

Conformal Sensitivity Analysis for Individual Treatment Effects

Mingzhang Yin Claudia Shi [†] Yixin Wang [‡] David M. Blei [§]

July 13, 2022

Abstract

Estimating an individual treatment effect (ITE) is essential to personalized decision making. However, existing methods for estimating the ITE often rely on unconfoundedness, an assumption that is fundamentally untestable with observed data. To assess the robustness of individual-level causal conclusion with unconfoundedness, this paper proposes a method for sensitivity analysis of the ITE, a way to estimate a range of the ITE under unobserved confounding. The method we develop quantifies unmeasured confounding through a marginal sensitivity model [47, 54], and adapts the framework of conformal inference to estimate an ITE interval at a given confounding strength. In particular, we formulate this sensitivity analysis as a conformal inference problem under distribution shift, and we extend existing methods of covariate-shifted conformal inference to this more general setting. The resulting predictive interval has guaranteed nominal coverage of the ITE and provides this coverage with distribution-free and nonasymptotic guarantees. We evaluate the method on synthetic data and illustrate its application in an observational study.

1 Introduction

Consider a person who ponders whether to take the COVID-19 vaccine. She is interested in understanding how much risk the COVID vaccine can reduce for her. However, most large-scale observational studies are conducted to estimate the average vaccine efficacy over a whole population [20], and such population-level estimates provide a summary that cannot reflect individual heterogeneity.

The causal estimand that captures individual heterogeneity is the individual treatment effect (ITE), the per-individual difference between the potential outcomes. However, estimation of the ITE is fundamentally challenging, even beyond the usual population-level estimands, because of its inherent uncertainty. To address this challenge, researchers have recently adapted the method of conformal inference [58] to estimate ITE intervals with good theoretical guarantees [33, 37]. Conformal inference helps estimate an interval that contains the true ITE with a guaranteed minimal probability.

Conformal inference for ITE estimation is an important innovation, but it comes with assumptions. In particular, it relies on the usual assumption of unconfoundedness [33, 37] that the treatment assignment is conditionally independent of the potential outcomes. In practice, this assumption can be difficult to accept for many observational studies [19], and violations of unconfoundedness will introduce hidden biases into the estimation of the ITE. In the context of COVID-19 vaccine studies, for example, unmeasured confounding may come from coexisting conditions, medical resources, and socioeconomic status [1].

To assess the robustness of individual-level causal conclusions with unconfoundedness,

this paper develops a method for sensitivity analysis of the ITE. The idea of sensitivity analysis is to quantify the violation of the required assumptions and then to produce intervals of causal estimates that account for such violations. In the context of the ITE, a sensitivity analysis must account for two sources of uncertainty: the inherent uncertainty of the estimand itself and the uncertainty due to violations of the required assumptions.

We develop conformal sensitivity analysis (CSA), a method for sensitivity analysis of ITE interval estimation. Given a pre-specified amount of unmeasured confounding, CSA estimates an interval that captures the true ITE with a guaranteed probability. We develop CSA by relaxing the assumption of unconfoundedness with a marginal sensitivity model (MSM) [47, 54], a general model of the treatment assignment and potential outcomes that includes a real-valued parameter for the strength of unmeasured confounding. With the MSM in hand, we then show how sensitivity analysis can be formulated as a predictive inference of the missing potential outcomes, but under a general distribution shift. Finally, we extend weighted conformal prediction [55], a predictive inference method developed in the setting of covariate shift, to this more general setting of distribution shift.

The CSA algorithm contains two stages. Given a specification of an MSM, it first computes the range of weight functions of the weighted conformal prediction. While covariate shift leads to a single weight function, distribution shift requires a range. Then it uses these functions to quantify the bounds of the ITE, found by solving an optimization problem with constrained weights. The resulting algorithm provides a valid interval estimate of an ITE whenever the true data generation is consistent with the MSM.

CSA has several practical and theoretical strengths. By leveraging conformal inference, it makes minimal assumptions about the underlying distribution of the observed data,

and its theoretical guarantees are valid with finite data. By using an MSM, it does not impose additional untestable assumptions over the distribution of a latent confounder and its effects on other variables. CSA can be used with any predictive functions to fit the treatment and outcome, and it can be applied after fitting such functions with a light computational cost.

1.1 Related Work

Conformal Inference. The framework of conformal inference was pioneered by Vladimir Vovk and his collaborators [41, 57, 58, 59]. Recent developments of conformal inference improve its accuracy [36, 44], efficiency [35], and extend its applicable domains [10, 35].

First, regarding accuracy, a variety of conformal inference algorithms were proposed to reduce the length of predictive band. Some algorithms rely on the conditional quantile regression of the outcome given the covariates to capture the individual heterogeneity [32, 44, 51], some adapt to skewed data by estimating the conditional histograms [52], and others estimate the conditional density function to produce nonconvex predictive bands [22, 28]. Second, to improve efficiency, the split conformal inference framework is proposed; it uses data splitting to avoid multiple re-fitting of the predictor [34, 40, 53]. Such data-splitting will also be adopted in this paper. Finally, regarding domain extensions, the weighted conformal prediction is proposed to handle non-i.i.d. data [55], generalizing conformal inference from exchangeable data to data with covariates shift.

Sensitivity analysis. Sensitivity analysis dates back to the study of the average treatment effect (ATE) of smoking on lung cancer [13]. More recent advances for sensitivity analysis

posit a hypothetical latent confounder and evaluate its impact on a causal conclusion [12, 14, 15, 24, 27, 45, 56]. Though intuitive, introducing a latent confounder often entails additional untestable assumptions [17]. As an alternative, some methods directly model the dependency between treatment assignment and potential outcomes given the covariates, such as the MSM in this paper [43, 54]. With this strategy, some sensitivity models focus on modeling the potential outcome given the treatment [6, 9], while others focus on modeling the treatment distribution given the potential outcomes [17, 54, 61, 63].

Other papers consider different frameworks to evaluate the sensitivity of a causal estimate. Some sensitivity analysis methods measure the association between a latent confounder and the treatment or outcome that produces a specific amount of estimation bias [12, 14, 27, 56]. Another way to evaluate sensitivity is to compute an interval estimate of the target estimand for a specific level of unmeasured confounding. For the ATE, the percentile bootstrap produces a partial identified region with asymptotically valid coverage [63]. For the conditional average treatment effect (CATE), data-dependent interval estimations have been proposed via nonparametric and (semi-)parametric approaches [29, 31, 61]. This work further explores the interval estimation of the ITE under an unmeasured confounding.

In an independent and concurrent paper, Jin et al. [30] also develops sensitivity analysis procedures for the ITE based on robust conformal inference. Jin et al. [30] derives a sensitivity analysis based on the MSM and proposes an extended conformal inference algorithm that is equivalent to Alg. 1. However, this paper and Jin et al. [30] propose the methods of analysis that are complementary and offer different perspectives. The present paper defines the MSM without explicitly having to posit a latent confounder and uses Tukey’s factorization for an alternative derivation of Lem. 1 (same as Lem. 3.1 [30]). We propose

and implement an algorithm to improve the sharpness of the predictive set, provide tools of calibration from observed data, and design methods to evaluate the estimation over different sensitivity models in the MSM.

2 Conformal Inference of Individual Treatment Effects

We first set up the problem of ITE estimation. Next, we formulate the ITE estimation in observational study as a conformal inference problem under distribution shift, and introduce existing estimation methods under the assumption of unconfoundedness. Then we discuss the challenges presented to ITE estimation when there is unmeasured confounding.

2.1 Problem Setup

Consider N statistical units. Each unit $i \in \{1, 2, \dots, N\}$ is associated with a tuple of random variables $(X_i, T_i, Y_i(0), Y_i(1))$. $X_i \in \mathcal{X} \subset \mathbb{R}^p$ is a vector of covariates, $T_i \in \{0, 1\}$ is the treatment, $Y_i(1), Y_i(0) \in \mathcal{Y} \subset \mathbb{R}$ are the potential outcomes under treatment and control [38, 48]. We use $\mathbb{P}_0(X, T, Y(0), Y(1))$ to denote the true joint distribution of these variables.

We make the stable unit treatment value assumption (SUTVA) [49]. Under SUTVA, the observed outcome $Y_i \in \mathbb{R}$ is one of the potential outcomes $Y_i = T_i Y_i(1) + (1 - T_i) Y_i(0)$.

Assumption 1 (SUTVA). *There is no interference between units, and there are no unrepresented treatments.*

We further assume that each unit has a positive probability of being assigned to all

treatment groups and the probability is bounded away from the extremes [46].

Assumption 2 (Strong overlap). $\exists \eta > 0, \eta < p(T_i = 1 | X_i) < 1 - \eta$ with probability 1.

The causal estimand of interest is the ITE. The ITE of unit i is defined as the difference between its potential outcomes, $\tau_i = Y_i(1) - Y_i(0)$.

Estimating the ITE is challenging. The fundamental problem of causal inference is that we can at most observe one potential outcome of each unit [23]. Therefore, the ITE, which requires knowing both the potential outcomes, can never be observed. Furthermore, unlike population-level causal estimands, an ITE is inherently random. Even with a known joint distribution $\mathbb{P}_0(X, T, Y(0), Y(1))$, an ITE is not point-identifiable [21].

To tackle these challenges, the problem of ITE estimation has been re-framed as a predictive inference problem [33, 37].

2.2 Predictive Inference in Observational Studies

The idea of predictive inference is to form a covariate-dependent predictive band that contains the outcome of a new data point with a guaranteed probability [5, 58]. For predicting potential outcomes, predictive inference aims to use observed data $\{X_i, Y_i(t)\}_{i:T_i=t}$ from the treatment group t to learn a mapping from the covariates X to an interval estimate $\hat{C}_t(X) \subset \mathbb{R}$ of the potential outcome $Y(t)$. For a new data point $(X, Y(t)) \sim \mathbb{P}(X, Y(t))$, the band must have a valid coverage probability $\mathbb{P}(Y(t) \in \hat{C}_t(X)) \geq 1 - \alpha$, where the probability is taken over both X and $Y(t)$ and $\alpha \in [0, 1]$ is a pre-determined level.

Conformal inference is a collection of methods that realize the goal of predictive inference [58]. Classic conformal inference assumes the training data and the target data are *exchangeable*. Based on exchangeability, the predictive band is constructed by the quantiles of the prediction residuals. Weighted conformal prediction (WCP) extends the setting to covariate shift [55], where distribution of the covariates $\mathbb{P}(X)$ changes from the training data to the target data but the outcome distribution $\mathbb{P}(Y(t)|X)$ remains the same. Under covariate shift, WCP produces a valid predictive interval [55].

WCP has been applied to the ITE estimation [37]. Suppose we want to estimate the missing outcome $Y(t)$ of a randomly sampled unit. The relationship between the observed data and the inference target $(X, Y(t))$ is

$$\begin{aligned} \text{Training: } (X_i, Y_i(t)) &\stackrel{i.i.d.}{\sim} p(X|T=t) \cdot p(Y(t)|X, T=t), \quad i \in \{i : T_i = t\}; \\ \text{Target: } (X, Y(t)) &\sim p(X) \cdot p(Y(t)|X). \end{aligned} \tag{1}$$

For the training data, we observe both the covariates X_i and outcome $Y_i(t)$. For a target data point, we only observe covariates X and the goal is to infer the missing outcome $Y(t)$.

WCP for the ITE estimation crucially relies on the assumption of *unconfoundedness* [33, 37], that the units are assigned to the treatment groups based only on the observed covariates, i.e. $(Y_i(0), Y_i(1)) \perp\!\!\!\perp T_i | X_i$. Under unconfoundedness, the conditional distributions of a potential outcome remain invariant across treatment groups, $P(Y(t)|X, T=t) = P(Y(t)|X)$. And Eq. (1) becomes

$$\begin{aligned} \text{Training: } (X_i, Y_i(t)) &\stackrel{i.i.d.}{\sim} p(X|T=t) \cdot p(Y(t)|X), \quad i \in \{i : T_i = t\}; \\ \text{Target: } (X, Y(t)) &\sim p(X) \cdot p(Y(t)|X). \end{aligned} \tag{2}$$

The only difference between the training and the target distribution is on the covariates distribution. In other words, unconfoundedness reduces the setting of counterfactual inference from the general distribution shift in Eq. (1) to covariate shift in Eq. (2), for which WCP is readily applicable.

2.3 ITE Estimation under Unconfoundedness

We explain how WCP tackles the predictive inference problem in Eq. (1) and point out the challenges when unconfoundedness is violated.

Denote each training data pair as $Z_i := (X_i, Y_i(t))$, $Z_{1:n} = (Z_1, \dots, Z_n)$. Given a predictive function $\hat{\mu}(\cdot) : \mathcal{X} \mapsto \mathcal{Y}$, conformal inference uses a scalar-valued function $V : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}$ to measure the predictive error. For instance, V_i might be chosen as the absolute residual function $V(X_i, Y_i(t)) = |Y_i(t) - \hat{\mu}(X_i)|$ with mean prediction $\hat{\mu}(\cdot)$ [58]; we will discuss how to fit the predictor $\hat{\mu}(\cdot)$ later and take it as a fixed mapping for now. The *nonconformity score* is defined for each data point as $V_i := V(Z_i)$.

Denote the α -th quantile of a random variable $X \sim p(X)$ as $Q_\alpha(X)$, where $Q_\alpha(X) = \inf\{x : p(X \leq x) \geq \alpha\}$, $\alpha \in [0, 1]$. Let $\delta_v(V)$ be the Dirac delta function, defined as $\delta_v(V) = 1$ if $V = v$ and $\delta_v(V) = 0$ otherwise. We denote the quantile of a discrete distribution and the quantile of an empirical distribution as

$$Q_\alpha\left(\sum_{i=1}^n p_i \delta_{v_i}\right) := Q_\alpha(V), \quad V \sim \sum_{i=1}^n p_i \delta_{v_i}; \quad Q_\alpha(v_{1:n}) := Q_\alpha\left(\sum_{i=1}^n \frac{1}{n} \delta_{v_i}\right).$$

We define the *conformal weights* as the density ratio of the training and target distributions,

$$w_t(x, y) := \frac{p(X = x)p(Y(t) = y | X = x)}{p(X = x | T = t)p(Y(t) = y | X = x, T = t)}. \quad (3)$$

Then for units $1 \leq i \leq n$, let the normalized weights be

$$p_i^t(Z_{1:n}, (x, y)) := \frac{w_t(Z_i)}{\sum_{i=1}^n w_t(Z_i) + w_t(x, y)}, \quad p_{n+1}^t(Z_{1:n}, (x, y)) := \frac{w_t(x, y)}{\sum_{i=1}^n w_t(Z_i) + w_t(x, y)}.$$

where p_i^t are the weights for the observed data and p_{n+1}^t is the weight for a new data. When the conformal weights in Eq. (3) are known or computable, we can use the WCP to derive a predictive interval [55],

$$\hat{C}_t(x) = \{y \in \mathbb{R} : V(x, y) \leq Q_{1-\alpha}\left(\sum_{i=1}^n p_i(Z_{1:n}, (x, y))\delta_{V_i} + p_{n+1}(Z_{1:n}, (x, y))\delta_\infty\right)\}. \quad (4)$$

The interval $\hat{C}_t(x)$ is guaranteed with a pre-set $1 - \alpha$ coverage probability [37, 55], i.e.

$$\mathbb{P}_{(X, Y(t)) \sim p(X)p(Y(t)|X)}(Y(t) \in \hat{C}_t(X)) \geq 1 - \alpha.$$

Computing the predictive interval $\hat{C}_t(x)$ relies on the conformal weights being accessible. In an ideal randomized controlled trial (RCT) with perfect compliance, the training and target data in Eq. (1) are i.i.d., hence the conformal weights $w_t(x, y) \equiv 1$. In an observational study under unconfoundedness, the conformal weights $w_t(x, y) = p(X = x)/p(X = x | T = t)$ can be estimated from the observed data [37].

However, when unconfoundedness is violated, the joint distribution of the covariates and outcome shifts from training to target as shown in Eq. (1). We will see that the conformal weights $w_t(x, y)$ are nonidentifiable under such distribution shift. When unconfoundedness

is violated, existing conformal inference cannot be directly applied to ITE estimation.

3 Sensitivity Analysis for ITEs

In this section, we develop an individual-level sensitivity analysis for estimating a missing outcome and generalize it to a sensitivity analysis for the ITE. We first define what it means to deviate from unconfoundedness. We then show how to incorporate the uncertainty from an unknown confounding into the construction of a valid predictive interval.

3.1 Confounding Strength and the Marginal Sensitivity Model

A sensitivity analysis quantifies the deviation from unconfoundedness and evaluates the corresponding range of causal estimates. We quantify the strength of unmeasured confounding by the marginal sensitivity model (MSM) [54, 63]. Under unconfoundedness, the *propensity score*, $e(x) := p(T = 1 | X = x)$ [46], is the same as the *selection score*, $s_t(x, y) := p(T = 1 | X = x, Y(t) = y)$ [43, 50]. Without unconfoundedness, the selection scores no longer equal to the propensity score. Their difference represents the strength of confounding, which can be measured by the odds ratio (OR), $OR(s_t(x, y), e(x)) := [s_t(x, y)/(1 - s_t(x, y))] [e(x)/(1 - e(x))]$. The MSM assumes that under the true data distribution $\mathbb{P}_0$, the odds ratio between the selection score and the propensity score is bounded by a given range [54, 63].

Definition 1 (Marginal Sensitivity Model). *Under the distribution $\mathbb{P}_0$ over $(X, T, Y(1), Y(0))$,*

assume the propensity score $e(x)$ and selection score $s_t(x, y)$ satisfy $s_t(x, y) \in \mathcal{E}(\Gamma)$, where

$$\begin{aligned} \mathcal{E}(\Gamma) = \{s(x, y) : s(x, y) : \mathcal{X} \times \mathcal{Y} \mapsto [0, 1], \\ 1/\Gamma \leq \text{OR}(s(x, y), e(x)) \leq \Gamma, \text{ for all } x \in \mathcal{X}, y \in \mathcal{Y}\}, \end{aligned} \quad (5)$$

and the sensitivity parameter $\Gamma \geq 1$.

The magnitude of Γ is the degree of deviation from unconfoundedness. The set $\mathcal{E}(\Gamma)$ expands with an increasing Γ , representing more possible ways of the treatment assignment that are not explained by the observed covariates. By specifying Γ , the MSM assumes a rich set of data generating distributions, which avoids imposing parametric assumptions on how an unobserved confounder interacts with the treatment and outcome.

Under the assumption of an MSM, we will develop CSA in a two-stage approach. In the first stage, we quantify how the uncertainty from unmeasured confounding propagates to the conformal weights. In the second stage, we leverage the uncertainty in the conformal weights to create a valid predictive interval.

3.2 From Confounding Strength to the Conformal Weights

We illustrate that under unmeasured confounding, the predictive interval in Eq. (4) cannot be computed by the observational data, which is the main challenge in applying conformal inference for sensitivity analysis.

The conformal weights in Eq. (3) decompose to two terms. The first term $p(X)/p(X | T =$

$t) = p(T = t)/p(T = t | X)$ can be inferred from data. The second term is,

$$\frac{p(Y(t)|X)}{p(Y(t)|X, T = t)} = p(T = t | X) + \frac{p(Y(t)|X, T = 1 - t)}{p(Y(t)|X, T = t)}p(T = 1 - t | X). \quad (6)$$

Without unconfoundedness, the density ratio on the right hand side of Eq. (6) involves the nonidentifiable distribution $p(Y(t)|X, T = 1 - t)$ of the missing potential outcome.

To deal with this challenge, we transfer the uncertainty from the unknown confounding to the uncertainty of the conformal weights. The nonidentifiable density ratio term in the conformal weights is related to the odds ratio in the MSM. Applying Bayes rule,

$$\begin{aligned} p(T = 1 | X, Y(t)) &= \frac{p(Y(t)|X, T = 1)p(T = 1 | X)}{p(Y(t)|X)} \\ &= 1 / \left(1 + \frac{1 - e(X)}{e(X)} \frac{p(Y(t)|X, T = 0)}{p(Y(t)|X, T = 1)} \right). \end{aligned} \quad (7)$$

Eq. (7) is also known as Tukey's factorization [8, 17, 18].

Based on Tukey's factorization, the following lemma shows that the conformal weight is proportional to the inverse selection score and the density ratio of a potential outcome in the two treatment groups is bounded by the sensitivity parameter.

Lemma 1. (i) For the conformal weights in Eq. (3), we have $w_t(x, y) = p(T = t)/p(T = t | X = x, Y(t) = y)$. (ii) The MSM with parameter Γ equivalently assumes

$$\frac{1}{\Gamma} \leq \frac{p(Y(t) = y | X = x, T = 1)}{p(Y(t) = y | X = x, T = 0)} = \text{OR}(s(x, y), e(x)) \leq \Gamma \quad (8)$$

The sensitivity parameter of the MSM specifies the range of plausible conformal weights.

Lemma 2. *Given an MSM with sensitivity parameter $1 \leq \Gamma < \infty$, the weight function for the weighted conformal prediction in Eq. (3) is bounded by*

$$\left(1 + \frac{1}{\Gamma} \left(\frac{1 - e(x)}{e(x)} \right)^{2t-1} \right) p(T = t) \leq w_t(x, y) \leq \left(1 + \Gamma \left(\frac{1 - e(x)}{e(x)} \right)^{2t-1} \right) p(T = t) \quad (9)$$

Note that the bounds in Eq. (9) are uniform for all y . When $\Gamma = 1$, the upper and lower bounds of the conformal weights are the same. When $\Gamma > 1$, the conformal weights can not be point identified. The range in Eq. (9) represents the weight uncertainty.

3.3 From Conformal Weights to the Predictive Band

We first define a valid predictive band in sensitivity analysis. Then we demonstrate the validity of a predictive interval given a specific sensitivity model. The union of such intervals becomes a valid predictive band for the MSM. Finally, as a practical way to obtain the union set, we propose and solve a constrained quantile optimization problem.

Valid Predictive Bands under Sensitivity Models. By Eq. (8), each selection score $s_t(x, y)$ specifies a missing outcome distribution

$$p^{(s_t)}(Y(t) | X, T = 1 - t) = \text{OR}(s_t(X, Y(t)), e(X))^{1-2t} \cdot p(Y(t) | X, T = t). \quad (10)$$

For a selection score s_t in the collection of sensitivity models $\mathcal{E}(\Gamma)$, the target data in Eq. (1) is generated by a distribution depending on s_t , i.e.,

$$p^{(s_t)}(Y(t) | X) = p(T = t | X) p(Y(t) | X, T = t) + p(T = 1 - t | X) p^{(s_t)}(Y(t) | X, T = 1 - t). \quad (11)$$

With the notation above, the validity of the predictive interval is defined as a worst case guarantee under *all* plausible sensitivity models in $\mathcal{E}(\Gamma)$.

Definition 2. *Under a set of sensitivity models $\mathcal{E}(\Gamma)$, the predictive band for the potential outcome $Y(t)$ with $(1 - \alpha)$ marginal coverage is a band that satisfies*

$$\mathbb{P}_{X, Y(t) \sim p(X)p^{(s_t)}(Y(t)|X)}(Y(t) \in \hat{C}_t(X)) \geq 1 - \alpha, \quad (12)$$

for any data generating distribution $\mathbb{P}_0$ with the corresponding selection score $s_t \in \mathcal{E}(\Gamma)$.

The goal is to construct a predictive interval that satisfies Def. 2 with $\mathcal{E}(\Gamma)$ defined by the MSM. Our first step is to create a valid predictive interval under a sensitivity model.

Coverage Guarantees for a Fixed Sensitivity Model. Given a fixed $s_t \in \mathcal{E}(\Gamma)$, plugging Eq. (11) to Eq. (3), the conformal weight $w_t^{(s_t)}(x, y)$ becomes a function of s_t . Let $w_i^{(s_t)} = w_t^{(s_t)}(Z_i)$ be the conformal weight for Z_i , the predictive band in Eq. (4) becomes

$$\hat{C}^{(s_t)}(x) = \{y \in \mathbb{R} : V(x, y) \leq Q_{1-\alpha}(\sum_{i=1}^n p_i^{(s_t)} \delta_{V_i} + p_{n+1}^{(s_t)} \delta_{\infty})\}, \quad (13)$$

where $\{p_i^{(s_t)}\}_{i=1}^{n+1}$ normalizes $\{w_i^{(s_t)}\}_{i=1}^{n+1}$ and n is the number of data points.

In the following theorem, we show that $\hat{C}^{(s_t)}(x)$ has a valid coverage given a specific sensitivity model s_t , when the propensity score is either known or estimable.

Lemma 3. *Under SUTVA and strong overlap, for a selection score $s_t \in \mathcal{E}(\Gamma)$, we have*

(1) With a known propensity score $e(X)$, the predictive band in Eq. (13) has coverage

$$1 - \alpha \leq \mathbb{P}_{X, Y(t) \sim p(X)p^{(s_t)}(Y(t)|X)}(Y(t) \in \hat{C}_t^{(s_t)}(X)) \leq 1 - \alpha + \frac{\Gamma/\eta}{n + \Gamma/\eta} \quad (14)$$

(2) With an estimated propensity score $\hat{e}(X)$, if $\eta < \hat{e}(X_i) < 1 - \eta$ almost surely for a constant $\eta \in (0, 0.5)$, the predictive band $\hat{C}^{(s_t)}(x)$ in Eq. (13) has a coverage probability

$$1 - \alpha - \Delta \leq \mathbb{P}(Y(t) \in \hat{C}^{(s_t)}(X)) \leq 1 - \alpha + \frac{\Gamma/\eta}{n + \Gamma/\eta} + \Delta, \quad (15)$$

$$\Delta = \frac{\Gamma}{2} p(T = t) \mathbb{E}_{x \sim p(X|T=t)} \left| \frac{1}{\hat{e}(x)^t (1 - \hat{e}(x))^{1-t}} - \frac{1}{e(x)^t (1 - e(x))^{1-t}} \right|.$$

With a known propensity score, Eq. (14) demonstrates that the coverage of the predictive band $\hat{C}^{(s_t)}(x)$ is valid and is close to the nominal level. The closeness depends on the overlapping and confounding strength. When the estimated propensity score $\hat{e}(X)$ differs from the true propensity score $e(X)$, as shown in Eq. (15), the coverage probability might have an extra slack quantity Δ . The reason for $\hat{e}(X) \neq e(X)$ could be the estimation error from the finite sample or the inference error from a misspecified treatment model.

Union Method. Based on the predictive band $\hat{C}^{(s_t)}(x)$, we propose a union method that achieves the valid coverage under the MSM. That is, we now consider the worst case coverage for all sensitivity models $s_t \in \mathcal{E}(\Gamma)$.

Proposition 1. Suppose the predictive interval $\hat{C}^{(s_t)}(X) = [L^{(s_t)}(X), U^{(s_t)}(X)]$ satisfies

$$\mathbb{P}_{X, Y(t) \sim p(X)p^{(s_t)}(Y(t)|X)}(Y(t) \in \hat{C}_t^{(s_t)}(X)) \geq 1 - \alpha \quad (16)$$

for each $s_t \in \mathcal{E}(\Gamma)$. Then let $L = \inf_{s_t \in \mathcal{E}(\Gamma)} L^{(s_t)}$ and $U = \sup_{s_t \in \mathcal{E}(\Gamma)} U^{(s_t)}$, the interval $\hat{C}_t^\Gamma(X) = [L, U] = \cup_{s_t \in \mathcal{E}(\Gamma)} [L^{(s_t)}, U^{(s_t)}]$ is a predictive interval for $Y(t)$ with at least $(1 - \alpha)$ coverage under the sensitivity models $\mathcal{E}(\Gamma)$.

Prop. 1 states that to obtain a valid predictive interval for the MSM, we can first compute the predictive interval under a specific sensitivity model as in Eq. (13), then take the union set by finding the extreme end points of such intervals over all the sensitivity models. By Eq. (13), finding the extreme end points is equivalent to solving

$$\max_{s_t \in \mathcal{E}(\Gamma)} Q_{1-\alpha} \left(\sum_{i=1}^n p_i^{(s_t)}(Z_{1:n}, (X, y)) \delta_{v_i} + p_{n+1}^{(s_t)}(Z_{1:n}, (X, y)) \delta_{\infty} \right). \quad (17)$$

However, in practice, it is difficult to directly search over the sensitivity models in $\mathcal{E}(\Gamma)$, because the elements of $\mathcal{E}(\Gamma)$ are not defined parametrically.

Quantile Optimization with Linear Constraints. To operationalize Eq. (17), we can search over the conformal weights instead of the sensitivity models. As Eq. (17) shows, a sensitivity model influences the predictive band only through the conformal weights.

In § 3.2, we find the range of conformal weights under an MSM. Denote the upper and lower bounds of the conformal weights in Lem. 2 as

$$w_{lo}^\Gamma(x) := \left(1 + \frac{1}{\Gamma} \left(\frac{1-e(x)}{e(x)} \right)^{2t-1} \right) p(T=t), \quad w_{hi}^\Gamma(x) := \left(1 + \Gamma \left(\frac{(1-e(x))}{e(x)} \right)^{2t-1} \right) p(T=t). \quad (18)$$

Algorithm 1: CSA for Estimating an Unobserved Potential Outcome

Input: Data $\mathcal{Z} = (X_i, Y_i, T_i)_{i=1}^N$, where Y_i is missing if $T_i = 1 - t$; level α , sensitivity parameter Γ , target point covariates X .

Step I: Preliminary processing

- 1: Split the data into two folds $\mathcal{Z}_{\text{pre}}$ and $\mathcal{Z}_{\text{cal}}$; let $\mathcal{J}_{\text{pre}} = \{i : Z_i \in \mathcal{Z}_{\text{pre}}, T_i = t\}$,
 $\mathcal{J}_{\text{cal}} = \{i : Z_i \in \mathcal{Z}_{\text{cal}}, T_i = t\}$
- 2: Estimate propensity score $\hat{e}(x)$ on $\mathcal{Z}_{\text{pre}}$
- 3: Estimate predictor $\hat{\mu}(\cdot)$ on $\{X_i, Y_i\}_{i \in \mathcal{J}_{\text{pre}}}$

Step II: Predictive interval for $Y_i(t)$ at the target point

- 1: Compute nonconformity scores $\mathcal{V} = \{V_i\}_{i \in \mathcal{J}_{\text{cal}}}$, $\tilde{\mathcal{J}}_{\text{cal}} = \mathcal{J}_{\text{cal}} \cup \{N+1\}$, $V_{N+1} = \infty$
- 2: Compute the bounds $(w_{lo}^\Gamma(X_i), w_{hi}^\Gamma(X_i))$ for $i \in \tilde{\mathcal{J}}_{\text{cal}}$ by Eq. (18), $X_{N+1} = X$;
- 3: For $i \in \tilde{\mathcal{J}}_{\text{cal}}$, initialize the weights $w_i = w_{lo}^\Gamma(X_i)$
- 4: Sort $\mathcal{V}$ in ascending order and re-label the ordered elements from 1 to $|\mathcal{V}|$
- 5: Re-label $\{w_i\}_{i \in \tilde{\mathcal{J}}_{\text{cal}}}$, $\{X_i\}_{i \in \tilde{\mathcal{J}}_{\text{cal}}}$ according to the labels of the sorted $\mathcal{V}$; set $k = |\mathcal{V}|$
- 6: **do**

$$w_k \leftarrow w_{hi}^\Gamma(X_k)$$

$$\text{Compute normalized weights } p_i = \frac{w_i}{\sum_{j=1}^{|\mathcal{V}|} w_j}, \text{ for } i \in \{1, 2, \dots, |\mathcal{V}|\}$$

$$k \leftarrow k - 1$$

$$\text{while } \sum_{i=k+1}^{|\mathcal{V}|} p_i < \alpha$$

Output: Compute $\hat{C}_t^\Gamma(X)$ by Eq. (20) with $\hat{Q}(Z_{1:n}, X) = V_{k+1}$

Then the optimization in Eq. (17) simplifies to a constrained optimization problem,

$$\begin{aligned}
 & \max_{w_{1:n+1}} \quad Q_{1-\alpha} \left(\sum_{i=1}^n p_i \delta_{V_i} + p_{n+1} \delta_\infty \right). \\
 & \text{subject to} \quad p_i = \frac{w_i}{\sum_{i=1}^{n+1} w_i}, \quad 1 \leq i \leq n+1 \\
 & \quad w_{lo}^\Gamma(X_i) \leq w_i \leq w_{hi}^\Gamma(X_i), \quad 1 \leq i \leq n, \quad w_{lo}^\Gamma(X) \leq w_{n+1} \leq w_{hi}^\Gamma(X),
 \end{aligned} \tag{19}$$

where the conformal weights $\mathbf{w} = (w_1, \dots, w_n, w_{n+1})$ are the optimizing variables. For notational convenience, we suppress the superscript t and denote $w_i = w(X_i, Y_i)$ for $1 \leq i \leq n$, and $w_{n+1} = w(X, y)$.

An efficient algorithm to solve Eq. (19) can be designed by characterizing its optima.

Proposition 2. *Without loss of generality, suppose $X_{1:n}$ are labeled such that the nonconformity*

scores are ordered, $V_1 \leq V_2 \leq \dots \leq V_n < V_{n+1} = \infty$, and let

$$\hat{k} = \max \left\{ k \in [n+1] : \text{for } k \leq j \leq n, w_j = w_{hi}^\Gamma(X_j), w_{n+1} = w_{hi}^\Gamma(X), \sum_{j=k}^{n+1} p_j \geq \alpha; \right. \\ \left. \text{for } j < k, w_j = w_{lo}^\Gamma(X_j) \right\}$$

Then the optima of Eq. (19) is $\hat{\mathbf{w}} = (w_{lo}^\Gamma(X_1), \dots, w_{lo}^\Gamma(X_{\hat{k}-1}), w_{hi}^\Gamma(X_{\hat{k}}), \dots, w_{hi}^\Gamma(X_n), w_{hi}^\Gamma(X))$.

Furthermore, the optimal objective value $\hat{Q}(Z_{1:n}, X; \Gamma, \alpha, t) = V_{\hat{k}}$.

According to Prop. 2, to solve Eq. (19), we first sort $V_{1:n+1}$ in ascending order and initialize the conformal weights $w_i = w_{lo}^\Gamma(X_i)$ for $1 \leq i \leq n$, $w_{n+1} = w_{lo}^\Gamma(X)$. Then we iteratively flip w_k from $w_{lo}^\Gamma(X_k)$ to $w_{hi}^\Gamma(X_k)$ for $k = n+1, n, \dots, 1$ until $\sum_{i=k}^{n+1} p_i \geq \alpha$. Supposing the iteration stops at $k = m$, the optimal objective value in Eq. (19) is uniquely determined as $\hat{Q}(Z_{1:n}, X; \Gamma, \alpha, t) = V_m$.

To sum up, by Lem. 3, the interval $\hat{C}_t^{(s_t)}(x)$ in Eq. (13) satisfies the coverage of Eqs. (14) and (15). With $\hat{Q}$ given in Prop. 2,

$$\hat{C}_t^\Gamma(x) = \{y \in \mathbb{R} : V(x, y) \leq \hat{Q}(Z_{1:n}, x; \Gamma, \alpha, t)\} \quad (20)$$

is the union set $\cup_{s_t \in \mathcal{S}(\Gamma)} \hat{C}_t^{(s_t)}(x)$. According to Prop. 1, $\hat{C}_t^\Gamma(x)$ is a valid predictive interval of a missing counterfactual outcome under the MSM.

Theorem 1. Under the condition of Lem. 3, with known propensity score $e(X)$, the predictive band $\hat{C}_t^\Gamma(x)$ in Eq. (20) has nominal coverage $1 - \alpha$ of $Y(t)$ under the collection of sensitivity models $\mathcal{E}(\Gamma)$; with an estimated $\hat{e}(X)$, the coverage is at least to the lower bound in Eq. (15).

Implementation and Computational Cost. We compute the predictive interval by adopting the framework of split conformal prediction [34, 41]. Classic conformal inference fits the predictive function using the leave-one-out observed data to ensure the exchangeability and has to fit a predictor multiple times. Split conformal prediction reduces the computational cost by randomly splitting the observed data into a preliminary set and a calibration set. The prediction model is fitted on the preliminary set for one time, set as fixed, and used to compute the nonconformity scores on the calibration set and target set.

For CSA, the predictive interval in Eq. (20) can be computed analytically on top of a specific conformal inference algorithm. As an example, for the split conformal inference with nonconformity score $V_i = |Y_i - \hat{\mu}(X_i)|$ [35], where $\hat{\mu}(\cdot)$ is the mean response function, Eq. (20) becomes $\hat{C}_t^\Gamma(x) = [\hat{\mu}(x) - \hat{Q}(Z_{1:n}, x; \Gamma, \alpha), \hat{\mu}(x) + \hat{Q}(Z_{1:n}, x; \Gamma, \alpha)]$. For split conformal quantile regression with nonconformity score $V_i = \max\{\hat{q}_{\alpha/2}(X_i) - Y_i, Y_i - \hat{q}_{1-\alpha/2}(X_i)\}$ [37, 44], where $\hat{q}(\cdot)$ is the conditional quantile function, Eq. (20) becomes $\hat{C}_t^\Gamma(x) = [\hat{q}_{\alpha/2}(x) - \hat{Q}(Z_{1:n}, x; \Gamma, \alpha), \hat{q}_{1-\alpha/2}(x) + \hat{Q}(Z_{1:n}, x; \Gamma, \alpha)]$. The full algorithm is summarized in Alg. 1.

For each target unit, to solve the optimization in Eq. (19), the computational complexity is $\mathcal{O}(mn)$ if the loop ends in m iterations and the worst-case complexity is $\mathcal{O}(n^2)$. When the target coverage $1 - \alpha$ is high, m is close to 1 and the total computation time is close to the optimal rate that is needed to evaluate the objective function for one time. Other computations are sorting $V_{1:n+1}$ and fitting the treatment and outcome models, which can be shared by different target units. Therefore, CSA is highly efficient, inducing little extra computation comparing to the conformal prediction under unconfoundedness.

3.4 Predictive Band for the Individual Treatment Effect

We now develop a sensitivity analysis for the ITE of a target unit, for which both potential outcomes are unobserved. Let the covariates of a target unit be X . Using the data of the treatment group t , by Alg. 1, we can construct an interval $\hat{C}_t^\Gamma(X) = [L_t^\Gamma(X), U_t^\Gamma(X)]$ which has $1 - \alpha_t$ coverage of $Y(t)$ under the sensitivity models $\mathcal{E}(\Gamma)$. Let $\hat{C}^\Gamma(X) = [L_1^\Gamma(X) - U_0^\Gamma(X), U_1^\Gamma(X) - L_0^\Gamma(X)]$ and $\alpha_1 + \alpha_0 = \alpha$. By the Bonferroni correction,

$$\mathbb{P}(Y(1) - Y(0) \in \hat{C}^\Gamma(X)) \geq 1 - \mathbb{P}(Y(1) \notin \hat{C}_1^\Gamma(X) \text{ or } Y(0) \notin \hat{C}_0^\Gamma(X)) \geq 1 - \alpha. \quad (21)$$

So the predictive interval $\hat{C}^\Gamma(X)$ has the desired coverage. Though computationally simple, the Bonferroni method might produce overly conservative interval $\hat{C}^\Gamma(X)$ for the ITE, because the coverage $1 - \alpha_t$ for each potential outcome is higher than $1 - \alpha$.

To mitigate this problem, we follow [37] and develop a nested approach. The idea is to first randomly sample a subset of data as the validation set (indexed by $\mathcal{J}_{\text{val}}$) and set the rest of the observed data as the non-validation set. For each individual $i \in \mathcal{J}_{\text{val}}$, let $\hat{C}^\Gamma(X_i) = \hat{C}_1^\Gamma(X_i) - Y_i(0)$ if $T_i = 0$ and $\hat{C}^\Gamma(X_i) = Y_i(1) - \hat{C}_0^\Gamma(X_i)$ if $T_i = 1$. The coverage probability decomposes as

$$\begin{aligned} \mathbb{P}(Y_i(1) - Y_i(0) \in \hat{C}^\Gamma(X_i)) &= \mathbb{P}(T_i = 1) \mathbb{P}(Y_i(0) \in \hat{C}_0^\Gamma(X_i) | T_i = 1) \\ &\quad + \mathbb{P}(T_i = 0) \mathbb{P}(Y_i(1) \in \hat{C}_1^\Gamma(X_i) | T_i = 0). \end{aligned}$$

If the interval $\hat{C}_t^\Gamma(X_i)$ has a coverage probability of $Y_i(t)$ higher than $1 - \alpha$, the coverage probability of $\hat{C}^\Gamma(X)$ for the ITE is also higher than $1 - \alpha$. The dataset $\tilde{\mathcal{D}} = \{X_i, \hat{C}^\Gamma(X_i)\}_{i \in \mathcal{J}_{\text{val}}}$

Algorithm 2: CSA for the ITE estimation with Nested Method

- 1 **Input:** Data $(X_i, T_i, Y_i(T_i))_{i=1}^N$, level α , sensitivity parameter Γ , target covariates X
 - 2 **Step I: Preliminary processing**
 - 1: Split the data into two folds, indexed by $\mathcal{J}$ and $\mathcal{J}_{\text{val}}$
 - 2: Denote the treated and control group data in $\mathcal{J}$ ($\mathcal{J}_{\text{val}}$) as $\mathcal{J}^t$, $\mathcal{J}^c$ ($\mathcal{J}_{\text{val}}^t$, $\mathcal{J}_{\text{val}}^c$) respectively
 - Step II: Predictive interval for the ITE τ_i at the target point**
 - 1: Run Alg. 1 with data in $\mathcal{J}$, $\mathcal{J}_{\text{pre}} \cup \mathcal{J}_{\text{cal}} = \mathcal{J}^t$ and for each target point $i \in \mathcal{J}_{\text{val}}^c$; the bounds of weight $w_{lo}^\Gamma(x) = \hat{e}(x)/(\Gamma(1 - \hat{e}(x)))$ and $w_{hi}^\Gamma(x) = \Gamma\hat{e}(x)/(1 - \hat{e}(x))$; return $\hat{C}_1^\Gamma(X_i)$
 - 2: For $i \in \mathcal{J}_{\text{val}}^c$, compute $\hat{C}^\Gamma(X_i) = \hat{C}_1^\Gamma(X_i) - Y_i(0)$
 - 3: Run Alg. 1 with data in $\mathcal{J}$, $\mathcal{J}_{\text{pre}} \cup \mathcal{J}_{\text{cal}} = \mathcal{J}^c$ and for each target point $i \in \mathcal{J}_{\text{val}}^t$; the bounds of weight $w_{lo}^\Gamma(x) = (1 - \hat{e}(x))/(\Gamma\hat{e}(x))$ and $w_{hi}^\Gamma(x) = \Gamma(1 - \hat{e}(x))/\hat{e}(x)$; return $\hat{C}_0^\Gamma(X_i)$
 - 4: For $i \in \mathcal{J}_{\text{val}}^t$, compute $\hat{C}^\Gamma(X_i) = Y_i(1) - \hat{C}_0^\Gamma(X_i)$
 - 5: Learn the predictive function $X \rightarrow \hat{C}^\Gamma(X)$ with training data $\{X_i, \hat{C}^\Gamma(X_i)\}_{i \in \mathcal{J}_{\text{val}}}$; predict $\hat{C}^\Gamma(X)$ for the target data with the learned predictive function
 - Output:** $\hat{C}^\Gamma(X)$
-

with $X_i \stackrel{i.i.d.}{\sim} p(X)$ can be used to fit a predictive function $X \mapsto \hat{C}^\Gamma(X)$, which maps to a predictive interval $\hat{C}^\Gamma(X)$ for a data point with covariates $X \sim p(X)$. The mapping can be two regressions with the input as X_i , $i \in \mathcal{J}_{\text{val}}$ and the output as the upper and lower end points of $\hat{C}^\Gamma(X_i)$ respectively. This becomes a relatively easy in-sample prediction problem.

We use Alg. 1 to obtain the predictive intervals $\hat{C}_t^\Gamma(X_i)$ for the data points in the validation set. The training data are from the treatment group $1 - t$ in the non-validation set and the target data are from the treatment group t in the validation set, $t = 0, 1$. Similar to Lem. 2, the bounds of the conformal weights $w_t(x, y)$ can be computed as

$$\frac{p(X | T = t)p(Y(t) | X, T = t)}{p(X | T = 1 - t)p(Y(t) | X, T = 1 - t)} \in \left[\frac{1}{\Gamma} \left(\frac{e(x)}{1 - e(x)} \right)^{2t-1}, \Gamma \left(\frac{e(x)}{1 - e(x)} \right)^{2t-1} \right]. \quad (22)$$

The algorithm is summarized in Alg. 2.

3.5 Sharpness via Covariates Balancing

Notion of sharpness. Consider the sharpness on the sensitivity models. A sharp sensitivity model should be data compatible and not have observational implications [16, 17]. For the MSM, we define the sharp MSM as

$$\mathcal{E}^*(\Gamma) = \{s_t(x, y) \in \mathcal{E}(\Gamma) : \int p^{(s_t)}(Y(1) = y | X = x, T = 0) dy = 1\}, \quad (23)$$

where $\mathcal{E}(\Gamma)$ is defined in Eq. (5) and $p^{(s_t)}(Y(1) = y | X, T = 0)$ is the induced counterfactual distribution in Eq. (10). The sharp MSM is a subset of the selection scores in $\mathcal{E}(\Gamma)$ that induces proper counterfactual density. By Lem. 1, for example, $\mathcal{E}^*(\Gamma)$ excludes the selection scores with an odds ratio $\text{OR}(s_t(X, Y(t)), e(X))$ uniformly greater (or less than) one.

Recent work improves the sharpness of the MSM in estimating the ATE [16, 63]. Dorn and Guo [16] shows that the selection score s_1 is data compatible if it satisfies the constraint $\mathbb{E}[\frac{T}{s_1(X, Y(1))} | X] = 1$ (the unobserved confounder in Dorn and Guo [16] is replaced with $Y(1)$). This constraint is equivalent to the constraint in Eq. (23) as shown in Prop. 3, Appendix B. We consider estimating $Y(1)$ for simplicity and the discussion applies to $Y(0)$ similarly. The derivation and computation details of this section are presented in Appendix B.

Sharpness by Covariates Balancing. The integral constraint in Eq. (23) is easy to interpret but is infeasible to compute because we often only observe one outcome value for a given X . However, the constraint, equivalent to $\mathbb{E}[\frac{T}{s_1(X, Y(1))} | X] = 1$ by Prop. 3, indicates

that for an arbitrary vector-valued function $g(X)$,

$$\mathbb{E}\left[\frac{g(X_i)T_i}{s_1(X_i, Y_i(1))}\right] = \mathbb{E}_{X_i}\left[g(X_i)\mathbb{E}\left[\frac{T_i}{s_1(X_i, Y_i(1))} \mid X_i\right]\right] = \mathbb{E}[g(X_i)]. \quad (24)$$

By enforcing the condition in Eq. (24) with different covariates function $g(X)$, we can reduce $\mathcal{E}(\Gamma)$ close to $\mathcal{E}^*(\Gamma)$. Since Eq. (24) holds similarly for the control group, it represents the covariate balancing between the treated and control group. This means encouraging the covariate balancing improves the sharpness of the MSM.

We incorporate the balancing condition Eq. (24) to CSA. By Lem. 1, we transform the condition in Eq. (24) to the constraints in the quantile optimization in Eq. (19). Specifically, we optimize Eq. (19) with additional constraints

$$\frac{1}{N_t} \sum_{i: T_i=t} g_k(X_i) w_i^\Gamma = \frac{1}{N} \sum_{i=1}^N \frac{T_i^t (1 - T_i)^{1-t}}{\hat{e}(X_i)^t (1 - \hat{e}(X_i))^{1-t}} g_k(X_i), \quad 1 \leq k \leq K, \quad (25)$$

where $g_k(X)$, $k \in \{1, 2, \dots, K\}$ are the balancing functions specified by the researcher. We call this algorithm conformalized sharp sensitivity analysis (CSSA) and summarize it in Alg. 3, Appendix B. The optima of Eq. (19) with additional constraints Eq. (25) is smaller than that of Eq. (19), thereby reducing the size of predictive band for the ITE estimates. In simulations, we find choosing $g(X) = \hat{e}(X)$ effectively improves the sharpness. Including additional balancing functions such as the quantile function of the outcome distribution [16], the identity function, and the derivative of the estimated propensity score [26] may further reduce $\mathcal{E}(\Gamma)$ to $\mathcal{E}^*(\Gamma)$.

Finally, though the sharpness is necessary for claiming a causal estimate to be sensitive to unmeasured confounding, sensitivity analysis is often applied to corroborate a nonzero

causal effect identified in the primary analysis. From this perspective, the deviation from the sharpness might be interpreted as conservativeness [12, 14, 56]. For the ITE estimation, such conservativeness increases our confidence that a positive (or negative) ITE is indeed robust to unmeasured confounding when the sensitivity analysis suggests so.

4 Practical Considerations of the Algorithms

We now discuss how to interpret the coverage probability of CSA, choose the conformal inference algorithms, calibrate the sensitivity parameter, and evaluate the ITE estimation.

Marginal and Conditional Coverage. The probability in the coverage statement of CSA is over both the covariates and the outcomes. Hence, the coverage guarantee should be interpreted in a marginal way instead of a conditional way. In other words, suppose the estimand τ is either the missing potential outcome $Y(t)$ or the ITE $Y(1) - Y(0)$. $\mathbb{P}(\tau \in \hat{C}(X))$ means that if we construct a predictive band $\hat{C}(X)$ for a unit randomly sampled as the target, the probability that $\hat{C}(X)$ captures τ is at least $1 - \alpha$. The randomness is over both the covariates and the potential outcomes.

The marginal coverage measures the quality of prediction *averaged* over the target units. It does not guarantee the coverage of τ for a given *fixed* target unit. The loss of conditional coverage is unavoidable if no distributional assumption is imposed on the observed data [4]. However, it is possible for an algorithm with marginal coverage to achieve conditional coverage asymptotically, under additional regularization conditions, or to satisfy a relaxed conditional coverage definition [4, 37]. We refer to Barber et al. [4] for a detailed discussion on the definitions, limitations, and connections of different types of coverages.

Choice of Conformal Inference Methods. CSA is compatible with a variety of conformal inference algorithms. The main components of a conformal inference are the prediction model and the corresponding nonconformity score [3]. The choice of conformal inference algorithm hinges on the properties of the underlying outcome distribution, such as the homogeneity, skewness and multimodality. A good choice of inference method leads to high interpretability and small predictive interval. For example, to estimate the ITE, the predictive band as a single interval may be more interpretable than a nonconvex set [52]; an algorithm capturing individual heterogeneity might produce a shorter interval and more informative estimate [44]. Nevertheless, the coverage validity of the predictive band does not depend on the choice of conformal inference method.

Calibration of the Sensitivity Parameter. In the MSM, the sensitivity parameter Γ quantifies the confounding strength. While setting Γ to a proper value requires domain knowledge, the observed data can provide useful reference [25, 27, 31]. In the definition of MSM, Γ measures the effect of knowing a potential outcome on the treatment assignment. We can view the potential outcome as a type of covariate [43] and compute the effect of an observed covariate on the treatment assignment. Specifically, we compute $\Gamma_{ij} = \text{OR}(e(X_i), e((X_{\setminus j})_i))$ as the effect of the j -th covariates on the treatment assignment of the i -th unit, where $e(X_{\setminus j})$ is the propensity score estimated without the j -th covariates. The domain experts can assess a plausible magnitude of Γ by referring to the magnitude of $\{\Gamma_{ij}\}_{i,j}$. Here, approximating $e(X_i)$ by $e((X_{\setminus j})_i)$ may introduce conservativeness to the estimated confounding strength. We refer to [12, 56] for a discussion on this issue.

Evaluating the Predictive Band of an ITE. When evaluating the ITE estimation by simulations, we need to sample the true ITEs, which requires generating random samples of

all the potential outcomes. To generate $Y_i(t) \sim p(Y(t)|X_i)$, we can sample $T_i \sim \text{Bern}(e(X_i))$ and $Y_i(t) \sim p(Y(t)|X_i, T_i)$. However, when $T_i = 1 - t$, generating $Y_i(t)$ depends on a sensitivity model, which is not defined parametrically in the MSM. To solve this problem, we propose a rejection sampling method to generate counterfactual samples. The details of this sampling method is presented in Appendix C.

5 Empirical Studies

In this section, we answer the following questions using synthetic data: can CSA provide a desired coverage? Are the predictive intervals of the ITE overly conservative? How do the predictive intervals of ITE compare to the interval estimates of population-level causal estimands? Finally, we illustrate how to apply CSA in an observational study. Implementation and examples in this paper are available at <https://github.com/mingzhang-yin/Conformal-sensitivity-analysis>.

5.1 CSA for Estimating Counterfactual Outcome

Following the synthetic data generation in [37, 60], the potential outcome $Y_i(1)$ is from

$$\begin{aligned} Y_i(1) &= \mathbb{E}[Y_i(1) | T_i = 1, X_i] + \epsilon_i, \quad \epsilon_i \sim \mathcal{N}(0, \sigma^2); \\ \mathbb{E}[Y_i(1) | T_i = 1, X_i] &= f(X_{i1})f(X_{i2}), \quad f(x) = \frac{2}{1 + \exp(-5(x - 0.5))}, \end{aligned} \tag{26}$$

where the covariates $X_i = (X_{i1}, \dots, X_{id})^\top$, $X_{ij} \sim \text{Unif}(0, 1)$. The propensity score is $e(X_i) = \frac{1}{4}(1 + \beta_{2,4}(1 - X_{i1}))$, where $\beta_{2,4}$ is the CDF of beta distribution with parameters (2, 4). We

Figure 1: Distribution of $Y(1)$ for the synthetic data. Given the covariates X , Obs denotes the distribution $p(Y(1) | T = 1, X)$ in the observed group. Cf denotes the distribution of counterfactual outcome $p(Y(1) | T = 0, X)$. The three plots correspond to different sensitivity models in $\mathcal{E}(\Gamma)$.

generate $n = 3000$ training data points $(X_i, Y_i(1))_{i:T_i=1}$ with dimension of covariates $d = 20$. We take 75% of the training data as the preliminary set and the rest as the calibration set. For a calibration set with n_{cal} data points, the coverage probability of a new target data follows distribution $\text{Beta}(n_{\text{cal}} + 1 - \lfloor (n_{\text{cal}} + 1)\alpha \rfloor, \lfloor (n_{\text{cal}} + 1)\alpha \rfloor)$ [2]. We set the nominal level $1 - \alpha = 0.8$ in this simulation. We consider two settings: in the homoscedastic case, $\sigma \equiv 1$, and in the heteroscedastic case, $\sigma \sim \text{Unif}(0.5, 1.5)$.

For CSA, we use the split conformal prediction with mean prediction [35, 41] and conformal quantile regression [44], denoted as CSA-M and CSA-Q respectively. We implement CSSA in § 3.5 with mean prediction, denoted as CSSA-M and set the balancing constraints $g(X_i)$ in Eq. (25) as the estimated propensity score $\hat{e}(X_i)$. We report the ITE estimated under no unobserved confounding (NUC) as a benchmark, denoted as ITE-NUC [37]. For all conformal inference methods, we use the random forest [7] as the regression function.

We first assume the baseline outcome $Y(0) \equiv 0$. The estimation of ITE then reduces to estimating a single potential outcome $Y(1)$. Fig. 1 demonstrates several counterfactual distributions $p(Y(1)|X, T = 0)$ that are generated by the rejection sampling method de-

scribed in § 4 with sensitivity models in $\mathcal{E}(\Gamma)$, $\Gamma = 4$. Unmeasured confounding is reflected as the difference between $p(Y(1)|X, T = 0)$ and $p(Y(1)|X, T = 1)$. Fig. 1 show that the nonparametric MSM probes a variety of potential violations to unconfoundedness. We find the counterfactual distribution in the middle of Fig. 1 results in the lowest coverage among the counterfactual cases in Fig. 1 due to the mismatch of the high density regions between the observed and counterfactual distributions. Since the interval estimate by CSA has coverage guarantee for any sensitivity model in $\mathcal{E}(\Gamma)$, we report the results with counterfactual in the middle of Fig. 1 as an adversarial case to test the validity of CSA.

In Appendix E table 2, we compare the interval estimates of CSA with those by a sensitivity analysis of the ATE [63] and an estimation of the CATE [11]. The (sub)population-based interval estimates underestimate the individual-level uncertainty and undercover the true ITE. This validates the necessity of individual-level sensitivity analysis.

Fig. 2 illustrates the properties of the estimates by CSA and CSSA. The top panels show the empirical coverage under different confounding strengths. The empirical coverage is computed as $(\sum_{i=1}^m \mathbb{1}[Y_i(1) \in \hat{C}_1^\Gamma(X_i)]) / m$ for $m = 10,000$ target points. We observe that ITE-NUC achieves the target coverage under unconfoundedness ($\Gamma = 1$) but its coverage decreases as the confounding strength increases. In contrast, CSA-M and CSA-Q have valid coverage across all levels of Γ . The coverage of CSSA-M is above the nominal level and is lower than that of CSA-M, which demonstrate its validity and sharpness. For $\Gamma \leq 2.5$, CSSA-M has coverage centered at the nominal level which suggests its sharpness.

The middle panels in Fig. 2 show the average interval length on the target units. We observe that the length of ITE-NUC remains the same as Γ changes. In comparison, the length of CSA and CSSA methods scales up with Γ , reflecting an increased uncertainty with

stronger unmeasured confounding. On average, CSA-M produces shorter intervals than CSA-Q when the data is homoscedastic, and they have similar interval lengths when the data are heteroscedastic. CSSA-M creates shorter interval than CSA-M for all $\Gamma > 1$.

To further analyze the sharpness of CSA prediction, we manually shrink the length of the predictive intervals by a constant factor for all the units and keep the interval centers unchanged. The maximum shrinkage factor without losing the target coverage reflects the sharpness. From the bottom panels in Fig. 2, we observe that the empirical coverage drops below the $1 - \alpha$ level if the shrink factor is above 10% and 15% for homoscedastic and heteroscedastic data, respectively. The maximal shrinkage factor being low means CSA methods produce relatively sharp intervals.

In Fig. 3, we visualize the ITE estimates for multiple individuals. For each unit i , we compute the difference between the predictive interval and the true ITE as $\hat{C}^\Gamma(X_i) - \tau_i$ which contains 0 if and only if $\hat{C}^\Gamma(X_i)$ contains τ_i . For each method, we consider two confounding strengths $\Gamma \in \{1, 3\}$, set the coverage $1 - \alpha = 0.8$, and randomly sample 70 units. When there is unmeasured confounding, ITE-NUC produces a large fraction of intervals that do not contain the ITE, but CSA methods have a small fraction of undercovered intervals on average (less than $\alpha = 0.2$) for both confounding strengths.

Figure 2: **Top:** Empirical coverage of the ITE. Dashed line denotes the target coverage level. Across Γ , the predictive intervals produced by CSA and CSSA methods reach the valid coverage. CSSA-M improves sharpness over CSA-M. **Middle:** The average length of the predictive intervals. The interval lengths by CSA and CSSA methods increase with Γ , reflecting increased uncertainty under unmeasured confounding. **Bottom:** The sharpness of CSA. The maximal shrinkage factor that preserves the nominal coverage is low, which suggests CSA methods are relatively sharp. The error bar is by 100 independent trials.

5.2 CSA for the ITE Estimation

We further study when both $Y_i(1)$ and $Y_i(0)$ of a unit are unobserved. The outcome $Y(1)$ is generated according to Eq. (26) and the observed outcome $Y(0)$ is generated by

$$\begin{aligned} Y_i(0) &= \mathbb{E}[Y_i(0) | T_i = 0, X_i] + \epsilon_i, \quad \epsilon_i \sim \mathcal{N}(0, \sigma^2); \\ \mathbb{E}[Y_i(0) | T_i = 0, X_i] &= f(X_{i1})f(X_{i2}) + \frac{10 \sin(X_{i3})}{1 + \exp(-5X_{i3})}, \end{aligned} \tag{27}$$

where $f(x)$ follows the definition in Eq. (26). The construction of the counterfactual distribution $p(Y(0)|X = x, T = 0)$ is similar to the single missing outcome case, the details of which are in Appendix E. We analyze the Bonferroni correction and the nested approach wrapped around CSA-M, CSA-Q and ITE-NUC. For the nested approach, following Lei and Candès [37], we learn the mapping $X \mapsto \hat{C}^\Gamma(X)$ in § 3.4 by fitting 40% quantile of the lower end point and 60% quantile of the upper end point with quantile forest function in R package grf.

The results of coverage and interval length are shown in Appendix E Fig. 7. The Bonferroni correction provides conservative interval estimates. In comparison, the interval estimation of CSA methods with the nested method are less conservative. Similar to § 5.1, ITE-NUC has poor coverage when the unconfoundedness is violated, but CSA methods have valid coverages across different levels of confounding strength.

Figure 3: The figure reports predictive intervals for random individuals with confounding strengths. Each interval is the predictive interval minus the true ITE for one individual. Solid intervals contain 0 and dashed intervals do not contain 0. When $\Gamma = 1$, all methods have similar coverage at $1 - \alpha = 0.8$; when $\Gamma = 3$, ITE-NUC has high miscoverage while CSA maintains a valid coverage.

5.3 Application: ITEs of Fish Consumption on Blood Mercury

Finally, we illustrate the application of CSA using survey responses from the National Health and Nutrition Examination Survey (NHANES) 2013-2014. The causal question we study is the effect of high fish consumption on individuals' blood mercury levels when there is potentially unmeasured confounding.

Following Zhao et al. [63], we define the high fish consumption as more than 12 servings of fish a person consumes in the previous month and low fish consumption as 0 or 1 serving of fish. The outcome of interest is the blood mercury level, which is measured in ug/L and transformed to the logarithmic scale. The dataset contains $n = 1107$ units, where 80% are randomly sampled as training data and the rest 20% are the target units. There are $p = 8$

Figure 4: When the confounding strength is within the range of the study, we can say with high confidence that for a group of individuals, high fish consumption increases their blood mercury levels. The figures are produced using the NHANES fish consumption data. The predictive intervals are estimated by CSA-M. (a) provides reference information for the magnitude of the sensitivity parameter Γ from the observed covariates. (b) shows the fraction of intervals with positive lower bounds; (c) shows the fraction of intervals with negative upper bounds.

covariates about the demographics and health conditions [62]. We use random forest and quantile forest to fit the observed outcome, the gradient boosting to estimate the propensity score and the nested method with quantile forest as the interval prediction function.

We calibrate the sensitivity parameter Γ with the observed data. As discussed in § 4, we compute Γ_{ij} as the effect of j -th covariate on the treatment assignment of the i -th unit in terms of odds ratio. Fig. 4 (a) shows the distribution of $\{\tilde{\Gamma}_{ij}\}_{i=1:n}^{j=1:p}$ where $\tilde{\Gamma}_{ij}$ equals to Γ_{ij} if $\Gamma_{ij} \geq 1$ and $1/\Gamma_{ij}$ otherwise. By Fig. 4 (a), we may consider $\Gamma \in [1, 3]$ as a plausible range of confounding strength. The choice of a proper sensitivity parameter often needs further domain knowledge in addition to the reference information from data.

For each target unit k , CSA produces an interval estimation $\hat{C}^\Gamma(X_k) = [l_k, u_k]$. We call $\hat{C}^\Gamma(X_k)$ a positive interval if $l_k > 0$, which represents a positive individual effect, and call $\hat{C}^\Gamma(X_k)$ a negative interval if $u_k < 0$. Fig. 4 reports the fraction of positive and negative

Figure 5: Predictive intervals for the target individuals with different unmeasured confounding strength. In top panels, when $\Gamma = 1$, a large fraction of individuals have positive effects. In the bottom panels, when $\Gamma = 2$, we can still identify individuals whose effects remain positive.

intervals in the target units against the target coverage $1 - \alpha$ and the sensitivity parameter Γ . Overall, the fraction of positive intervals increases when the confounding strength and the target coverage decrease. There is a relatively strong evidence of positive effects when $\alpha \leq 0.2$ and $\Gamma \leq 2$, and there is no evidence of negative effects for $\alpha \leq 0.5$ and $\Gamma \leq 3$.

The results of individual-level estimates are reported in Fig. 5. We randomly sample 70 individuals in the target set and show the predictive intervals of their ITEs with target coverage $1 - \alpha = 0.8$. In Fig. 5, the interval prediction of the treatment effect is heterogeneous across individuals. Under unconfoundedness, the ITEs for most individuals are likely to be positive. When $\Gamma = 2$, the effects of fish consumption for some individuals are explained away by the unmeasured confounding. From Fig. 5, we can tell the subgroup for whom the effect of fish consumption on the blood mercury level is relatively insensitive to the unmeasured confounding. The predictive intervals given by the sensitivity analysis can thus provide useful information to guide personal decisions on fish consumption.

6 Discussion

In this paper we developed a sensitivity analysis method for the ITE called CSA. We developed CSA by extending conformal inference to distribution shift. We adopted a two-stage design to propagate the uncertainty of an unmeasured confounding to the predictive interval of the ITE. We provided theoretical guarantees on the coverage property of the predictive interval, designed CSSA to improve the sharpness of CSA, and developed a rejection sampling method to evaluate the performance in simulation. Finally, we analyze CSA using synthetic data and demonstrate its application in an observational study.

There are many directions for future research. We quantified the confounding strength by the MSM. Further research could explore alternative types of sensitivity models. If the nature of confounding is known, it might be preferable to model the effect of a confounder parametrically. We can also make a sensitivity assumption on the dependency structure between potential outcomes, which may improve the sharpness. Such dependencies can, for example, be modeled by a copula [17, 64]. Finally, the extended conformal prediction might be used to test other untestable assumptions, such as the invariant causal mechanism [42].

SUPPLEMENTARY MATERIAL

A Proofs

Proof of Lemma 1. By Eq. (3), we have

$$\begin{aligned}
 w_t(X, y) &= \frac{p(x)p(Y(t) = y | X)}{p(X | T = t)p(Y(t) | X, T = t)} \\
 &= \frac{p(T = t)}{p(T = t | X)} \left[p(T = t | X) + \frac{p(Y(t) = y | X, T = 1 - t)}{p(Y(t) = y | X, T = t)} \cdot p(T = 1 - t | X) \right].
 \end{aligned} \tag{28}$$

Direct computation from Eq. (7) shows

$$\left(\frac{1 - s_t(X, y)}{s_t(X, y)} \frac{e(X)}{1 - e(X)} \right)^{2t-1} = \frac{p(Y(t) = y | X, T = 1 - t)}{p(Y(t) = y | X, T = t)}. \tag{29}$$

Plug Eq. (29) to Eq. (28), we have

$$\begin{aligned}
 w_t(X, y) &= p(T = t) \left[1 + \left(\frac{1 - s_t(X, y)}{s_t(X, y)} \right)^{2t-1} \right] \\
 &= p(T = t) \frac{1}{s_t(X, y)^t (1 - s_t(X, y))^{1-t}} \\
 &\propto \frac{1}{p(T = t | X, Y(t) = y)}.
 \end{aligned}$$

By Tukey's factorization in Eq. (7), it is straightforward to obtain the following equality

$$\frac{p(Y(t) = y | X = x, T = 1)}{p(Y(t) = y | X = x, T = 0)} = \text{OR}(s_t(x, y), e(x)). \tag{30}$$

Therefore by the MSM, $1/\Gamma \leq p(Y(t) = y|X = x, T = 1)/p(Y(t) = y|X = x, T = 0) \leq \Gamma$.

QED

Proof of Lemma 2. By Eq. (7), when $t = 1$, we have

$$\begin{aligned} s_1(X, y)^{-1} &= 1 + \frac{1 - e(X)}{e(X)} \frac{p(Y(t) = y | X, T = 0)}{p(Y(t) = y | X, T = 1)} \\ &\in \left[1 + \frac{1 - e(X)}{\Gamma e(X)}, 1 + \Gamma \frac{1 - e(X)}{e(X)} \right], \end{aligned}$$

where the interval is obtained from the density ratio bound in Eq. (8).

Similarly, for $t = 0$,

$$\begin{aligned} s_0(X, y)^{-1} &= 1 + \frac{e(X)}{1 - e(X)} \frac{p(Y(t) = y | X, T = 1)}{p(Y(t) = y | X, T = 0)} \\ &\in \left[1 + \frac{e(X)}{\Gamma(1 - e(X))}, 1 + \Gamma \frac{e(X)}{1 - e(X)} \right]. \end{aligned}$$

With the above ranges of selection score, by Lem. 1, we get

$$w_t(x, y) \in \left[\left(1 + \frac{1}{\Gamma} \left(\frac{1 - e(x)}{e(x)} \right)^{2t-1} \right) p(T = t), \left(1 + \Gamma \left(\frac{1 - e(x)}{e(x)} \right)^{2t-1} \right) p(T = t) \right].$$

QED

Proof of Proposition 1. By Def. 2, for true data generating distribution with $s_t^* \in \mathcal{E}(\Gamma)$

$$\begin{aligned} \mathbb{P}_{(X, Y(t)) \sim p(X) p^{(s_t^*)}(Y(t)|X)}(Y(t) \in [L, U]) &\geq \mathbb{P}_{(X, Y(t)) \sim p(X) p^{(s_t^*)}(Y(t)|X)}(Y(t) \in [L^{(h_0)}, U^{(h_0)}]) \\ &\geq 1 - \alpha, \end{aligned}$$

where the first inequality is true because $[L^{(s_t^*)}, U^{(s_t^*)}] \subset [L, U]$.

QED

Proof of Proposition 2. Recall that the threshold m is the maximum value in $\{1, \dots, n+1\}$ which satisfies: (i) $\sum_{j=m}^{n+1} p_j \geq \alpha$; (ii) $w_j = w_{hi}(X_j)$ for $j \geq m$; (iii) $w_j = w_{lo}(X_j)$ for $j < m$.

We first prove the second claim about the objective value. Suppose the conformal weights are $\hat{w} = (w_{lo}(X_1), \dots, w_{lo}(X_{m-1}), w_{hi}(X_m), \dots, w_{hi}(X_{n+1}))$, and the normalized weight is $\hat{p}_i = \hat{w}_i / \sum_{i=1}^n \hat{w}_i$. We prove that $Q_{1-\alpha}(\sum_{i=1}^n \hat{p}_i \delta_{V_i}) = V_m$. By definition

$$\begin{aligned} Q_{1-\alpha}(V) &= \inf\{v : p(V \leq v) \geq 1 - \alpha\} \\ &= \inf\{v : p(V > v) \leq \alpha\}. \end{aligned} \tag{31}$$

Plug in V_m , for $V \sim \sum_{i=1}^n \hat{p}_i \delta_{V_i}$, we have

$$\begin{aligned} p(V > V_m) &= \sum_{i=m+1}^n \hat{p}_i \\ &= \frac{\sum_{i=m+1}^{n+1} w_{hi}(X_i)}{\sum_{i=1}^{m-1} w_{lo}(X_i) + \sum_{i=m}^{n+1} w_{hi}(X_i)} \\ &< \frac{\sum_{i=m+1}^{n+1} w_{hi}(X_i)}{\sum_{i=1}^m w_{lo}(X_i) + \sum_{i=m+1}^{n+1} w_{hi}(X_i)} \\ &< \alpha. \end{aligned}$$

The first inequality is because $w_{hi}(X_m) > w_{lo}(X_m)$. The second inequality is because of the definition of m , that is, if the inequality is not true, the maximum index satisfying (i)-(iii) is at least $m+1$, not m .

On the other hand, for $\forall v < V_m$,

$$p(V > v) \geq p(V \geq V_m) = \sum_{i=m}^{n+1} \hat{p}_i \geq \alpha,$$

where the last inequality is by definition of m . Then, by the quantile definition in Eq. (31),

$$Q_{1-\alpha}(\sum_{i=1}^n \hat{p}_i \delta_{V_i}) = V_m.$$

Next, we prove $\hat{w}$ is the optima by contradiction. Suppose $\exists w_{1:n+1}$ such that $Q_{1-\alpha}(\sum_{i=1}^{n+1} p_i \delta_{V_i}) = V_M > V_m$, where $w_{1:n+1}$ satisfy the optimization constraints, and $p_i = w_i / \sum_{i=1}^{n+1} w_i$. Since $V_{1:n+1}$ are ordered, we have $M > m$. By definition of quantile, we have $\sum_{i=M}^{n+1} p_i > \alpha$. Then

$$\begin{aligned} \alpha &< \sum_{i=M}^{n+1} p_i \\ &= \frac{\sum_{i:i \geq M} w_i}{\sum_{i:i < M} w_i + \sum_{i:i \geq M} w_i} \\ &\leq \frac{\sum_{i:i \geq M} w_i}{\sum_{i:i < M} w_{lo}(X_i) + \sum_{i:i \geq M} w_i} \\ &\leq \frac{\sum_{i:i \geq M} w_{hi}(X_i)}{\sum_{i:i < M} w_{lo}(X_i) + \sum_{i:i \geq M} w_{hi}(X_i)} \end{aligned}$$

The second to last inequality is because of the constraints $w_i \geq w_{lo}(X_i)$, and the last inequality is because of the fact that $y = x/(a+x)$, $a > 0$ is a monotonically increasing function of x for $x > 0$. Therefore, the maximum value satisfying (i)-(iii) is at least M with $M > m$, which contradicts with the definition of m being the maximum. QED

Proof of Lemma 3. For completeness, we first re-introduce the weighted exchangeability from Tibshirani et al. [55, Definition 1].

Definition 3. The variables $Z_{1:n}$ are weighted exchangeable if the joint distribution factorizes

$$f(Z_{1:n}) = \left(\prod_{i=1}^n \pi_i(Z_i) \right) \cdot g(Z_{1:n}), \quad (32)$$

where $g(Z_1, \dots, Z_n) = g(Z_{\sigma(1)}, \dots, Z_{\sigma(n)})$ for any permutation $\sigma(\cdot)$, and $\pi_i(\cdot)$ are adjusting functions.

We prove the result for estimated propensity score $\hat{e}(X)$. The result for $\hat{e}(X) = e(X)$ follows as a special case. For notational convenience, we first consider the prediction band for the outcome $Y(1)$ if the unit were treated; we suppress the superscript that involves the sensitivity model since here we always consider the DGP under a fixed sensitivity model. Denote

$$h(x, y) := \log(\text{OR}(s_t(x, y), e(x))) = \text{logit}(s_t(x, y)) - \text{logit}(e(x)). \quad (33)$$

By the assumption of the MSM, $|h(x, y)| \leq \log \Gamma$.

Consider the preliminary data $\mathcal{X}_{\text{pre}}$ and the calibration data $\mathcal{X}_{\text{cal}} = Z_{1:n}$ that are i.i.d. data points sampled from $p(X | T = 1)p(Y(1) | X, T = 1)$, and the target data $Z_{n+1} \sim Q(X, Y(1)) = p(X)p(Y(1) | X)$. By Lem. 1 and eqs. (7) and (33), the weights

$$\begin{aligned} w_1(x, y) &= \frac{p(T = 1)}{s_1(x, y)} \\ &= p(T = 1) \left(1 + \frac{1 - e(x)}{e(x)} \exp(-h(x, y)) \right). \end{aligned} \quad (34)$$

The estimated conformal weights are

$$\hat{w}_1(x, y) = p(T = 1) \left(1 + \frac{1 - \hat{e}(x)}{\hat{e}(x)} \exp(-h(x, y)) \right). \quad (35)$$

Redefine $\hat{w}_1(x, y)$ as $\hat{w}_1(x, y)/\mathbb{E}[\hat{w}_1(x, y)]$ where the expectation is over $p(X = x | T = 1)p(Y(1) = y | x, T = 1)$. Define $\tilde{Q}(X, Y(1)) = \hat{w}_1(X, Y(1))p(X | T = 1)p(Y(1) | X, T = 1)$. Since $\tilde{Q}(X, Y(1))$ is positive and integrates to 1, it is a density function. Consider $\tilde{Z}_{n+1} = (\tilde{X}_{n+1}, \tilde{Y}_{n+1}(1)) \sim \tilde{Q}(X, Y(1))$ and let $\tilde{Z}_{1:n} \stackrel{d}{=} Z_{1:n}$. By Def. 3, $\tilde{Z}_{1:n+1}$ are weighted exchangeable with adjusting function $(1, \dots, 1, \hat{w}_1)$. For the band $\hat{C}_1^\Gamma(x)$ in Eq. (13),

$$\mathbb{P}(\tilde{Y}_{n+1}(1) \in \hat{C}_1^\Gamma(\tilde{X}_{n+1}) | \mathcal{Z}_{\text{pre}}) = \mathbb{P}(\tilde{V}_{n+1} \leq Q_{1-\alpha} \left(\sum_{i=1}^n \hat{p}_i \delta_{\tilde{V}_i} + \hat{p}_{n+1} \delta_\infty \right) | \mathcal{Z}_{\text{pre}})$$

where $\tilde{V}_i = V(\tilde{Z}_i)$, $\hat{p}_i = \hat{w}_1(\tilde{Z}_i) / \sum_{i=1}^{n+1} \hat{w}_1(\tilde{Z}_i)$. By Tibshirani et al. [55, Lemma 3] and its proof, the right hand side of Eq. (34) is within $[1 - \alpha, 1 - \alpha + \max_i \{\hat{p}_i\}_{i=1}^{n+1}]$. Therefore

$$1 - \alpha \leq \mathbb{P}(\tilde{Y}_{n+1}(1) \in \hat{C}_1^\Gamma(\tilde{X}_{n+1}) | \mathcal{Z}_{\text{pre}}) \leq 1 - \alpha + \max_i \{\hat{p}_i\}_{i=1}^{n+1}. \quad (36)$$

We first prove the lower bound of the coverage probability. By definition of total variation distance $d_{\text{TV}}(\cdot)$,

$$\left| p(Y_{n+1}(1) \in \hat{C}_1^\Gamma(X_{n+1}) | \mathcal{Z}_{\text{pre}}, \mathcal{Z}_{\text{cal}}) - p(\tilde{Y}_{n+1}(1) \in \hat{C}_1^\Gamma(\tilde{X}_{n+1}) | \mathcal{Z}_{\text{pre}}, \mathcal{Z}_{\text{cal}}) \right| \leq d_{\text{TV}}(Q, \tilde{Q}), \quad (37)$$

where $d_{\text{TV}}(Q, \tilde{Q}) = d_{\text{TV}}(Q(X, Y(1)), \tilde{Q}(X, Y(1)))$. Then

$$\mathbb{P}(Y_{n+1}(1) \in \hat{C}_1^\Gamma(X_{n+1}) | \mathcal{Z}_{\text{pre}}, \mathcal{Z}_{\text{cal}}) \geq p(\tilde{Y}_{n+1}(1) \in \hat{C}_1^\Gamma(\tilde{X}_{n+1}) | \mathcal{Z}_{\text{pre}}, \mathcal{Z}_{\text{cal}}) - d_{\text{TV}}(Q, \tilde{Q}).$$

Marginalizing over $\mathcal{Z}_{\text{cal}}$ and by Eq. (36),

$$\mathbb{P}(Y_{n+1}(1) \in \hat{C}_1^\Gamma(X_{n+1}) | \mathcal{Z}_{\text{pre}}) \geq 1 - \alpha - d_{\text{TV}}(Q, \tilde{Q}).$$

By the integral definition of total variance,

$$d_{\text{TV}}(Q, \tilde{Q}) = \frac{1}{2} \int |\hat{w}(X, Y(1)) - w(X, Y(1))| p(X | T = 1) p(Y(1) | X, T = 1).$$

Plug in Eqs. (34) and (35)

$$\begin{aligned} |\hat{w}(X, Y(1)) - w(X, Y(1))| &= p(T = 1) \left| \frac{1 - \hat{e}(X)}{\hat{e}(X)} - \frac{1 - e(X)}{e(X)} \right| \exp(-h(X, Y(1))) \\ &\leq \Gamma p(T = 1) \left| \frac{1 - \hat{e}(X)}{\hat{e}(X)} - \frac{1 - e(X)}{e(X)} \right|. \end{aligned}$$

Hence, we have

$$d_{\text{TV}}(Q, \tilde{Q}) \leq \frac{\Gamma}{2} p(T = 1) \mathbb{E}_{X \sim p(X | T=1)} \left| \frac{1 - \hat{e}(X)}{\hat{e}(X)} - \frac{1 - e(X)}{e(X)} \right| \quad (38)$$

Finally, marginalizing over $\mathcal{Z}_{\text{pre}}$ gives

$$\mathbb{P}(Y_{n+1}(1) \in \hat{C}_1^\Gamma(X_{n+1}) | \mathcal{Z}_{\text{pre}}) \geq 1 - \alpha - \frac{\Gamma}{2} p(T = 1) \mathbb{E}_{X \sim p(X | T=1)} \left| \frac{1 - \hat{e}(X)}{\hat{e}(X)} - \frac{1 - e(X)}{e(X)} \right|.$$

Now we prove the upper bound. Back to Eq. (36), we first bound $\max_i \{\hat{p}_i\}_{i=1}^{n+1}$. By Eq. (35)

$$\begin{aligned}
\hat{p}_i &\leq \frac{1 + \Gamma \frac{1-\hat{e}(X_i)}{\hat{e}(X_i)}}{1 + \Gamma \frac{1-\hat{e}(X_i)}{\hat{e}(X_i)} + \sum_{j \neq i} (1 + \frac{1}{\Gamma} \frac{1-\hat{e}(X_j)}{\hat{e}(X_j)})} \\
&\leq \frac{1 + \Gamma \frac{1-\eta}{\eta}}{1 + \Gamma \frac{1-\eta}{\eta} + n + \frac{1}{\Gamma} \frac{\eta}{1-\eta}} \\
&\leq \frac{\Gamma/\eta}{n + \Gamma/\eta}
\end{aligned} \tag{39}$$

where the first inequality is by the MSM assumption and the second is by the bounds of propensity score. Then by Eqs. (36) and (37), we have

$$p(Y_{n+1}(1) \in \hat{C}_1^\Gamma(X_{n+1}) | \mathcal{Z}_{\text{pre}}) \leq 1 - \alpha + \max_i \{\hat{p}_i\}_{i=1}^{n+1} + d_{\text{TV}}(Q, \tilde{Q}) \tag{40}$$

Plugging the bounds in Eqs. (38) and (39) to Eq. (40) and marginalizing out $\mathcal{Z}_{\text{pre}}$ we get the upper bound.

We can proceed the proof similarly to the case of $t = 0$. Hence, the proof is completed.

QED

B Conformalized Sharp Sensitivity Analysis

We first show the sharpness constraint in Dorn and Guo [16, Proposition 3, Corollary 2] is equivalent to the constraint in the sharp MSM Eq. (23).

Proposition 3. *The condition $\int p^{(s_t)}(Y(1) = y | X, T = 0) dy = 1$ in the sharp MSM is*

equivalent to $\mathbb{E}[\frac{T}{s_1(X, Y(1))} | X] = 1$.

Proof of Prop. 3. We prove for the potential outcome under treatment and the claim for the PO under control follows similarly. By Eq. (30), for a given X ,

$$\begin{aligned} \int p(Y(1) = y | X, T = 0) dy &= \int p(Y(1) = y | X, T = 1) \frac{e(X)}{1 - e(X)} \frac{1}{s_1(X, y)} dy - \frac{e(X)}{1 - e(X)} \\ &= \mathbb{E}[\frac{e(X)}{s_1(X, Y(1))} | X, T = 1] \frac{1}{1 - e(X)} - \frac{e(X)}{1 - e(X)} \\ &= \mathbb{E}[\frac{T}{s_1(X, Y(1))} | X] \frac{1}{1 - e(X)} - \frac{e(X)}{1 - e(X)} \end{aligned}$$

where the last equality is because

$$\mathbb{E}[\frac{T}{s_1(X, Y(1))} | X] = \mathbb{E}[\frac{1}{s_1(X, Y(1))} | X, T = 1] e(X).$$

Therefore, we have

$$\int p(Y(1) = y | X, T = 0) dy = 1 \Leftrightarrow \mathbb{E}[\frac{T}{s_1(X, Y(1))} | X] = 1. \quad (41)$$

QED

Covariate Balancing Selection Score. For the control group, similar sharpness constraint as Eq. (24) in main paper can be obtained by flipping the binary treatment label. By Eq. (24), we get

$$\mathbb{E}[\frac{g(X_i)T_i}{s_1(X_i, Y_i(1))}] = \mathbb{E}[\frac{g(X_i)(1 - T_i)}{1 - s_0(X_i, Y_i(0))}] = \mathbb{E}[g(X_i)]. \quad (42)$$

Eq. (42) encourages the covariate balancing by moment matching. As a related work, the idea to tighten the interval estimation by covariate balancing has been applied to generalizing RCT estimates across different locations [39].

Note that under unconfoundedness, i.e. $\Gamma = 1$ and $s_1(X, Y(1)) = s_0(X, Y(0)) = e(X)$, Eq. (42) recovers the constraints of the covariate balancing propensity score (CBPS) [26]. Hence we call the selection scores that satisfies Eq. (42) the covariate balancing selection score (CBSS). For the choice of covariates function $g(X)$, Dorn and Guo [16] proposes $g(X) = Q_\tau(Y|X, T = 1)$; Imai and Ratkovic [26] takes $g(X)$ as X and the derivative of the treatment model w.r.t. its parameters.

Derivation of the Constraints Eq. (25) in § 3.5. By Lem. 1, we re-write the balancing condition in Eq. (24) in terms of the conformal weights,

$$\begin{aligned}\mathbb{E}[g(X_i)] &= \mathbb{E}\left[\frac{g(X_i)T_i}{s_1(X_i, Y_i(1))}\right] \\ &= \mathbb{E}\left[\frac{g(X_i)Tw_1(X_i, Y_i(1))}{p(T_i = 1)}\right] \\ &= \mathbb{E}[g(X_i)w_1(X, Y_i(1))|T_i = 1].\end{aligned}\tag{43}$$

By definition of the propensity score, we also have

$$\mathbb{E}\left[\frac{g(X_i)T_i}{e(X_i)}\right] = \mathbb{E}[g(X_i)]\tag{44}$$

Hence by Eq. (24), $\mathbb{E}[g(X_i)w_1(X, Y_i(1))|T_i = 1] = \mathbb{E}\left[\frac{g(X_i)T_i}{e(X_i)}\right]$. The empirical estimation to

this balancing condition is the equality constraint in Eq. (25), i.e.,

$$\frac{1}{N_t} \sum_{i:T_i=t} g(X_i) w_i^\Gamma = \frac{1}{N} \sum_{i=1}^N \frac{T_i g_k(X_i)}{\hat{e}(X_i)}.$$

Similar condition can be derived for the control group by flipping the treatment label.

In sum, CSSA solves the optimization in Eq. (19) with additional constraints in Eq. (25),

$$\begin{aligned} & \max_{w_{1:n+1}} Q_{1-\alpha} \left(\sum_{i=1}^n p_i \delta_{V_i} + p_{n+1} \delta_\infty \right). \\ & \text{subject to } p_i = \frac{w_i}{\sum_{i=1}^{n+1} w_i}, \quad 1 \leq i \leq n+1 \\ & w_{lo}^\Gamma(X_i) \leq w_i \leq w_{hi}^\Gamma(X_i), \quad 1 \leq i \leq n, \quad w_{lo}^\Gamma(X) \leq w_{n+1} \leq w_{hi}^\Gamma(X) \\ & \frac{1}{N_t} \sum_{i:T_i=t} g_k(X_i) w_i^\Gamma = \frac{1}{N} \sum_{i=1}^N \frac{T_i^t (1 - T_i)^{1-t}}{\hat{e}(X_i)^t (1 - \hat{e}(X_i))^{1-t}} g_k(X_i), \quad 1 \leq k \leq K. \end{aligned} \tag{45}$$

For example, when $t = 1$, $K = 1$, let the covariate function be the estimated propensity score, i.e. $g_1(X_i) = \hat{e}(X_i)$. The balancing constraint in Eq. (45) becomes

$$\frac{1}{N_t} \sum_{i:T_i=1} e(X_i) w_i / p(T_i = 1) = 1, \tag{46}$$

where the propensity score $e(X)$ can be replaced by $\hat{e}(X_i)$ in practice. Note that by the range of conformal weights in Lem. 2, this balancing condition is automatically satisfied under unconfoundedness, i.e. $\Gamma = 1$, and Eq. (45) reduces to the standard WCP.

Computational Methods for Solving Eq. (45). The difficulty for solving the quantile

optimization in Eq. (45) is that the objective function is the empirical quantile, which is not continuous. To solve this problem, we consider a sequence of simplified optimization with continuous objective. For a given integer $1 \leq J \leq n + 1$,

$$\begin{aligned}
& \max_{w_{1:n+1}} \frac{\sum_{i=J}^{n+1} w_i}{\sum_{i=1}^{n+1} w_i} \\
& \text{subject to } w_{lo}^\Gamma(X_i) \leq w_i \leq w_{hi}^\Gamma(X_i), \ 1 \leq i \leq n, \ w_{lo}^\Gamma(X) \leq w_{n+1} \leq w_{hi}^\Gamma(X) \quad (47) \\
& \frac{1}{N_t} \sum_{i: T_i=t} g_k(X_i) w_i = \frac{1}{N} \sum_{i=1}^N \frac{T_i^t (1 - T_i)^{1-t}}{\hat{e}(X_i)^t (1 - \hat{e}(X_i))^{1-t}} g_k(X_i), \ 1 \leq k \leq K.
\end{aligned}$$

The problem in Eq. (47) is a nonlinear programming with linear constraints, which can be solved efficiently with existing computation tools (e.g., the sequential quadratic programming in Python package `scipy` and R package `nloptr`). Denote the optima of Eq. (47) as $\hat{\alpha}_J$. It is clear that $1 = \hat{\alpha}_1 \geq \hat{\alpha}_2 \geq \dots \geq \hat{\alpha}_{n+1}$. Supposing $V_1 \leq \dots \leq V_n \leq V_{n+1}$, by the definition of quantile, the solution of Eq. (25) is V_j where $j = \max\{j : \hat{\alpha}_j \geq \alpha\}$. We can then solve Eq. (47) for $J = n + 1, n, \dots, 1$ until the first time $\hat{\alpha}_J \geq \alpha$ (say $J = m$) and the optima of Eq. (45) is V_m . This process can be implemented efficiently with binary search because of the ordering in $\hat{\alpha}_{1:n+1}$. Hence we only need to solve Eq. (47) at most $\mathcal{O}(\log n)$ times. In practice, to further improve the computational efficiency, we can first run Alg. 1 to find an upper bound of the optimal index m before the binary search. CSSA is summarized in Alg. 3.

C Rejection Sampling for Counterfactual Outcome

We design an algorithm to generate $Y_i \sim p(Y(t) | X_i, T_i = 1 - t)$ that is consistent with the MSM. Let the proposal distribution be $q(y | x) = p(Y(t) = y | X = x, T = t)$. The target

Algorithm 3: CSSA for Estimating a Potential Outcome

Input: Data $\mathcal{X} = (X_i, Y_i, T_i)_{i=1}^N$, where Y_i is missing if $T_i = 1 - t$; level α , sensitivity parameter Γ , target point covariates X , covariate balancing functions $\{g_k(X)\}_{k=1}^K$

- 1: Run Alg. 1 with data $\mathcal{X}$; return the scores $\mathcal{V} = \{V_i\}_{i=1}^{|\mathcal{V}|}$, the score index $k + 1$, and the optima $\hat{\mathbf{w}} = (w_1, \dots, w_{|\mathcal{V}|})$ from Step II of Alg. 1
- 2: Let $L = 1$, $R = k + 1$, $M = \lceil (L + R)/2 \rceil$, and initialization $\mathbf{w}_0 = \hat{\mathbf{w}}$
- 3: **while** $R - L > 1$ **do**
 - Solve Eq. (47) by a nonlinear programming solver (e.g. `slsqp`($\cdot$) in R) with $J = M$, $n + 1 = |\mathcal{V}|$ and initialization $\mathbf{w}_0$; return the optimal objective value $\hat{\alpha}_J$ and optima $\hat{\mathbf{w}}_J$
 - if** $\hat{\alpha}_J \geq \alpha$, $L \leftarrow M$ **else** $R \leftarrow M$; $M \leftarrow \lceil (L + R)/2 \rceil$
 - Set initialization $\mathbf{w}_0 = \hat{\mathbf{w}}_J$

Output: Compute $\hat{C}_t^\Gamma(X)$ by Eq. (20) with $\hat{Q}(Z_{1:n}, X) = V_R$

distribution is

$$p(y | x) = \eta(y | x)q(y | x)/M(x), \quad (48)$$

where $\eta(y | x)$ is a positive tilting function and $M(x) = \int \eta(y | x)q(y | x)dy$ is the normalizing constant. The tilting function is chosen so that $1/\Gamma \leq \eta(y | x)/M(x) \leq \Gamma$. By construction, the density ratio $p(y | x)/q(y | x)$ is bounded between $1/\Gamma$ and Γ . Let the missing outcome distribution be $p(Y(t) = y | X = x, T = 1 - t) = p(y | x)$. By Lem. 1, the corresponding selection score belongs to $\mathcal{E}(\Gamma)$.

Samples from $p(y | x)$ can be generated by the rejection sampling. Since the density ratio is bounded by Γ , we generate $Y(t) \sim q(y|x)$, and accept it with probability

$$p_{\text{accept}} = \frac{p(Y(t)|x)}{q(Y(t)|x)\Gamma} = \frac{\eta(Y(t)|x)}{\Gamma M(x)}. \quad (49)$$

The rejection sampling guarantees the accepted samples are generated from $p(Y(t) | X, T = 1 - t)$ with a sensitivity model belonging to $\mathcal{E}(\Gamma)$. The choice of tilting function decides

which sensitivity model that the true data generating distribution $\mathbb{P}_0$ corresponds to. By choosing different tilting functions, we can evaluate CSA over different $\mathbb{P}_0$ which are all compatible with the observed data and the MSM.

For Fig. 1, $q_l(x)$ and $q_r(x)$ are set to be the $1/(2(\Gamma+1))$ and $1-1/(2(\Gamma+1))$ quantile of the observed outcome distribution $p(Y(1)|X=x, T=1)$, respectively. The tilting function $\eta(y|x)$ is set as $1/\Gamma$ when $q_l(x) \leq y \leq q_r(x)$, and as Γ otherwise. To generate samples of the potential outcome, the normalization constant $M(x) = 1$ due to the tilting function design.

D Coverage Limit of a Finite-length Interval

We discuss a maximum coverage that a finite-length predictive interval can achieve in conformal inference. For weighted conformal prediction, the width of the predictive interval is determined by the maximum $(1-\alpha)$ -quantile of the distribution, i.e. $\sum_{i=1}^n p_i^{(h)} \delta_{v_i} + p_{n+1}^{(h)} \delta_{\infty}$. The maximum $(1-\alpha)$ -quantile is infinite if there exist a sensitivity model $h \in \mathcal{H}(\lambda)$, such that the probability mass is greater than the miscoverage rate, i.e. $p_{n+1}^{(h)} \geq \alpha$.

To infer $Y(1)$, by Prop. 2, we get the minimal miscoverage α^* that an informative predictive interval can achieve

$$\begin{aligned}
\alpha^* &:= \max_{h \in \mathcal{H}(\lambda)} p_{n+1}^{(h)}(Z_{1:n}, X; \Gamma, t=1) \\
&= \frac{w_{hi}^{\Gamma, t=1}(X)}{\sum_{i=1}^n w_{lo}^{\Gamma, t=1}(X_i) + w_{hi}^{\Gamma, t=1}(X)} \\
&= \frac{\Gamma(e(X)^{-1} - 1) + 1}{n + 1 + \sum_{i=1}^n (e(X_i)^{-1} - 1)/\Gamma + \Gamma(e(X)^{-1} - 1)}. \tag{50}
\end{aligned}$$

The smaller the α^* is, the higher coverage an informative interval can reach. By setting $\Gamma = 1$ in Eq. (50), we get the minimal miscoverage α^* under unconfoundedness, and by further setting $e(X) = 1/2$, we get α^* for randomized trials. These results are in Table 1.

Table 1: The minimal miscoverage for a finite-length predictive band. The target is $Y(t)$ of a new unit in population with covariates X , and the observed data are at treatment level t .

	1:1 Randomized Trial	Unconfoundedness	Confounding Specified by the MSM
α^*	$\frac{1}{n+1}$	$\frac{p(T=t X)^{-1}}{\sum_{i=1}^{n+1} p(T=t X_i)^{-1}}$	$\frac{w_{ht}^{\Gamma,t}(X)}{\sum_{i=1}^n w_{to}^{\Gamma,t}(X_i) + w_{ht}^{\Gamma,t}(X)}$

Eq. (50) reveals that to predict $Y(1)$ for a target unit, α^* decreases when the number of observed units n increases and when the sensitivity parameter Γ decreases. α^* decreases when the propensity score $e(X_i)$ of the observed units decreases and when $e(X)$ of the target point increases. This change in propensity score indicates that there is overlap between the target unit’s covariates and the covariates of the training units.

E Additional Simulation Details and Results

The counterfactual distributions in §§ 5.1 and 5.2 are generated by the rejection sampling method in Appendix C. Specifically, the middle figure in Fig. 1, which we adopt as the adversarial case in the MSM, is generated by the tilting function in Eq. (48) as $\eta(y|x) = 1/\Gamma$ if $q_l(x) \leq y \leq q_r(x)$ and $\eta(y|x) = \Gamma$ otherwise. Here, $q_l(x)$ and $q_r(x)$ are the $1/(2(\Gamma+1))$ and $1-1/(2(\Gamma+1))$ quantiles of the observed outcome distribution, respectively. Such construction makes the normalizing constant $M(x) = 1$ in Eq. (48) and produces a counterfactual distribution with high density on the low density region of the observed distribution, which is an adversarial case to test the validity of the predictive band by

Table 2: Empirical coverage of the ITE by different interval estimations. CSA is implemented with mean prediction. Γ is the sensitivity parameter. For all methods, the target coverage is 0.8. When there is unmeasured confounding, CSA-M produces better coverage than alternative methods.

CSA. In § 5.2, the counterfactual distribution $p(Y(0)|X = x, T = 1)$ is constructed by the rejection sampling with the observed outcome distribution $p(Y(0)|X = x, T = 0)$ and the aforementioned tilting function $\eta(y|x)$.

Table 2 shows the coverage of different interval estimates. The estimations that CSA is compared with are percentile bootstrap sensitivity analysis of the ATE (Boot.Sens.) [63], the Bayesian Additive Regression Tree estimation of the CATE (BART) [11], and ITE estimation under unconfoundedness [37]. Fig. 6 shows the percentage of positive and negative intervals at different confounding strength and coverage rate. The predictive interval is constructed by the conformal quantile prediction. Fig. 7 shows that CSA produces valid and relatively sharp predictive interval for the ITE under unmeasured confounding.

Figure 6: Analysis of NHANES fish consumption data. The predictive interval is estimated by the CSA with quantile prediction. Left panel: fraction of intervals with positive lower bounds; Right panel: fraction of intervals with negative upper bounds.

Figure 7: **Top:** Empirical coverage of the ITE. The dashed lines is the target coverage. **Middle:** The length of predictive interval. CSA with Bonferroni correction produces a wide interval and high coverage. CSA with nested method has valid coverage and provides sharper intervals. **Bottom:** The sharpness of CSA predictions. CSA-M is less conservative than CSA-Q on homoscedastic data. To keep the nominal coverage, the maximal shrinkage factor is below 20% for CSA-M and is slightly higher for CSA-Q.
