Abstract

In this study, we demonstrate sustainable and green nanotechnology for roomtemperature synthesis of H_xWO_3 (0<x<0.5) via a novel reaction pathway induced by mechanical energy. A simple mixture of monoclinic WO₃ powder and polyolefin (polypropylene) is used to obtain H_xWO_3 nanoparticles that show high crystallinity even through high-energy ball milling synthesis. The composite of H_xWO_3 nanoparticles and nanocarbon by-products exhibit unique optoelectronic properties along with outstanding enhancement of photocatalytic performance in the decomposition of azo-dye water pollutants under visible light. The formation mechanism of the obtained functional material is also discussed. The findings of this study provide insights into the limitations for mass production of H_xWO_3 nanoparticles, such as a specific setup for electrochemical reactions and precious metal catalysis.

Keywords: Hydrogen tungsten bronze, Ball milling, Nanocarbon composite, Photocatalyst

1. Introduction

Transition metal bronze (e.g., tungsten or molybdenum bronze) nanoparticles have attracted considerable attention owing to their high carrier density, high electrical conductivity [1], and intense light-absorbing capacity ranging from the visible to nearinfrared (NIR) region [2], [3], revealed via localized surface plasmon resonance (LSPR), similar to metal nanoparticles (e.g., Au and Ag) [4], [5]. Thus, they are used in various applications such as superconductors [6], fuel cells [7], supercapacitor [8], smart windows [9], [10], and heterogeneous catalysts [11], [12]. These bronzes have a general formula of M_xWO_3 or M_xMoO_3 , where M is usually H⁺, alkali metal, alkaline earth metal, or lanthanide intercalated in the WO₃ or MoO₃ lattice. Typically, a high-temperature thermal treatment (at minimum of 500 K) is required to form H_xWO₃ via dissociative chemisorption of hydrogen on the surface of WO3 as a hydrogen spillover (H-spillover) reaction [13], unless otherwise associated with precious metal catalysts (e.g., Pt or Pd) [12]. H-spillover is one of the main pathways for the formation of H_xWO₃ under thermochemical conditions, where H₂ or another hydrogen donor dissociatively adsorbs at the metal catalyst sites and the resultant surface-bound hydrogen migrates to the WO₃ support. An alternative approach is electrochemical formation through hydrogen intercalation in acidic electrolytes. The dynamics of HxWO3 bronze formation from WO3 via thermochemical as well as electrochemical reduction were investigated using timeresolved optical microscopy [14], revealing that the reaction occurs via a congruent mechanism involving electron transfer coupled with proton uptake. Industrial mass production is limited by a specific setup for electrochemical reactions and precious metal catalysis in a hydrogen-rich atmosphere to overcome potential energy barriers [13]. Recently, some research groups have reported a mechanically induced reaction to

synthesize H_xWO₃ as a third pathway. In these cases, specific conditions are needed in the ball milling process for efficient formation, such as the use of metastable WO₃ (hexagonal phase) [15] or metal catalyst [16], a reactive atmosphere (e.g., hydrogen) [15, 17]. In this study, we demonstrate a novel, sustainable, and green nanotechnology for the room-temperature synthesis of H_xWO₃ (0<x<0.5) via mechanically induced H-spillover in an inert atmosphere without utilizing precious metal catalysts, using a simple mixture of monoclinic WO₃ powder (m-WO₃) and polyolefin (polypropylene; PP). The proposed synthesis involves the simultaneous mechanical activation of WO₃, which facilitates the catalytic production of gaseous fragments as proton suppliers in an inert atmosphere, accompanied by the generation of graphitic nanocarbon as a by-product. The prepared H_xWO₃ has a highly ordered nanostructure and demonstrates outstanding enhancement of the photocatalytic reaction rate by an order of magnitude toward decomposing azo-dye water pollution under visible light.

2. Experimental

Commercially available highly pure WO₃ powder (>99.5%, Nacalai Tesque Co., Ltd.) and PP (Seishin Enterprise Co., Ltd.) powder were used as raw materials. These (powder volume ratio of WO₃ and PP = 6:1) were subjected to high-energy ball milling (rotation speed = 400 rpm for 3 h in an Ar-filled glovebox) in a commercial planetary ball mill apparatus (Pulverisette-7 premium line, Fritsch GmbH) using zirconia balls (diameter = 10 mm) and a zirconia vessel (80 mL).

The composition of the studied samples was investigated using X-ray diffraction (XRD, Ultima-IV, Rigaku). Raman spectroscopy was carried out using a Raman spectrometer (NRS-3100, Jasco, or Via Raman microscope, Renishaw plc.). Fourier transform infrared (FT-IR) spectra were recorded using an FT-IR spectrometer (FT-IR

6600, JASCO). Nanostructured surfaces of the as-synthesized particles were examined using transmission electron microscopy (TEM; JEM-2100F, JEOL). Particle morphology was analyzed using field-emission scanning electron microscopy (JSM-7000F, JEOL). The chemical state of the initial sample surface was investigated using X-ray photoelectron spectroscopy (XPS, M-probe, Surface Science Instrument) with an Al K α source (hv = 1486.6 eV). Electron spin resonance (ESR) spectra were measured using a JEOL JES-FA200 spectrometer. Optical properties in the UV to visible range and the UV to the near-infrared range were analyzed using UV-vis spectrophotometry (V-7100, Jasco).

Photocatalytic performance was evaluated by the degradation of methyl orange (MO) as an azo-dye water pollutant under visible light. First, 5 mg of either raw WO₃ or the as-prepared powder were loaded into a vessel containing 10 mL of an MO solution at 15 ppm. A 300 W Xe lamp (MAX-350, ASAHI SPECTRA, Japan) with a band-path filter (385–740 nm) was used as the visible-light source. Before irradiation, the solution containing the WO₃ photocatalysts was allowed to sit in the dark for approximately 60 min to ensure equilibrium adsorption of the dye molecules. Thereafter, MO degradation was monitored by measuring changes in the UV-vis absorption spectra at regular intervals under light irradiation. Photoluminescence (PL) spectra were measured using a commercial spectrofluorometer (FP-8500, Jasco, Japan) at an excitation wavelength of 350 nm.

3. Results and discussion

The XRD patterns show the phase transformation of WO₃ from monoclinic to tetragonal in the as-prepared powder only through milling with PP (S2) (**Fig. 1**), whereas crystallinity decreases due to the strong lattice distortion without PP during the highenergy ball milling process (S1). Considering that M_xWO_3 exhibits a tetragonal phase

 $(0 \le x \le 0.5)$ [15], the obtained material with a tetragonal phase was identified as H_xWO₃. The presence of tetragonal H_xWO₃ with a highly ordered nanostructure was confirmed by TEM (Fig. 2a). Although the mechanically treated powder shows lattice distortion (black contrast in Fig. 2b), amorphous layers (thickness of few nanometers) were formed initially on the surfaces of the particles, which are typically found in ceramic powders after the milling process [18]. In contrast, the ball-milled WO3 nanoparticles without PP (S1) display the aggregation and the amorphous surface structure (presented in Fig. 2b). Raman spectra shown in Fig. 3a show that the spectrum of the m-WO₃ raw powder displays two intense peaks at 720 cm⁻¹ and 807 cm⁻¹, which are attributed to phonons in crystalline WO₃ [19]. In the mechanically treated WO₃ powder (S1), a weak peak appeared at 940 cm⁻¹, which was assigned to the amorphous phase of WO₃ [19]. In contrast, ball milling with PP produces graphitic nanocarbon as a by-product with intense G-band and D-band peaks (Fig. 3b). These peaks represent in-plane sp² bonded carbons in an aromatic ring stretching and disorder in the sp^2 carbon network, respectively [20]. The by-product nanocarbon plays an essential role in protecting the generated H_xWO₃ lattice from further breakdown and amorphization during high-energy ball milling. As seen from the XPS spectra of the W4f orbital (Fig. 4a), the broadened peak toward lower binding energy attributed to W⁵⁺ species [21] appears in the treated WO₃ (S1) compared to the pristine powder (S0). As reviewed in Ref [22], the mechanical stressing during ball milling initiates the formation of defects such as oxygen vacancies, causing the generation of W⁵⁺ species. Besides, the synthesized H_xWO₃ (S2) also displays W⁵⁺ species. It is well known that migration of proton and electron proceeds in the bulk of WO₃ lattice via classical H-spillover, leading to the formation of H_xWO_3 with W^{5+} species [8,23]. The FT-IR spectra exhibit further evidence of the H_xWO₃ formation (Fig. 4b). The broadband in the range of 850–650 cm⁻¹ is attributed to the W-O stretching vibrations of crystalline

WO₃ [23]. An increase in wide-ranging IR absorption above 1100 cm⁻¹ was observed in the prepared powder through ball milling with PP (S2), reflecting the presence of quasifree electrons that cause metallic reflectivity in H_xWO₃ [23]. An extra broad feature (<600 cm⁻¹) attributed to the W-O stretching modes strongly coupled with protons was also observed [23]. In this case, the C-H bond as residual organic carbon in the range of 2900– 2700 cm⁻¹ disappeared in S2. Furthermore, the ESR spectra suggest a notable difference in the structure formed through the ball milling with polyolefin. As shown in **Fig. 4c**, S1 displays a strong signal at g = 2.004 associated with unpaired electrons trapped by oxygen vacancies [24, 25] rather than by W⁵⁺ (g = 1.89 [24], 1.94 or 2.19 [25]). In contrast, the intense radical in S2 can be assigned as not the trapped electrons in oxygen vacancies but free-electrons in H_xWO₃, which is consistent with the broad IR adsorption above 1100 cm⁻¹.

A significant increase in the light-absorbing capacity, ranging from the near-infrared region, was observed in the composite powder (**Fig. 5a-b**). A color change from yellow to blue associated with the formation of H_xWO_3 has been used to confirm the existence of atomic hydrogen via hydrogen spillover [13], [26]. It is due to the Fermi level shifts toward the CBM [27] because electrons are supplied by heavy hydrogen doping, giving a characteristic metallic feature such as LSPR in hydrogen metal bronze. This specific characteristic is featured only by tungsten and molybdenum oxides [3]. Herein, we need to note that S2 shows the red-shift in the absorption edge. A similar red-shift has been reported in semiconductor particle/nanocarbon composite, caused by the formation of the chemical

bonding in the interface [28], [29]. In this case, it is difficult to determine the actual optical bandgap from UV-vis spectra since the presence of carbon component involves a continuous absorption band in the range of 400-800 nm.

The outstanding enhancement of photocatalytic activity is demonstrated by the photodegradation of MO under visible-light irradiation (>385 nm) compared to the pristine WO₃ and the mechanically treated WO₃ powders, as shown in Fig. 6a-b. MO possesses strong absorption at 465 nm and 270 nm, corresponding to the azo bond (-N=N-) and the benzene ring, respectively [30], [31]. The central absorption peak (465 nm) red-shifted and decreased quickly due to the cleavage of the conjugated double bond with decolorization, starting after photodegradation. Azo-dye is commonly used as a pH indicator that exhibits a color change from yellow to red with increasing acidity. The OH groups formed in H_xWO₃ would have Bronsted acidic features, functioning as active sites for the catalytic reaction in this case. Moreover, the absorption peak attributed to the benzene ring is shifted toward shorter wavelengths (240-260 nm) during photocatalysis, indicating that the degraded products could be attributed to sulfanilic acid and N, Ndimethyl-p-phenylenediamine [30], [31]. The new absorption of nitrophenols arises from the π (benzene ring)– π^* (nitro group) transition at 330 nm [32], as well as the peak of amine [25] in the UV region (<240 nm) throughout photodegradation. The photocatalytic degradation kinetics follow the first-order law, expressed as $\ln(C_0/C) = kt$, where t is the irradiation time, and k is the degradation rate constant. The value of k was determined as 2.79×10^{-2} min⁻¹ from the slope of the linear graphs in Fig. 6b, which enhances the photocatalytic reaction rate by one order of magnitude. It is generally known that the H_xWO_3 phase possesses high electrical conductivity and promotes the charge separation of photoexcited carriers (electrons and holes) by forming a heterojunction with WO₃, leading to the enhancement of photocatalytic activity [11]. However, the observed visible-

light photocatalytic activity of a single phase of H_xWO₃ is atypical. In evaluating the carrier recombination rates by photoluminescence (PL), a further decrease in PL intensity was observed in the synthesized composites (Fig. 6c). As a further experiment to understand the enhancement of photocatalytic activity in the synthesized material, the heat treatment was conducted for S2 at 400 °C (10 K/min without temperature keeping) in the inert atmosphere (Ar) to release hydrogen in H_xWO₃ [15], [17]. Fig. 7a shows the XRD patterns, where the phase transition from tetragonal (H_xWO_3) to monoclinic (WO_3) is found in the thermally treated particle (S3). As well as the characteristic IR absorption originated from H_xWO₃, this result supports the formation of H_xWO₃ via the ball-milling process. Moreover, S3 shows a thermal inactivation in the photocatalytic performance (displayed in Fig. 7b). Thus, the presence of H_xWO₃ should be a crucial factor in enhancing photocatalytic activity. In this case, the adsorption amount of methyl orange after adsorption/desorption equilibrium (reaction time = 0 min) is negligibly minor than the decomposition amount. Besides, the disappearance of H_xWO₃ causes a higher carrier recombination rate (shown in Fig.7 (c)). Nevertheless, the possibility should be noted that nanocarbon facilitates photocatalytic reaction as cocatalyst [33] more or less for efficient adsorption of dye molecules and excited carrier separation.

To understand the specific reaction pathway for the room-temperature formation of H_xWO₃ without thermal or electrochemical effects, the in situ measurement of pressure change in the zirconia vessel was carried out during the mechanical treatment in various atmospheres (Fig. 8a). In the milling of m-WO₃ only, the pressure increased followed by saturation within 60 min, which might be due to the vaporization of physisorbed water molecules on the particle surface. In contrast, the milling of the mixture powder caused a considerable increase in pressure, resulting from the mechanical decomposition of polyolefin and leading to the production of the gaseous component of hydrocarbon fragments, similar to that reported in Ref [34]. Notably, a sharp decrease in pressure was observed in air condition followed by a temporary increase. It follows from the XRD patterns of the composite powder prepared in different atmospheres during the ball milling, that the phase transition from monoclinic to tetragonal is retarded greatly by the treatment in the air (Fig. 8b). Furthermore, a distinct change between the two different powders was observed in the structure of the carbonaceous by-product material from the Raman spectra (Fig. 8c). Mechanical treatment in an inert atmosphere causes a much more highly ordered graphitic structure, whereas the defective nanocarbon is preferably formed by ball milling in air. This fact suggests that the loss of active fragments acting as proton suppliers through oxidation negatively impacts the effective formation of H_xWO₃. Moreover, the structural difference is reflected by the optical property, and the powder treated in the oxidation atmosphere displays a weaker absorbance up to the visible region (>400 nm) (see Fig. 8d). As our co-authors have reported for a mechano-chemical reduction of metal oxides through high-energy ball milling in the presence of an organic polymer [35], this phenomenon might be associated with the reduction of the WO₃ surface in air. It follows from the XRD patterns shown in Fig. 8e that the mixed crystalline structures of m-WO₃ and tetragonal H_xWO₃ appeared after 1 h of treatment, and the phase

transformation completed within 3–5 h during ball milling. The migration of hydrogen from the terminal oxygen on the molybdenum oxide surface to the bulk is known to be the rate-limiting step with an activation barrier of 0.6 eV [13]. Because the proton diffusion in the solid-state of WO₃ is much faster (50–175 μ m/s) [14] than the observed time lag to complete the phase transformation, the structural modifications such as lattice distortion have to be a key component to serve as the catalytic function in H-spillover promoted by the active fragment to lower the energy potential.

In this study, we propose a new scheme for the room-temperature formation of H_xWO_3 via mechanically induced H-spillover without precious metal catalysis (**Fig. 9**). The high-energy ball milling process is associated with the simultaneous lattice distortion of m-WO₃ and the mechanical depolymerization of PP in the first stage. In an inert atmosphere, the generation of a gaseous fragment is effectively facilitated, as the defective surface of the transition metal oxide assists the catalytic reaction to further decomposition of hydrocarbons. It must be a pivotal pathway for room-temperature H-spillover to form H_xWO_3 (tetragonal) with a highly ordered nanostructure. On the other hand, the strongly chemisorbed intermediate carbon species efficiently converted into the graphitic nanocarbon as a by-product, protecting the H_xWO_3 is firmly blocked in an air atmosphere because of the physical/chemical stabilization or relaxation of active fragments and the modified WO₃ surface by oxidation.

Fig. 9. Schematic illustration of the room-temperature synthesis of H_xWO_3 in mechanically induced H-spillover.

4. Conclusions

We proposed the room-temperature synthesis of H_xWO_3 achieved by a mechanically induced reaction under inert atmospheric conditions, where the starting materials include only a dry powder mixture of m-WO₃ and PP. The synthesized highly crystalline H_xWO_3 nanoparticles (tetragonal; 0<x<0.5) showed a specific optoelectronic feature, exhibiting outstanding enhancement of photocatalytic activity toward the degradation of azo-dye water pollutants (MO) under visible light. Furthermore, the formation mechanism of H_xWO_3 with the graphitic nanocarbon by-product is also addressed, involving H-spillover on the mechanically activated m-WO₃ surface. The catalytic generation of a gaseous fragment as a proton supplier would be effectively facilitated in an inert atmosphere followed by the simultaneous mechanical depolymerization of PP. Additional work is required for detailed understanding of the mechanism and electronic structure of H_xWO_3 nanocarbon composites, however, we believe that the sustainable and green nanotechnology for the synthesis of H_xWO_3 breaks down the limitation for mass production constrained from the use of a specific setup for electrochemical reactions and precious metal catalysis to surmount the potential energy barrier for H-spillover.
