Abstract

The study on quantum spin Hall effect and topological insulators formed the prologue to the surge of research activities in topological materials in the past decade. Compared to intricately engineered quantum wells, three-dimensional weak topological insulators provide a natural route to the quantum spin Hall effect, due to the adiabatic connection between them and a stack of quantum spin Hall insulators, and the convenience in exfoliation of samples associated with their van der Waals-type structure. Despite these advantages, both theoretical prediction and experimental identification of weak topological insulators remain scarce. Here, based on first-principles calculations, we show that AuTe₂Br locates at the boundary between a strong and a weak topological insulating state. More interestingly, the critical topology of AuTe₂Br persists up to an applied pressure of ~ 15.4 GPa before a structural phase transition accompanied by a change of electronic topology and the onset of superconductivity. Our results establish AuTe₂Br as a new candidate for weak topological insulators with the potential to realize various other topological phases of matter.

Introduction

For the classification of states of matter, the role of topology as a principle beyond spontaneous symmetry breaking was first demonstrated in quantum Hall states^{1–9}. However, the extensive current research interest in topological materials started with topological insulators (TIs), preluded by the discovery of quantum spin Hall (QSH) states in quantum wells. QSH insulators, often synonymously referred to as two-dimensional (2D) TIs, are characterized by a finite bulk band gap and gapless helical edge states carrying opposite spins^{1–9}. Time-reversal symmetry dictates the destructive interference between backscattering paths, resulting in dissipationless spin currents, bearing huge significance for electronic and spintronic applications^{10–13}. Despite the intense pursuit in the past decade for QSH insulators beyond quantum-well systems, the only candidates found are monolayer WTe₂ ^{5–8} and WSe₂ ⁹.

Compared to the case of a time-reversal-invariant 2D TI classified by the \mathbb{Z}_2 index, 3D TIs are classified by four \mathbb{Z}_2 indices (v_0 ; \mathbf{v}) \equiv (v_0 ; $v_1v_2v_3$). A strong TI (STI) is indicated by a nonzero v_0 , in which the bulk gap is closed by surface states featuring an odd number of Dirac cones on all surfaces of the sample^{1.2}. In contrast, a zero v_0 and finite \mathbf{v} point to a weak TI (WTI), in which gapless surface states associated with an even number of Dirac cones appear only on the side surfaces. Compared to 2D TIs and 3D STIs, the territory of WTIs remains relatively less explored, with only a few candidates found to date^{13–17}, such as ZrTe₅, HfTe₅, Bi₁₄Rh₃I₉, β -Bi₄I₄, and CaSn. All these compounds consist of weakly coupled layers, a structure desirable for realizing WTI, as a WTI is topologically equivalent to a stack of 2D TI layers^{13–17}. Considering how the sample can be readily cleaved to few layers or even monolayer, WTIs with a van der Waals-type structure provide a promising platform for realizing QSH states. Moreover, contrary to initial perceptions and what is implied in their name, WTIs have been demonstrated to be robust even under strong disorders, provided the time-reversal symmetry remains intact^{13–17}.

Here, by performing density functional theory calculations, we found that the van der Waals-type compound AuTe₂Br is an STI or WTI, depending on whether the raw experimental (Expt.) or fully optimized (Opt.) structural parameters are used as input for the calculations, respectively. This dichotomy indicates that AuTe₂Br may locate at the boundary between an STI and a WTI state. Despite its sensitivity to structural variations, the critical topology is found to persist up to an applied pressure of ~ 15.4 GPa, where a pressure-induced structural phase transition from $Cmc2_1$ to Pmmm occurs. The robustness against pressure might originate from the opposite trend in the pressure dependence of certain structural parameters. The low-pressure TI phase emerges from a topological nodal-line metal (TNLM) protected by mirror symmetry when the spin-orbit coupling (SOC) is ignored. In contrast, the high-pressure phase in the absence of SOC is a TNLM stabilized by a distinct mechanism due to the recovery of inversion symmetry. Furthermore, superconductivity is observed in a wide pressure range in the high-pressure phase. Our results not only add another candidate to the list of WTIs and hence QSH insulators, but also provide a fertile playground for the exploration of topological phase

transitions and topological superconductivity.

Results and discussion

AuTe₂*X* (*X* = Cl, Br) crystallize in an orthorhombic structure, consisting of halogen atoms inserted between layers of AuTe₂ networks stacking along the *b* axis [Fig. 1(a)], despite their space groups differing from each other—*Cmcm* (No. 63) and *Cmc*2₁ (No. 36) for Cl, and Br, respectively^{18–21}. The topological properties of AuTe₂*X* remained unexplored until recently^{21,22}. Transport measurements revealed the compensated semimetal nature of AuTe₂Br with ultrahigh carrier mobility of ~ 10⁵ cm²V⁻¹s⁻¹ and a nonsaturated magnetoresistance reaching ~ 3 × 10⁵ at 4.2 K and 58 T ²¹. More interestingly, it was proposed that the QSH effect can be realized in monolayer AuTe₂Cl through the confinement effect²². Our calculations on the band structure of bulk AuTe₂Cl (Supplementary Fig. 1) give unanimously a topological nontrivial gap along the Γ –Y direction and a Z₂ of (1; 110), regardless of whether Expt. or Opt. structural parameters are used, confirming the STI nature of AuTe₂Cl. Note that such an STI is topologically equivalent to the topological semimetal suggested by previous studies²², considering the complete separation of the valence and conduction bands.

Our calculation results for AuTe₂Br in the monolayer limit are presented in Supplementary Fig. 2. Fully optimized structure parameters are adopted for the monolayer, giving relaxed lattice constants close to the experimental values for the bulk counterpart. Similar to the case of monolayer AuTe₂Cl, monolayer AuTe₂Br is shown to be a 2D TI, rendering it a candidate platform for the study of the QSH effect.

Turning to the bulk AuTe₂Br, the calculation results in the absence of SOC are shown in Figs. 1(c–e) and Figs. 1(f–h) for Expt. and Opt. structural parameters, respectively. The results are similar for the two sets of parameters. We find a metallic ground state with electron pockets at the X and M points and hole pockets at the Γ and Y points. The bands exhibit crossing points in the high symmetry directions Γ -Y and Y-K that are tied to the Γ YKZ plane of the bulk Brillouin zone. By projecting the states onto atomic orbitals, we find that the two bands forming the crossing points are contributed by the Au d_{xz+yz} orbital and Te p_z orbital, respectively, as shown in Figs. 1(d) and 1(g). The band order is inverted around the Y point, indicating a nontrivial topology. Due to the presence of mirror symmetry associated with the Γ YKZ plane, the crossing points actually form a nodal line in this plane centering around Y, as depicted in Figs. 1(e) and 1(h).

The calculation results for the band structure of bulk AuTe₂Br with SOC included are shown in Figs. 2(a-d) and Figs. 2(e-h) for Expt. and Opt. structural parameters, respectively. The nodal line is gapped for both cases. Surprisingly, however, topologically distinct results are found for the two sets of parameters. Before structural optimization, there is a gapped Dirac cone arising from the band hybridizations between Au d_{xz+yz} and Te p_z orbitals along Γ -Z, resulting in inverted bands at the Y point [Fig. 2(b)]. With structural optimization, the band order at Γ is inverted as well [Fig. (f)]. To further characterize the band topology, the Wannier charge centers (WCC) evolution on the time-reversal invariant planes is calculated using the Wilson loop method, as shown in Figs. 2(c) and 2(g). In a WCC plot, the \mathbb{Z}_2 indices can be obtained by counting the number of times the WCC curves intersect with any arbitrary horizontal reference line²³. For example, for the $k_x = 0$ plane, no intersection is found so that the associated $\mathbb{Z}_2 = 0$ [the top left panel in Fig. 2(c)], while for the $k_x = 0.5$ plane, one intersection is found so that the associated $\mathbb{Z}_2 = 1$ [the top right panel in Fig. 2(c)]. For a 3D TI, v₀ is determined by the parity of the sum of the \mathbb{Z}_2 associated with all the $k_i = 0$ (i = x, y, z) and 0.5 planes, whereas v_i (i = 1, 2, 3) is determined by the \mathbb{Z}_2 associated with the $k_i = 0.5$ (i = x, y, z) planes. For the Expt. and Opt. case, respectively, we get (1; 110) and (0; 110) and, thus, an STI and a WTI. This is also reflected in the calculated surface states on the (001) projected surface (note that this is a side surface): one surface Dirac point is observed around \overline{Y} for the Expt. case [Fig. 2(d)], while two Dirac points locate around $\overline{\Gamma}$ and \overline{Y} for the Opt. case [Fig. 2(h)].

The dichotomy between the two cases indicates that AuTe₂Br exhibits a critical topology, where the balance is tipped towards an STI or a WTI state by a small variation in the crystal structure. It is therefore interesting to study how the band topology evolves under hydrostatic pressure. To obtain the structural parameters under pressure, high-pressure x-ray diffraction (XRD) measurements were performed, and the results are

displayed in Fig. 3(a). With increasing pressure, the $Cmc2_1$ phase persists up to ~ 18.8 GPa. Upon further compression, new diffraction peaks emerge, indicative of a structural phase transition. Enthalpy calculations show that above 15 GPa, the *Pmmm* symmetry is favored [Figs. 3(b) and 3(c)]. No imaginary modes are found in the phonon calculations above 20 GPa (Supplementary Fig. 4), confirming the robust dynamic stability of this *Pmmm* phase under high pressure. The lattice constants extracted from Rietveld refinements are displayed in Fig. 3(d), showing a drastic drop of *b* across the structural transition.

The band structure under pressure before the structural transition is shown in Supplementary Fig. 5. With increasing pressure, the band dispersion along Γ -Y increases. However, for both Expt. and Opt. structural parameters, the band order at Γ and Y is maintained. In other words, the critical topology of AuTe₂Br between an STI and WTI is robust against pressure, provided the space group stays the same.

At first glance, this seems to be inconsistent with the fact that the band topology is sensitive to variations in structural parameters. To solve this apparent discrepancy, we investigate the relation between the critical topology and the structural parameters. As discussed above and schematically shown in Figs. 2(b) and 2(f), the key difference between an STI and WTI state is the band order at Γ. We plot for AuTe₂Cl and AuTe₂Br the dependence of the energy difference of the two bands at Γ , $\Delta E_{\Gamma} \equiv \Delta E_{\Gamma}$ $E(\operatorname{Au} d_{xz/yz}) - E(\operatorname{Te} p_z)]$, on representative structural parameters [Figs. 4(a), 4(c) and 4(e)]. For simplicity, only the data points for ambient pressure are shown. As discussed, AuTe₂Cl being an STI is robust against structural variations. For AuTe₂Br, with Expt. structural parameters, the pressure-induced decreasing of the Au-Te bond length d_{Au-Te} and the distance between Au-Te layers d_{layer} [Figs. 4(b) and 4(d)] pushes the data points under pressure to the left of the ambient pressure data point Br (Expt.), meaning that AuTe₂Br is always an STI. However, for the Opt. case, one would expect a transition from WTI to STI with the considerable pressure-induced decreasing of d_{Au-Te} and d_{layer} since the ambient pressure data point Br (Opt.) is already very close to the boundary. Such a transition is not observed in our calculations (Supplementary Fig. 5). This may be explained by the counteracting effect by the pressure evolution of another parameter, namely, the height of an Au-Te layer h_{layer} [Fig. 1(a)]. As shown in Fig. 4(f), h_{layer} increases with pressure. This means that with increasing pressure, one is traversing to the right of the ambient pressure data point Br (Opt.) in Fig. 4(e), keeping AuTe₂Br in the WTI state.

We now turn to the band topology of the high-pressure *Pmmm* phase. In the absence of SOC, the band structure exhibits a 3D metallic nature with some bands featuring large energy dispersion across the Fermi level [Fig. 5(a)]. The 3D Brillouin zone is shown in Fig. 5(b). There are two band crossings along two paths in the $k_x = 0$ plane, Γ -Z and Γ -T [Fig. 5(c)]. The crossings are attributed mainly to the Te– p_x and p_z orbitals. At Γ , the p_z band lies above p_x , which is a signature of band inversion, implying the nontrivial band topology of the Pmmm phase. Moreover, due to the recovery of the inversion symmetry in this phase, a mechanism different from the ambient pressure one dictates the presence of a nodal line in the $k_x = 0$ plane and centering around Γ [Fig. 5(d)]. Here, the nodal line is protected by the combination of time-reversal, inversion, and spinrotation symmetries. With the inclusion of SOC, the nodal line is fully gapped with a gap size of ~ 0.02 eV, as shown in Fig. 5(a). The (100) surface band structures are shown in Fig. 5(e). Outside the projection of the nodal line crossings, the surface bands disperse upwards when SOC is ignored. Taking SOC into account, there is a metallic surface band connecting the projected bulk valence and conduction bands. This surface band exhibits spin-momentum-locked spin textures, as displayed in Fig. 5(f).

In addition to the nontrivial band topology, we observed superconductivity in a wide pressure range in the *Pmmm* phase. Temperature-dependent resistance data for AuTe₂Br single crystals are shown in Fig. 6(a). A superconducting transition emerges at ~ 19 GPa and persists to the highest pressure of ~51 GPa we measured. We then check the superconducting transition under magnetic field [Fig. 6(b)] and obtain the upper critical field H_{c2} at various pressures [Fig. 6(c)]. The pressure dependence of the superconducting transition temperature T_c is summarized in Fig. 6(d). Nevertheless, the nontrivial band topology of AuTe₂Br leaves the possibility of topological superconductivity an interesting topic for future studies.

Summary

In summary, AuTe₂Br is proposed as a new platform for the exploration of WTIs based on our first-principles calculations. Nontrivial topology was found both for the ambient pressure phase and the phase after a pressure-induced structural phase transition, the latter accompanied by superconductivity observed in our measurements. Importantly, our calculations also demonstrate the promising possibility of investigating QSH effect in monolayer AuTe₂Br, which can be readily obtained due to the van der Waals-type structure.

The fact that AuTe₂Br lies in close proximity to the topological transition between an STI and WTI state holds substantial potential in the continuous tuning of such a transition. Although we have shown that pressure may not be the ideal tuning knob, probably as a result of an opposite trend in the pressure evolution of structural parameters determining the electronic topology, specifically designed variation of these parameters may serve this purpose. This may be achieved by chemical substitution, strain, etc., or a combination with hydrostatic pressure. It would then be more interesting to see how superconductivity is affected when the topological transition is traversed.

Methods

Sample synthesis and magneto-resistivity measurements. AuTe₂Br single crystals were synthesized, as described in Ref. 21. The as-grown single crystals are soft, silver flakes with high quality, and the biggest natural plane is (0/0) plane [see Supplementary Fig. 3(a)]. Magneto-resistivity measurements under ambient pressure were performed in a physical property measurement system (PPMS; Quantum Design).

Resistance measurements under pressure. High-pressure resistance measurements were performed on AuTe₂Br single crystals with silicone oil as the pressure transmitting medium (denoted as S1, S2, S3 for different runs) by using a diamond anvil cell (DAC). The experimental pressures were determined by the pressure-induced fluorescence shift

of ruby at room temperature before and after each experiment. A direct current fourprobe technique was adopted. Resistance measurements were performed with a PPMS.

XRD measurements under pressure. AuTe₂Br single crystals were ground into powder by using a mortar for use in the high-pressure synchrotron angle dispersive X-ray diffraction measurement. The high-pressure synchrotron XRD experiments were carried out using a symmetric diamond anvil cell (DAC) with a 300-micron culet diamond. A rhenium gasket was drilled by laser with a 90-micron diameter hole as the sample chamber. The sample chamber was filled with a mixture of the sample, a ruby ball, and silicone oil as the pressure transmitting medium. The experimental pressures were determined by the pressure-induced fluorescence shift of ruby. Synchrotron angle-dispersive XRD measurements were carried out at beamline BL15U1 of the Shanghai Synchrotron Radiation Facility (SSRF) using a monochromatic beam of 0.6199 Å. The diffraction patterns were integrated by using the Dioptas software, and Rietveld refinement was performed by using the GSAS software.

Electronic band structure of AuTe₂X (X = Cl, Br). We carried out first-principles calculations within the framework of the projector augmented wave (PAW) method²⁴, as implemented in the Vienna Ab initio Simulation Package (VASP)^{25,26}. A kinetic energy cutoff of 500 eV and a Γ -centered *k* mesh of 11 x 11 x 7 were selected in all calculations. The energy and force difference criterion were defined as 10⁻⁶ eV and 0.01 eV/Å for self-consistent convergence. The van der Waals (vdW) corrections^{27,28} and spin-orbit coupling (SOC) effect are considered for all calculations. The electronic band structure for AuTe₂X (X = Cl, Br) were calculated with experimental structure and fully optimized lattice parameters (PBE+D2). PBE+D2 represents Perdew-Burke-Ernzerhof (PBE)²⁹, generalized gradient approximation (GGA) functional with D2 empirical vdW corrections. The WANNIER90 package^{30–32} was adopted to construct Wannier functions from the first-principles results without an iterative maximal-localization procedure. The WANNIERTOOLS code³³ was used to investigate the topological features of surface state spectra. The high-pressure electronic band structure of AuTe₂Br were also

calculated with experimental structure (Expt.) and fully optimized lattice parameters (Opt.), respectively. The cell parameters of AuTe₂Br under lower pressure for calculations are displayed in Supplementary Table 1.

High-pressure structure calculations for AuTe₂Br. Beyond the pressure where a pressure-induced structural phase transition takes place, we performed a high-pressure crystal structure searching of AuTe₂Br by using an in-house program called MAGUS (machine learning and graph theory assisted universal structure searcher), which is accelerated by the employment of Bayesian optimization and graph theory. This method has been successfully applied in many systems under high pressure, such as compounds inside plants and layered materials^{34–37}. The structural optimization and electronic structure calculations were carried out within density functional theory using the projector augmented-wave method as implemented in the VASP. We chose s^1d^{10} , s^2p^4 and s^2p^5 as the valence electrons for Au, Te and Br respectively while using the GGA in the PBE exchange-correlation functional. The plane-wave cutoff was set as 340 eV and the Brillouin zone (BZ) was meshed choosing the gamma-centered Monkhorst-Pack approximately $2\pi \times 0.025$ Å⁻¹.

(a) Crystal structure of AuTe₂Br with the *Cmc*2₁ space group. d_{layer} and h_{layer} represent the distance between the Au-Te layers, and the height of an Au-Te layer, respectively. (b) The 3D bulk Brillouin zone (BZ). (c–e) are the calculated band structure, orbital projected band structures along the Γ -Y-K directions, and the energy difference map between the Au d_{xz+yz} and Te p_z bands in the Γ YKZ plane of the BZ for AuTe₂Br with experimental (Expt.) structural parameters, respectively. (f–h) are those results with fully optimized (Opt.) structural parameters. The contour of the nodal ring is shown by the red line in (e) and (h). The background color represents the magnitude of the gap between the Au d_{xz+yz} and Te p_z bands. With the gap increasing, the color changes from white to blue. Red ellipse highlights the zero gap.

Figure 2 | Band structure calculations for AuTe₂Br with SOC included. (a–d) are the calculated band structure, orbital projected band structures along the Γ -Y direction, the evolution of the Wannier charge centers, and the calculated surface states on the (001) projected surface for AuTe₂Br with Expt. structural parameters, respectively. (e–h) are those results with Opt. structural parameters.

Figure 3 | Pressure evolution of the crystal structure of AuTe₂Br. (a) X-ray diffraction 2θ plot of AuTe₂Br at room temperature up to 52.2 GPa. The ambient-pressure *Cmc*2₁ structure persists to ~ 18.8 GPa, beyond which new diffraction peaks

emerge (each marked with a dashed line and asterisk), indicating the emergence of pressure-induced structural phase transition. (**b**) Crystal structure of the high-pressure AuTe₂Br with *Pmmm* space group. (**c**) Enthalpy calculations for several predicted structures. Above 15 GPa, the *Pmmm* symmetry has the lowest enthalpy. (**d**) Pressure dependence of the lattice constants derived from Rietveld refinement.

Figure 4 | The topology of AuTe₂Cl and AuTe₂Br as a function of representative structural parameters and pressure. (a), (c) and (e) show the topology—being a strong topological insulator (STI) or weak topological insulator (WTI)—of AuTe₂Cl (labeled as Cl) and AuTe₂Br (labeled as Br), as represented by the energy difference between Au- $d_{xz/yz}$ and Te- p_z bands at the Γ point, as a function of Au-Te bond length d_{Au-Te} , the distance between Au-Te layers d_{layer} , and the height of an Au-Te layer h_{layer} , respectively. (b), (d) and (f) show the pressure dependence of d_{Au-Te} , d_{layer} , and h_{layer} , respectively.

Figure 5 | Band structure calculations for AuTe₂Br at 50 GPa. (a) Calculated band structure of AuTe₂Br at 50 GPa. The red and blue lines represent the results without and with SOC. (b) The 3D bulk Brillouin zone (BZ). (c) Orbital-projected band structure near the Γ point. The contour of the nodal ring in the absence of SOC is shown by the red line in (d). The background color represents the magnitude of the gap between the Te p_x and Te p_z bands. With the gap increasing, the color changes from white to blue. Red ellipse highlights the zero gap. (e) Surface band structures without and with SOC for the (100) surface. (f) Fermi surface and corresponding spin texture at a fixed energy $E - E_F = 20$ meV of the topological surface states in the presence of SOC.

Figure 6 | Pressure-induced superconductivity in AuTe₂Br. (a) Temperature dependence of the resistance of AuTe₂Br single crystals with silicone oil as the pressure transmitting medium. S1, S2 and S3 represent different runs. (b) Magnetic field dependence of the superconducting transition of AuTe₂Br single crystal (S2) at 27.8 GPa. The superconducting transition temperatures T_c are defined as shown in the panel. (c)

Temperature dependence of the upper critical field $\mu_0 H_{c2}$. Solid lines are a guide to the eye. (d) Pressure dependence of T_c .

Supplementary Note 1: Topological band structure of AuTe₂Cl

Supplementary Figure 1 | **Band structure of AuTe₂Cl.** The calculated band structure for AuTe₂Cl with (**a**) experimental structure (Expt.) and (**b**) fully optimized lattice parameters (Opt.). The insets of (**a**) and (**b**) shows the enlarged view of the band dispersion near the Dirac cone. (**c**) The evolution of Wannier charge centers and Z_2 topological invariants for AuTe₂Cl. These results suggest that AuTe₂Cl is a strong topological material.

Supplementary Figs. 1(a) and 1(b) present the band calculations with SOC by using the experimental structure (Expt.) and the fully optimized lattice parameters (Opt.), respectively. For both cases, AuTe₂Cl is a strong topological insulator, considering the complete separation of the valence and conduction bands, whose topology is demonstrated by the plot of the evolution of Wannier charge centers and \mathbb{Z}_2 topological invariant calculations [Supplementary Fig. 1(c)]. Supplementary Note 2: Band structure and topology of monolayer AuTe₂Br

Supplementary Figure 2 | Band structures of AuTe₂Br monolayers. (a) The orbitally resolved band structure of monolayer AuTe₂Br without SOC. (b) The band structure of monolayer AuTe₂Br with SOC. The dashed curve represents the fictitious Fermi level. (c) The evolution of WCCs along k_x for monolayer AuTe₂Br. The green broken line stands for an arbitrary horizontal line crossing the WCC, and odd times crossing confirms the nontrivial topology.

Supplementary Fig. 2(a) shows the band structure of monolayer AuTe₂Br without

SOC. It is found that this system exhibits a metallic state, with two bands crossing the Fermi level. Intriguingly, there is a band crossing point near the Fermi level along the Γ -X direction. By projecting the states onto atomic orbitals, we find that the crossing point along the Γ -X direction is created by a band inversion between the band with Te p_z character and the band contributed by the mixture of Au d_{xy} and Te p_x orbitals at the Γ point. This inverted band structure suggests nontrivial band topology of monolayer AuTe₂Br.

With SOC, as shown in Supplementary Fig. 2(b), the crossing point along the Γ -X direction is gaped and there appears a gap between the valence and conduction bands in the whole Brillouin zone. Thus, monolayer AuTe₂Br can be considered as an insulator, considering the complete separation of the valence and conduction bands. The \mathbb{Z}_2 index is well defined for the bands below the curved Fermi level since there is a finite band gap at each *k* point. It is determined to be 1 by calculating Wannier charge center (WCC), as shown in Supplementary Fig. 2(c), where the number of crossings between an arbitrary horizontal line and the WCC is odd in half of the Brillouin zone.

Supplementary Note 3: General properties of as-grown AuTe₂Br single crystals

Supplementary Figure 3 | General properties of as-grown AuTe₂Br single crystals. (a) XRD measurements of one piece of single crystal. Inset shows the rocking curve of (040) plane. (b) Longitudinal resistivity of a typical single crystal, and the residual resistivity ratio (RRR) is 154. The RRR is defined as $RRR \equiv \rho_{300 \text{ K}} / \rho_0$, with residual resistivity $\rho_0 \sim 0.13 \,\mu\Omega$ cm. (c) Transverse, (d) longitudinal magneto-resistivity and (e) longitudinal conductivity at different temperatures. (f) The oscillatory component $\Delta \sigma_{xx}$ at different temperatures, extracted from σ_{xx} by subtracting a smooth background. (g) Fast Fourier transform (FFT) results for Shubonikov-de Haas oscillations (SdH)

oscillations. (**h**) Landau level index plots for the β_1 and β_2 bands.

Figure S3 shows the general properties of as-grown AuTe₂Br single crystals with high quality as demonstrated by the small value of the full width at half maximum (FWHM) of 0.04° [the inset to Supplementary Fig. 3(a)], and the large RRR of 154 [Supplementary Fig. 3(b)]. Supplementary Figs. 3(c–h) show the quantum oscillations and the analysis. By analyzing the oscillatory component $\Delta \sigma_{xx}$, we obtain the oscillation frequencies. According to the Landau level index [Supplementary Fig. 3(h)], the intercepts for β_1 and β_2 bands locate at 3/8 ~ 5/8 and -1/8 ~ 1/8, respectively, implying β_1 band has trivial Berry phase whereas β_2 band has nontrivial Berry phase.

Supplementary Note 4: Phonon calculations for the high-pressure *Pmmm* phase of AuTe₂Br

Supplementary Figure 4 | **Phonon calculations for the high-pressure** *Pmmm* **phase.** No imaginary modes (modes with a negative frequency) are found in the phonon calculations above 20 GPa, confirming the robust dynamic stability of this *Pmmm* phase under high pressure.

P (GPa)		<i>a</i> (Å)	<i>b</i> (Å)	<i>c</i> (Å)

Supplementary Note 5: Crystal parameters of AuTe₂Br under pressure

Supplementary Table 1 | Crystal parameters of AuTe₂Br for band calculations at ambient and high pressures. The data for experiment (Expt.) is derived from refinement. PBE and PBE+D2 represent Perdew-Burke-Ernzerhof (PBE) GGA functional and PBE GGA functional with D2 empirical VdW corrections, respectively.

Supplementary Note 6: Band structure of AuTe₂Br under pressure

Supplementary Figure 5 | Electronic band structures of AuTe₂Br before structural phase transition by using the experimental data (Expt.) and the fully optimized lattice parameters (Opt.).

The calculated band structures with experimental input at 1.3, 8.5 and 15.3 GPa are displayed in Supplementary Figs. 5(a–c), respectively, while the calculated band structures by using the fully optimized lattice parameters are shown in Supplementary Figs. 5(d–f), respectively. With increasing pressure, the band structure of AuTe₂Br displays more 3D-like feature. We also check the topology behavior at different pressures (data not shown), and found that the topological property of AuTe₂Br is robust against pressure, i.e., the band structures with experimental data at different pressures suggest AuTe₂Br is a strong topological insulator (STI), while it is a weak topological insulator (WTI) with fully optimized parameters.
