information that connects visual appearance and the underlying linguistic information. In other words, it is the information extracted from visual features which are very closely related to the text represented by the scene text image. Semantic information is distinguished from the term language or linguistic information, because the latter usually refers to the information extracted directly from text solely. Semantic feature extraction is not language modeling or word embedding because features are not computed directly from real character sequence, but rather learned from image appearance and forced to be consistent with language. The semantic feature is ready to convert into text characters using a simple linear
Related Work

Text recognition has been an active research area for decades. See (Long, He, and Yao 2021; Chen et al. 2021) for comprehensive reviews. Due to page limitation, we can only list a portion of recent work here.

Recently, (Nguyen et al. 2021) incorporate a dictionary in training and inference stage to help selecting the most compatible outcome for STR. (Feng et al. 2021) introduce character center segmentation branch to extract semantic features which encode the category and position of characters for improving video text detection performance. (Patel et al. 2016) propose to generate contextualized lexicons for scene images with only visual information. (Sabir, Moreno-Noguer, and Padró 2018) use language model to build the semantic correlation between scene and text in order to re-rank the recognition results. (Zheng, Wang, and Betke 2019) also propose to use pretrained language models for correcting predictions. Very recently, (Wang et al. 2021b) propose to learn the linguistic rules in the visual space by randomly mask out some characters from the image and predict them back.

Similar to speech recognition, scene text recognition can be treated as a sequence-to-sequence (seq2seq) mapping problem (Jaderberg, Vedaldi, and Zisserman 2014; Jaderberg et al. 2015; Qiao et al. 2020; Yue et al. 2020). (Li et al. 2019) combine convolution and LSTM as an encoder, then use another LSTM as decoder to predict text attentively, quite similar to the show, attend and tell work on image captioning (Xu et al. 2015). ASTER (Shi et al. 2018) takes a two-stage approach to first rectify curved text images and then perform recognition using seq2seq model with attention. CRNN (Shi, Bai, and Yao 2016) adapts CNN to obtain visual features, which are then fed into LSTM module with CTC loss (Graves et al. 2006) for text prediction. STAR-Net (Liu et al. 2016) uses spatial transformer (Jaderberg et al. 2015) to tackle challenges brought by image distortion. Attention can be added to the seq2seq models (Li et al. 2019; Bhunia et al. 2021) in a straightforward way to alleviate bottleneck effects brought by seq2seq models. (Litman et al. 2020) propose stacked block architecture with intermediate supervision to train a deep BiLSTM encoder, while attention is used in decoding stage to exploit contextualized visual features. (Aberdam et al. 2021) propose seq2seq contrastive learning of visual representations which can be applied to text recognition. DAN (Wang et al. 2020) decouples alignment from the decoding stage into the early conventional encoder network. (Wang et al. 2021a) propose an alignment module enabling text recognizer to recognize document level image. (Wang et al. 2019b) use adversarial loss to handle low-resolution image.

Transformers have also been successfully applied to STR. ABINet (Fang et al. 2021) enforces the bidirectional language-model (LM) to only learn linguistic rules by gradient-stopping in training. The decoding is in an iterative way allowing the predictions to be refined progressively. Their conv+transformer visual module and transformer-LM can be separately pretrained to improve performance. HRGAT (Yang et al. 2020) connects CNN feature maps to a transformer-based autoregressive decoder, where the cross-attention is guided by holistic representation obtained by average-pooling of 2d feature maps.

Perhaps more related, SRN (Yu et al. 2020) incorporates visual-to-semantic embedding block and cross-entropy loss to align with ground-truth text, but they use argmax embedding, which is different from our direct use of probability vector that enables smooth gradient flow in training. Our work is also innovative in many ways such as visual-semantic alignment, multiple-stage semantic processing and transformer-based visual-semantic interaction. Instead of using argmax, (Bhunia et al. 2021) use Gumbel-softmax (Jang, Gu, and Poole 2016) for extracting semantic information, which is then fed into succeeding transformer-based visual-semantic reasoning module. The decoding involves complex multiple-stage attentional LSTM that couples with feature pyramid networks. Our approach is not only conceptually much simpler and computationally more efficient, but also more effective in solving STR.

Figure 2: The architecture of vs-align module. Visual features (viewed as feature maps) are projected using a linear layer and further normalized using softmax operator, obtaining $t$ attention maps, each of which has the same spatial dimension as the origin feature map. The $t$ attention maps and the original $d$ visual feature maps together will reduce (by multiplication) to $t$ semantic features in $R^d$.

We will introduce the visual-semantic transformer (VST) in this section. The VST consists of several key modules, namely ConvNet (C), Visual module (V), Interaction module (I), Semantic module (S) and two weight-sharing Visual-Semantic Alignment (A, or vs-align) module. Module C can be any convnet, Module V, I, S are basically transformer blocks, while vs-align is an attention-based alignment block. Since a large portion of our model consists of transformer
blocks, we name it visual-semantic transformer, implying that it is a transformer that explicitly models visual and semantic information.

The overview of the architecture is shown Fig. 1. The convnet module extracts local visual features from cropped images. The visual module transforms the local visual features into contextualized global visual features, which we call primary visual features. The first vs-align module converts the primary visual features into primary semantic features. The interaction module then transforms primary visual and primary semantic features by allowing them to interact with each other through MHSA, producing secondary visual and secondary semantic features respectively. The secondary visual features are fed into the second vs-align module (which shares weights with the first one), obtaining tertiary (third) semantic features. Secondary and tertiary semantic features together will be processed by the final semantic module to obtain the resulting text prediction.

To enforce the learning of semantic information, the two vs-align modules share weights. In other words, the improvement of the second vs-align module is immediately helpful for improving the accuracy in aligning the primary semantic features, which in return will help improve the overall recognition accuracy. We found that this design is very useful for extracting primary semantic information, as seen in Fig. 3.

The VST has two variants, namely VST-F (full) or VST-B (basic), depending on whether the module S is used or not. In VST-F, there are three losses in training and the output of final softmax is used for text decoding. For VST-B, there are two losses (blue and green in Fig. 1) and the semantic stream of module I’s output are passed to softmax layer, while the visual stream will go through additional vs-align module before softmax and CE loss. The decoding for VST-B can be evaluated separately or jointly (by probability voting).

The ConvNet (C) Module
We use resnet-like architecture in extracting local features. The input images are first resized to have the same height, with aspect ratio kept unchanged. During training and testing, replication-paddling (padding using values from the image border) is used for batch processing.

Assuming that input image is of size $W \times H \times 3$, the convnet module will produce feature maps of size $w \times h \times d$. The features will be fed into the visual module.

The Visual (V) Module
Convnets are good at learning local features but hard to learn global correlation between features that locate far apart. Inspired from the success of transformers when applied to vision task, we insert a transformer module here in order to enhance the feature maps by allowing them to interact with each other. The visual modules takes the convolution feature maps as input, producing primary visual features. The primary visual features together encode completely the appearance information of the input image. They are then converted to primary semantic features by the vs-align module.

The visual module consists of MHSA, layer-norm, and feed-forward network, as described in (Vaswani et al. 2017), but with minor modification that puts layer-norm before MHSA (Dosovitskiy et al. 2020; Wang et al. 2019a). Note that Fig. 1 does NOT reflect this modification. The feature maps are viewed/reshaped as a sequence of dimension $d$ and length $n = w \times h$, the module V, takes the feature sequence as input and generate a sequence of the same dimension and length. The interaction between visual features themselves mainly takes place in the MHSA layers.

The Visual-Semantic Alignment (A) Module
Parallel attentions has been used to map visual features into semantics(Wang et al. 2021b; Lyu et al. 2019). Compared with previous work, the vs-align module in this work is much simpler but still effective. Note that we do not use the name semantic decoder here because the output of the module is not actually the character index, but rather the probability distribution of the characters. In other words, the semantic feature encodes the probability distribution at each candidate location, which can be readily converted into character index with argmax operation in decoding stage (not in training). This allows the gradients to flow smoothly inside the VST.

The architecture of vs-align is depicted in Fig. 2. As shown in the figure, the visual features (viewed as feature maps) are projected using a linear layer and normalize using softmax operator, obtaining $t$ attention maps each of which has the same spatial dimension as the origin feature map. The alignment module can also be formulated mathematically as follows,

$$S = \text{softmax}(QV^T)V$$

where $S \in R^{n \times d}$ is the semantic sequence, $V \in R^{n \times d}$ is the visual sequence and $Q \in R^{n \times d}$ is the trainable projection matrix.

Our VS-align module is able to learn the relation between the semantic and visual features. This is different from CTC (Graves et al. 2006), which is good at aligning two sequences with beam search, but not capable of handling information along the height direction.

As shown in Fig. 1, there are two vs-align modules, which share weights during training and inference. This weight-sharing scheme is the key to successfully learning 1st semantic information. It enables the weights learned in aligning 2nd visual features to transfer to aligning 1st visual features, making the early learning of 1st semantics possible. The 1st semantic in return enhances the 1st visual features through interaction module, further improving the training of the 2nd vs-align module. The early learning of semantics provides more chances to correct the semantic features through interaction in later stages. If semantic had been learned in the last stage, we would have not change to correct it, unless incorporating additional lexicon or dictionary information (Nguyen et al. 2021)

The Interaction (I) Module
The interaction module plays the key role of mixing primary semantic features and visual features. The modules takes
two streams, namely the primary semantic features and primary visual features as input, producing the secondary visual and semantic features. Fixed positional encoding are added into the visual stream. For the semantic stream, learnable position embedding is used. Other positional encoding schemes probably help as long as it breaks permutation invariant property of transformers.

The design of the interaction module follows from module $V$, comprising layers of transformer blocks. The module enables the feature interaction between a) the visual stream and semantic will interact with each other, and b) the features themselves inside the same stream.

The interpretation of module can be seen from eq. 2. Following from the notations in (Vaswani et al. 2017), the interaction ans loss type. Note that at inference time, the two loss branches are unneeded.

In this way, the primary semantic features will look for support from the spatial visual features. The interaction is useful for enhancing semantic features because they now have attentive access to all spatial location of the visual features. On the other hand, visual features are also enhanced not only because then can interact with all other spatial locations regardless of distance, but they can also learn from semantic features, which we hypothesize is useful for dealing with appearance degradation.

The semantic features can be seen as pseudo-linguistic features, distinguished from visual domain. Hence we add domain embedding before feeding two combined streams into the interaction module.

One of the outputs of interaction module is secondary visual sequence in $R^{n \times d}$, which will be converted to tertiary semantic features using vs-align module following by cross-entropy loss with softmax, against the ground-truth text. The other is semantic features in $R^{s \times d}$, which will be directly compared against ground-truth text with the same activation ans loss type. Note that at inference time, the two loss branches are unneeded.

### The Semantic (S) Module

The semantic module is inserted optionally to play the role of further fusing the two semantic streams. When inserted, our model is named VST-F (full); otherwise, it is named VST-B (basic). The two streams are the secondary semantic features generated from the intersection module and the tertiary (third) semantic features generated from the second vs-align module respectively.

The layer configuration of this module also follows from the design of module $V$ and $I$. Fixed positional encoding is added, but there is no domain or segment embedding because the two streams are both semantic. Since the transformer blocks keep the input shape, we concatenate the two streams along channel direction to $t \times 2d$ and feed it to linear and softmax layer, obtaining the final text predictions.
Mathematical interpretation

As shown in Fig. 1, there are three losses indicated by the ladders in different colors. The green one measures the discrepancy between the true text labels and semantic features output from second vs-align module using softmax activation and cross-entropy loss. The blue one measures how different are the secondary semantic features from the true text. The yellow one is the main loss for decoding final text containing 647 testing images. Following from (Wang, Babenko, and Belongie 2011), we select 867 cropped images from IC03 for testing. IC13 contains 1095 testing images and we discard images containing non-alphanumeric characters or contains fewer than three characters, resulting in 1015 images for testing, following from previous work (Yu et al. 2020).

For irregular datasets, IC15 contains 2077 cropped images by Google Glasses. We use 1811 images after discarding extremely distorted images. SVTP and CUTE contains 639 and 288 images respectively.

Implementation Details

Module C is implemented as a four-layers resnet, with each layer having 1, 2, 5 and 3 blocks respectively. Module V, I and S each consists of 3 transformer layers. The number of parameters is about 63.99M for VST-F, and 63.65M for VST-B.

The image patches are resized with aspect-ratio unchanged so that $H = 48$, and the width is trimmed or padded to $W = 160$ pixels. The feature map size is $6 \times 40 \times 512$, $w = 40$, $h = 6$, $n = 240$. The number of class is set to 38, including 0-9, a-z, [unk], [eos]. We assume that the maximum character length is 25, i.e., $t = 25$. We use online data augmentations including distortion, stretch, perspective transform, blurring, colour jitter etc. In training, we set the batch size to 256 and sample from ST, MJ, SA datasets with weight 0.4, 0.4 and 0.2 to balance the datasets (Baek et al. 2019). We use Adam optimizer with the initial learning rate 1e-4 and decreased lr to 1e-5 when the loss plateaus. We use for and the training takes roughly 3 days to converge on four Tesla V100 GPUs.

Comparison with State-of-the-Art

We compare VST-B and VST-F with previous work over seven public benchmarks in table 1. The proposed VST-B and VST-F both achieve or on par with state-of-the-art approaches. The large version of the very recent work by (Fang et al. 2021) performs slightly better than ours on three of the seven datasets, but they used extra curbersome pre-trained language models. Moreover, our VST-B and VST-F are about three times faster than theirs in inference. On the rest four datasets, we improve SOTA by large margins (0.2% IIIT, 0.3% SVT, 0.8% IC03, 2.8% CUTE).
Figure 4: Visualization of attention heatmaps of the primary and secondary vs-align modules. For each of the two examples, the top (bottom) row shows the heatmaps of the primary (secondary) vs-align module.

Figure 5: Successful cases for fairly hard examples.

Ablation Study
To verify whether each module is critical for the final performance, ablation study is conducted by subsequently adding one module starting from the most basic C+V configuration. The results are shown in table 2, from which we observe a consistent performance gain when a new module is added. Also note that C+V+A also performs better than C+V, which verifies the effectiveness of vs-align module. For the C+V+A+I configuration, there are three ways of decoding: decoding from secondary semantics ($s_2$), tertiary semantics ($s_3$) or by probability voting from both semantics.

Visualization
Inside the module I, each semantic vector will attend to visual features corresponding to some spatial locations. We can visualize which locations are attended to using heatmaps. Fig. 3 shows three examples. The heatmaps are computed by averaging all 8 attention heads and overlapping onto images after upsampling. Note that inside the module each head focuses on different aspects of the images, but on average the attention is mainly at the right spatial location for each decoded character. For some characters, the focus is slightly shifted, probably due to the translation-invariant property of convnet, which means that the visual features cannot be mapped back uniformly to the corresponding spatial locations. Overall, the visualization proves that the interaction module works as expected.

Likewise, we also visualize the attention heatmaps of the primary and secondary vs-align modules. Even though the two modules share the same weights, their attention maps should be different since the visual and semantic features are different. We expect that the attention maps of 2nd vs-align be more precise than the first one. This is verified in Fig. 4.

Beside visualization, we select some successful and failure cases for illustration purpose, shown in Fig. 5 and Fig. 6 respectively.

Figure 6: Failure cases for some confusing images.

Conclusion
In this paper, we propose visual-semantic transformer to solve scene text recognition problem. The VST consists of three model explicitly extract semantic features in the early stage by using weight-sharing visual-semantic alignment module, making the visual and semantic fusion and interaction possible int the following transforms modules. Our model is unified and end-to-end trainable, and it does not require autoregressive decoding. Extensive experiments on regular and irregular scene text recognition datasets have verified the effectiveness of our model.
