

# Imputation Maximization Stochastic Approximation with Application to Generalized Linear Mixed Models

Zexi Song<sup>1</sup> & Zhiqiang Tan<sup>1</sup>

January 26, 2022

**Abstract.** Generalized linear mixed models are useful in studying hierarchical data with possibly non-Gaussian responses. However, the intractability of likelihood functions poses challenges for estimation. We develop a new method suitable for this problem, called imputation maximization stochastic approximation (IMSA). For each iteration, IMSA first imputes latent variables/random effects, then maximizes over the complete data likelihood, and finally moves the estimate towards the new maximizer while preserving a proportion of the previous value. The limiting point of IMSA satisfies a self-consistency property and can be less biased in finite samples than the maximum likelihood estimator solved by score-equation based stochastic approximation (ScoreSA). Numerically, IMSA can also be advantageous over ScoreSA in achieving more stable convergence and respecting the parameter ranges under various transformations such as nonnegative variance components. This is corroborated through our simulation studies where IMSA consistently outperforms ScoreSA.

**Key words and phrases.** Stochastic approximation; Generalized linear mixed model; Latent variable model; Self consistency; Expectation maximization.

# 1 Introduction

Latent variable modeling involves both latent and observed variables such that their joint density is analytical tractable, but the marginal density of the observed variable is analytically intractable. Fitting latent variable models is known to be challenging due to analytically intractable likelihood functions. In particular, an important class of latent variable models is generalized linear mixed models (GLMMs) (McCulloch et al., 2008) or hierarchical generalized linear models (Gelman and Hill, 2007). Common existing methods for fitting GLMMs are hindered by various limitations including: requirement of a prior distribution for the parameters in the Bayesian approach; potential bias caused by analytical approximation; high computational cost or sensitive and difficult tuning in current methods using expectation maximization (EM) or stochastic approximation (SA) for likelihood inference. See Section 2.3 for further discussion. In this paper, we propose a new method called imputation maximization stochastic approximation, or IMSA for short, and present simulation studies in support of the superior performance of IMSA.

The remainder of the paper is organized as follows. In Section 2 we introduce GLMMs in the broader context of latent variable models and review existing methods; in Section 3 we derive the proposed method, discuss its theoretical properties and compare it with current SA methods; in Section 4 we present simulation studies on two normal-logistic mixed models; in Section 5 we provide a conclusion.

## 2 Background

### 2.1 Latent variables models

Latent variable models are widely used to deal with complex data by introducing latent or hidden variables. Formally, a latent variable model can be defined as follows. Let  $y$  be observed variables and  $u$  be latent variables such that the joint density function  $f(y, u; \theta)$  is analytically tractable in terms of  $(y, u, \theta)$ , where  $\theta$  is a parameter vector. Typically,  $f(y, u; \theta)$  is obtained as  $f(y, u; \theta) = f(y|u; \theta)f(u; \theta)$ , with both the marginal density  $f(u; \theta)$  and the conditional density  $f(y|u; \theta)$  analytically tractable. However, the marginal density of  $y$ , defined in the integral form  $f(y; \theta) = \int f(y, u; \theta) du$ , is analytically intractable. Since  $f(y; \theta)$  is also the likelihood function of parameter  $\theta$  for fixed data  $y$ , its intractability creates difficulties (at least numerically) to likelihood and Bayesian methods alike.

## 2.2 Generalized linear mixed models

For concreteness, we focus on a specific class of latent variable models called generalized linear mixed models (GLMMs), although our proposed method in Section 3 is applicable to general latent variable models. GLMMs are a natural extension from generalized linear models by incorporating random effects. They can also be obtained from linear mixed models by expanding the distribution of the response variables from Gaussian to an exponential family. There is an extensive literature about GLMMs (e.g., McCulloch et al., 2008; Gelman and Hill, 2007). Here we provide a brief description of GLMMs. Let  $y = (y_1, \dots, y_n)^T$  be observed response variables, and  $u = (u_1, \dots, u_q)^T$  be latent variables (also referred to as random effects in this context). We introduce covariates  $x_i$  and  $z_i$  for  $i = 1, \dots, n$ , associated with  $p$ -dimensional fixed effects  $\beta$  and random effects  $u$  respectively. Then conditional on  $u$ , the response variables  $(y_1, \dots, y_n)$  are independent and each  $y_i$  is distributed with its density  $f(y_i|u; \beta)$  in an exponential family. Through a link function  $g$ , the conditional mean satisfies  $E[y_i|u] = g^{-1}(x_i^T \beta + z_i^T u)$ . Finally a GLMM is fully specified with the marginal density  $f(u)$ , commonly chosen to be Gaussian.

In subsequent discussion, we mainly consider GLMMs with a binary response  $y$ , a logit link function, and normally distributed  $u$ . The resulting logistic-normal mixed model is defined as follows:

$$P(y_i = 1|u) = \text{expit}(x_i^T \beta + z_i^T u), \quad i = 1, \dots, n, \quad (1)$$

$$u \sim N(0, \text{diag}(\sigma^2)), \quad \sigma^2 = (\underbrace{\sigma_1^2, \dots, \sigma_1^2}_{q_1}, \underbrace{\sigma_2^2, \dots, \sigma_2^2}_{q_2}, \dots, \underbrace{\sigma_K^2, \dots, \sigma_K^2}_{q_K}), \quad (2)$$

where  $\sum_{k=1}^K q_k = q$ . In the formulation above we allow for  $K$  different groups of latent variables each with variance  $\sigma_k^2$  and group size  $q_k$ . The objective is then to estimate the parameter vector  $\theta = (\beta^T, (\sigma^2)^T)^T$ . Define the linear predictor  $\eta = (\eta_1, \eta_2, \dots, \eta_n)^T$  with  $\eta_i = x_i^T \beta + z_i^T u$ . Then according to (1) and (2), the joint (complete-data) density and log-likelihood are given in a closed-form as follows:

$$f(y, u; \theta) = \exp \left\{ \sum_{i=1}^n [y_i \eta_i - \log(1 + e^{\eta_i})] \right\} \cdot \exp \left\{ -\frac{1}{2} u^T [\text{diag}(\sigma^2)]^{-1} u \right\} \cdot |Det(\text{diag}(\sigma^2))|^{-\frac{1}{2}}, \quad (3)$$

$$\log f(y, u; \theta) = \sum_{i=1}^n [y_i \eta_i - \log(1 + e^{\eta_i})] - \frac{1}{2} u^T [\text{diag}(\sigma^2)]^{-1} u - \frac{1}{2} \sum_{k=1}^K q_k \log \sigma_k^2. \quad (4)$$

## 2.3 Existing methods

We briefly discuss existing methods for fitting GLMMs. Bayesian inference has been extensively studied, notably through various posterior sampling methods; see for example Gamerman

(1997) and Gelman et al. (2008). Such development is facilitated by the availability of a joint distribution for  $(u, \theta|y)$  once a prior distribution on  $\theta$  is introduced. The posterior credible intervals for fixed parameters and posterior predictive intervals for latent variables are operationally appealing to practitioners, although suitable frequentist justification remains to be fully developed (Jiang, 2013; Chae et al., 2019). From a methodological perspective, the necessity of a prior distribution may also be a limitation for the Bayesian approach, compared with likelihood based methods which are prior-free and can be used for similar purposes.

Existing likelihood based methods broadly fall into three categories. The first type is Laplace and related analytical approximation, such as penalized quasi-likelihood (Schall, 1991; Breslow and Clayton, 1993) and H-likelihood method (Lee et al., 2006) among others. While these methods are convenient, they are also potentially biased due to the approximate nature.

The second type includes expectation-maximization (EM) (Dempster et al., 1977) and its variants. For GLMMs, the expectation required for the E-step in EM is analytically intractable. By Monte Carlo EM (MCEM), the intractable expectation is approximated via Monte Carlo samples (Wei and Tanner, 1990; McCulloch, 1997; Booth and Hobert, 1999; Fort and Moulines, 2003). This procedure is computationally intense and the tuning of its hyper-parameters can be difficult. Alternatively, stochastic EM (StEM) (Celeux and Diebolt, 1986; Nielsen, 2000) alleviates the computational burden of MCEM by sampling a single copy of latent variables  $u$  at each update, instead of using multiple copies. We henceforth refer to StEM as imputation-maximization (IM) and describe an extension as follows, which in part motivates our proposed method.

- Imputation-maximization* (IM). Given initial values  $\tilde{\theta}_0$  and  $u_0$ , iterate for  $t = 1, 2, \dots$ ,
- Sample  $u_t$  by MCMC given  $u_{t-1}$  leaving  $f(u|y; \tilde{\theta}_{t-1})$  invariant.
  - Compute  $\tilde{\theta}_t = \operatorname{argmax}_{\theta} \log f(y, u_t; \theta)$ .

In fact, the IM algorithm has been studied in Nielsen (2000), assuming that  $u_t$  is exactly drawn from  $f(u|y; \tilde{\theta}_{t-1})$ , independently of  $u_{t-1}$ . For GLMMs, exact sampling from  $f(u|y; \theta)$  is infeasible and a direct extension based on Markov chain Monte Carlo (MCMC) can be used. Under suitable conditions, the IM sequence  $(\tilde{\theta}_0, \tilde{\theta}_1, \tilde{\theta}_2, \dots)$  may be expected to converge to a non-degenerate distribution, hence randomly fluctuating instead of converging to a fixed point. A point estimate can be formed by taking the average of  $\{\tilde{\theta}_t\}$  up to some large  $t$  (possibly after some burn-in iterations). However, as we find from numerical experiments, IM is prone to getting stuck near zero over long periods in estimating the variance component, i.e.  $\sigma^2$  in (2). This drawback may be caused by the fact that  $\tilde{\theta}_{t-1}$  is completely refreshed by a new maximizer in each iteration.

For the remainder of this section, we discuss the third type of likelihood methods: stochastic approximation (SA), which is also exploited by our proposed method. Pioneered by Robbins and Monro (1951), SA can be interpreted as a root finding algorithm. Consider a function  $h(\theta)$  that cannot be directly evaluated. Instead, only a stochastic version  $H(u; \theta)$  is available such that  $E_\theta[H(u; \theta)] = h(\theta)$ , where  $E_\theta[\cdot]$  denotes the expectation for  $u$  under a probability density function  $p(\cdot; \theta)$ . Then SA finds a solution  $\theta^*$  to the equation  $h(\theta) = 0$  by the following.

*Stochastic approximation (SA).* Given initial values  $\tilde{\theta}_0$  and  $u_0$ , iterate for  $t = 1, 2, \dots$ ,

- Sample  $u_t$  by MCMC given  $u_{t-1}$  leaving  $p(u; \tilde{\theta}_{t-1})$  invariant.
- Update  $\tilde{\theta}_t = \tilde{\theta}_{t-1} + \gamma_t H(u_t; \tilde{\theta}_{t-1})$ ,

where  $\gamma_t$  is a sequence of step sizes. For the classical SA in Robbins and Monro (1951),  $u_t$  is exactly drawn from  $p(u; \tilde{\theta}_{t-1})$ , independently of  $u_{t-1}$ . In the description above,  $u_t$  is sampled by MCMC depending on both  $\tilde{\theta}_{t-1}$  and  $u_{t-1}$ . Under regularity conditions, if the step sizes are chosen to be  $\gamma_t = 1/t$ , then  $\tilde{\theta}_t$  can be shown to converge to  $\theta^*$  almost surely (e.g., Benveniste et al., 1990; Chen, 2002). The SA framework is very flexible and can accommodate a wide range of problems. In order to apply SA to GLMMs, suitable functions  $h$  and  $H$ , and probability density  $p(u; \theta)$  need to be selected. For maximization of the marginal likelihood  $f(y; \theta)$ , a standard choice of  $h$  is  $h(\theta) = \frac{\partial}{\partial \theta} \log f(y; \theta)$ , with the corresponding  $H(u; \theta) = \frac{\partial}{\partial \theta} \log f(y, u; \theta)$  and  $p(u; \theta) = f(u|y; \theta)$ , where  $E_\theta[\cdot]$  denotes the expectation with respect to latent variables  $u \sim f(u|y; \theta)$ . Then it is straightforward to verify the SA condition  $E_\theta[H(u; \theta)] = h(\theta)$ . Fitting GLMMs with this type of SA is studied by Gu and Kong (1998) and Zhu and Lee (2002). We refer to it as ScoreSA since it aims to solve the score equation  $\frac{\partial}{\partial \theta} \log f(y; \theta) = 0$ , and formally define it in Algorithm 1.

---

**Algorithm 1:** ScoreSA

---

Initialize  $\hat{\theta}_0$  and  $u_0$   
**for**  $t = 0, 1, 2, \dots, T$  **do**  
    Sample  $u_t$  by MCMC given  $u_{t-1}$  leaving  $f(u|y; \hat{\theta}_{t-1})$  invariant  
    Update  $\hat{\theta}_t = \hat{\theta}_{t-1} + \gamma_t \left\{ \frac{\partial}{\partial \theta} \log f(y, u_t; \theta) \mid_{\theta = \hat{\theta}_{t-1}} \right\}$  with  $\gamma_t$  a step size  
Output  $\hat{\theta}_T$

---

The limiting point that ScoreSA converges to is the marginal MLE  $\hat{\theta}_{ML} = \operatorname{argmax}_\theta \log f(y; \theta)$ . The algorithms in Gu and Kong (1998) and Zhu and Lee (2002) are more sophisticated with additional features and the associated tuning such as approximation of the hessian matrix of  $\log f(y, u; \theta)$ . Nevertheless, Algorithm 1 conveys the main ideas and may perform adequately

subject to careful tuning. For ScoreSA, the magnitude of step size  $\gamma_t$  has no simple interpretation (compared with IMSA in Section 3) thus making the tuning challenging. As we illustrate in Section 4, the performance of ScoreSA can be sensitive to the choice of  $\gamma_t$ . Another disadvantage of ScoreSA is that the gradient  $\frac{\partial}{\partial \theta} \log f(y, u; \theta)$  can vary drastically for  $\theta$  defined on different parameter scales (e.g. original v.s. log scale for the variance components). To achieve reasonable performance, a suitable parameter scale often needs to be selected for parameter transformation when applying ScoreSA.

### 3 Proposed method

Motivated by the discussion in Section 2.3, we seek to develop a method that is prior-free, computationally efficient, easy to tune and also accommodates flexible parameter transformations, e.g., with variance components in the original or log scale. To achieve this, we build upon the IM algorithm. As mentioned in Section 2, the fluctuating behavior of IM can be problematic. Therefore instead of completely replacing  $\tilde{\theta}_{t-1}$ , we add an SA type update after the maximization step, such that only a portion of  $\tilde{\theta}_{t-1}$  is replaced by the maximizer, controlled through a learning rate or step size  $\gamma_t$ . This yields our proposed method, imputation maximization stochastic approximation (IMSA) as described in Algorithm 2

---

**Algorithm 2: IMSA**

---

Initialize $\tilde{\theta}_0$ and $u_0$	
<b>for</b> $t = 0, 1, 2, \dots, T$ <b>do</b>	
Sample $u_t$ by MCMC given $u_{t-1}$ leaving $f(u y; \tilde{\theta}_{t-1})$ invariant	#Imputation
Compute $\tilde{\theta}_{t-1/2} = \operatorname{argmax}_{\theta} \log f(y, u_t; \theta)$	#Maximization
Update $\tilde{\theta}_t = \tilde{\theta}_{t-1} + \gamma_t(\tilde{\theta}_{t-1/2} - \tilde{\theta}_{t-1})$ with $\gamma_t$ a step size	#Update/Shrinkage
Output $\tilde{\theta}_T$	

---

Our formulation of IMSA is not restricted to GLMMs and can potentially handle general latent variable models discussed in Section 2.1. The key consideration for practicality is whether the maximization step is easily implementable. In the GLMM case, the maximization can be carried out efficiently. In (4), the terms containing  $\beta$  are

$$\sum_{i=1}^n [y_i(x_i^T \beta) - \log(1 + e^{y_i})].$$

Therefore maximizing  $\log f(y, u; \theta)$  over  $\beta$  given  $u$  is equivalent to find the MLE for a GLM with offset (McCullagh and Nelder, 1989). Here the offset values are  $z_i^T u$ . This problem is well studied with fast algorithms readily available. For the experiments in Section 4 we use

Python module `statsmodel.api.GLM` which implements iteratively reweighted least squares. For  $\sigma^2$ , we denote as  $u^{(k)}$  the sub-vector of  $u$  corresponding to the  $k$ -th variance group. Then the derivative with respect to  $\sigma_k^2$  is

$$\frac{\partial}{\partial \sigma_k^2} \log f(y, u; \theta) = \frac{1}{2} \sigma_k^{-4} [u^{(k)}]^\top u^{(k)} - \frac{1}{2} q_k \sigma_k^{-2}.$$

Setting the above to zero, we obtain the maximizer  $\tilde{\sigma}_k^2 = [u^{(k)}]^\top u^{(k)} / q_k$ , which can be understood as the sample (zero-centered) variance of latent variables in the  $k$ -th group.

IMSA can be formally put in the SA framework as follows. By matching the update from  $\tilde{\theta}_{t-1}$  to  $\tilde{\theta}_t$  in Algorithm 2 with the general SA update in Section 2.3, the stochastic function associated with IMSA is

$$H(u; \theta) = M(u; \theta) - \theta, \quad \text{where} \quad M(u; \theta) = \arg\max_{\theta} \log f(y, u; \theta).$$

Then by construction, the corresponding  $h$  function is  $h(\theta) = E_{\theta}[M(u; \theta)] - \theta$ . Again  $E_{\theta}$  stresses that the expectation is taken over  $f(u|y; \theta)$ . Setting  $h(\theta) = 0$ , the limiting point of IMSA denoted by  $\tilde{\theta}_{IMSA}$ , satisfies the following,

$$\theta = E_{\theta}[M(u; \theta)]. \tag{5}$$

Equation (5) is called the self-consistency condition (Lee and Meng, 2007). Self-consistency principle states that: a desired parameter estimate  $\tilde{\theta}$  should equal to the expectation of possible parameter estimates obtained from randomly imputed data according to  $\tilde{\theta}$  (in conjunction with observed data  $y$ ). This can be seen to provide a statistical justification for IMSA.

In the following, we compare IMSA and ScoreSA in several ways. First, the IMSA estimator  $\tilde{\theta}_{IMSA}$  is in general numerically distinct from the MLE  $\hat{\theta}_{ML}$  solved by ScoreSA. Under standard regularity conditions, however, they can be shown to be asymptotically equivalent to each other (Lee and Meng, 2007):

$$\tilde{\theta}_{IMSA} = \hat{\theta}_{ML} + o_p(n^{-\frac{1}{2}}).$$

In fact, by asymptotic expansion in the complete-data model we have in the IMSA update,

$$\tilde{\theta}_{t-1/2} - \tilde{\theta}_{t-1} = - \left\{ \frac{\partial^2}{\partial \theta \partial \theta^\top} \log f(y, u_t; \theta) \Big|_{\theta=\tilde{\theta}_{t-1}} \right\}^{-1} \left\{ \frac{\partial}{\partial \theta} \log f(y, u_t; \theta) \Big|_{\theta=\tilde{\theta}_{t-1}} \right\} + o_p(n^{-1/2}).$$

Hence the leading term in  $\tilde{\theta}_{t-1/2} - \tilde{\theta}_{t-1}$  is the gradient of  $\log f(y, u_t; \theta)$  with its negative inverse hessian matrix multiplied in front. Contrasting this with the ScoreSA update

$$\hat{\theta}_t = \hat{\theta}_{t-1} + \gamma_t \left\{ \frac{\partial}{\partial \theta} \log f(y, u_t; \theta) \Big|_{\theta=\hat{\theta}_{t-1}} \right\},$$

we see that the IMSA update is a preconditioned version of the ScoreSA update. Preconditioning is analogous to the use of Newton-Raphson as opposed to gradient descent for achieving faster convergence (e.g. Girolami and Calderhead, 2011). Therefore, we expect that IMSA will generally enjoy faster and more stable convergence than ScoreSA, even though the limits of these algorithms may differ on a fixed dataset. In addition, in small or moderately-sized samples,  $\tilde{\theta}_{IMSA}$  can be less biased than  $\hat{\theta}_{ML}$  by related analysis in Fang and Hong (2018).

Second, the IMSA update  $\tilde{\theta}_t = \tilde{\theta}_{t-1} + \gamma_t(\tilde{\theta}_{t-1/2} - \tilde{\theta}_{t-1})$  can be viewed as a shrinkage update, related to the IM update  $\tilde{\theta}_{t-1/2}$ . The algorithm moves from  $\tilde{\theta}_{t-1}$  towards  $\tilde{\theta}_{t-1/2}$  while maintaining  $\tilde{\theta}_{t-1}$  by the amount of  $1 - \gamma_t$ . Thus the learning rate  $\gamma_t$  in IMSA has a clear interpretation as the proportion by which the maximizer obtained from newly imputed data  $\tilde{\theta}_{t-1/2}$  will be incorporated. The previously mentioned IM (Section 2.3) corresponds to the special case where  $\gamma_t \equiv 1$ . Because each  $\tilde{\theta}_{t-1/2}$  is already in the proper range of  $\theta$ , IMSA estimates  $\{\tilde{\theta}_t\}$  remain in the proper range for a convex parameter space. In this sense, IMSA is range-respecting and safeguards against invalid parameter values (e.g., a negative variance estimate), regardless of the scale that  $\theta$  is specified on. In contrast, when estimating  $\sigma^2$  directly with ScoreSA, it is possible to obtain a negative value since the magnitude of the gradient does not preserve the range of  $\sigma^2 \geq 0$ . Thus for ScoreSA, it is customary to update the variance on log  $\sigma$  scale, whereas IMSA is not bound by this constraint. One subtlety is that when applying a transformation of  $\theta$ , while the maximization step is invariant, the shrinkage step will lead to different results, as illustrated in Section 4.

Third, compared with ScoreSA, IMSA involves a higher computational cost per iteration due to the maximization of the log-likelihood  $\log f(y, u_t; \theta)$  with imputed data  $u_t$ . However, the cost increase is limited in the settings where fast algorithms are available for maximizing  $\log f(y, u_t; \theta)$ , such as in generalized linear mixed models. Moreover, the majority of computational cost per iteration in IMSA as well as ScoreSA is often incurred by MCMC sampling to impute the latent variable  $u_t$ . Hence the cost per iteration from IMSA may be only slightly higher than ScoreSA, while IMSA tends to achieve more stable convergence (with minimal tuning) and more accurate estimation, as shown in our numerical experiments.

As a side note, the variance matrix of  $\tilde{\theta}_{IMSA}$  can be estimated by exploiting the missing information identity in Louis (1982). Combined with online variance formulas (Welford, 1962), this calculation can be completed in a single pass of IMSA, hence no separate simulation is needed. Furthermore, the variance estimators can also be used to construct a preconditioned IMSA algorithm that is asymptotically optimal by SA theory, similarly as in Gu and Kong (1998) and Zhu and Lee (2002). Details are given by Algorithm 6 in the Appendix. Neverthe-

less the actual implementation of variance estimation requires complicated tuning and converge monitoring with multiple step sizes. Therefore the experiments in the following section focus solely on the point estimate of  $\theta$ .

## 4 Simulation studies

We compare IMSA with ScoreSA through two logistic-normal mixed models. We include both IMSA that updates variance on the original  $\sigma^2$  scale and IMSA that updates variance on the  $\log \sigma$  scale. We label the latter as IMSA-log. For ScoreSA, we always update variance on the  $\log \sigma$  scale. This decision is due to two reasons: first as previously mentioned, ScoreSA cannot guarantee the positivity of  $\sigma^2$  when updating on the original scale; secondly during trial runs, ScoreSA frequently encounters gradient explosion and breaks down when updating on the original scale. To emphasize the point that our proposed method can achieve good results with minimal amount of tuning, we simply set the learning rate  $\gamma_t = t^{-1}$  for both IMSA and IMSA-log. In contrast, ScoreSA is sensitive to the choice of  $\gamma_t$  and requires careful tuning for stable and reasonable performance. Therefore we choose a list of different  $\gamma_t$ 's for ScoreSA taking the form of  $\gamma_t = \min(t^{-1}, t_0^{-1})$  with the constant  $t_0 \in \{1, 5, 10, 25, 50, 100\}$ . We label these different versions of the algorithm as ScoreSA-1/2/3/4/5/6 corresponding to (in the increasing order) the six  $t_0$  values with ScoreSA-1 for  $t_0 = 1$ , ScoreSA-2 for  $t_0 = 5$ , etc. To sample from the intractable distribution  $f(u|y; \theta)$ , in the simulations we employ multiple MCMC samplers (in parallel). Specifically, we use preconditioned Metropolis-adjusted Langevin algorithm (pMALA) (Besag, 1994; Roberts and Tweedie, 1996), shown as Algorithm 5 in the Appendix. Further simulation details and additional results are also provided in the Appendix. All algorithms are implemented in Python. In both simulation settings, each individual run is carried out using an Intel Skylake CPU with two cores and 2000 megabytes of memory.

### 4.1 Booth–Hobert example

Consider a simple logistic-normal mixed model that is studied in Booth and Hobert (1999): for  $i = 1, \dots, 10$  and  $j = 1, \dots, 15$ ,

$$y_{ij}|u_i \text{ are independent Bernoulli variables with } P(y_{ij} = 1|u_i) = \text{expit}(\beta x_{ij} + u_i), \quad (6)$$

$$x_{ij} = \frac{j}{15}, \quad u_i \stackrel{i.i.d.}{\sim} N(0, \sigma^2).$$

This is a simplified version of the original model discussed in McCulloch (1997) and we refer to it as Booth–Hobert example. We use the reported true parameter values  $\beta = 5$  and  $\sigma^2 = 0.5$  as in Booth and Hobert (1999) and randomly generate 100 sets of data from (6). Then for

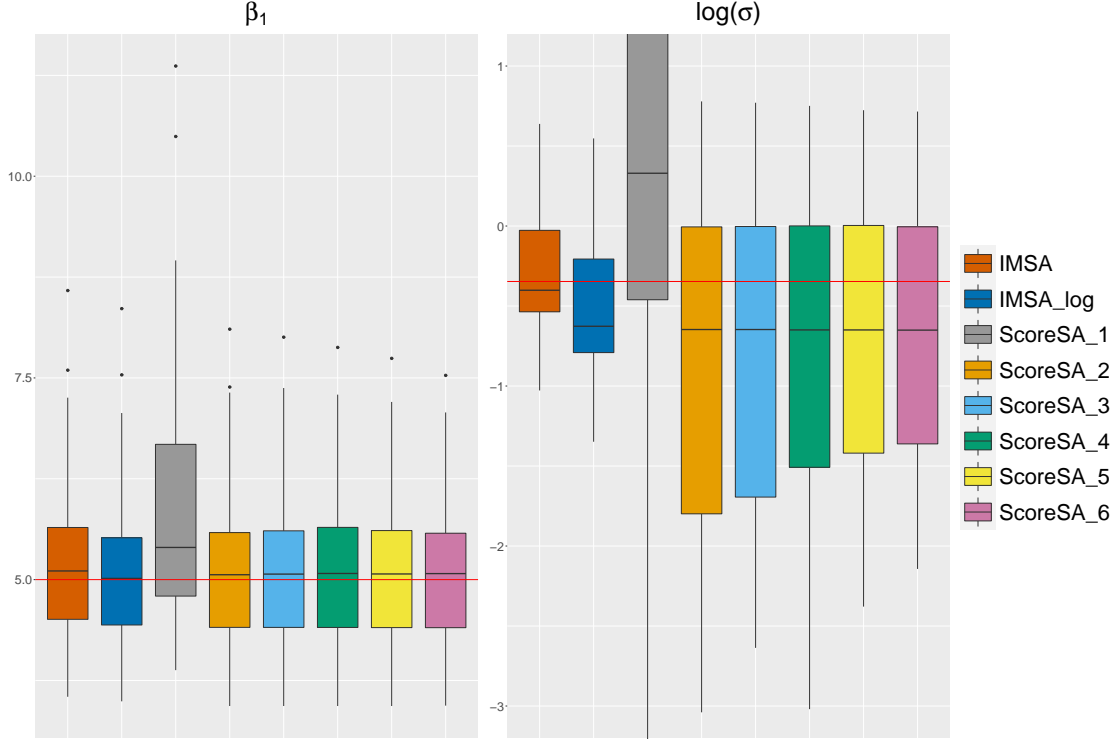

Figure 1: Boxplots of parameter estimates in Booth–Hobert example. Red lines mark true values.

every data set, we estimate  $(\beta, \sigma^2)$  with IMSA, IMSA-log, and ScoreSA-1/2/3/4/5/6. Each algorithm is run for 2000 iterations. On average, an individual run takes 67 seconds for IMSA and IMSA-log, and 37 seconds for ScoreSA-1/2/3/4/5/6. The initial values are dispersed (uniformly at random) over the intervals  $\beta \in (1, 2), \sigma^2 \in (0.5, 1.5)$  for each data set.

Boxplots of the estimates are presented in Figure 1 with ground truth marked by red horizontal lines. Notice that the variance component is plotted on the  $\log \sigma$  scale, although IMSA updates on the original  $\sigma^2$  scale. We see that for  $\beta$ , all methods except for ScoreSA-1 have comparable performance and yield satisfactory results, whereas ScoreSA-1 overestimates  $\beta$ . For the more challenging problem of estimating  $\sigma^2$ , IMSA clearly has the overall best performance followed by IMSA-log which shows similar spread but underestimates compared to IMSA. ScoreSA-1 estimates are non-stable and outside of the plotting limits which encapsulates all other methods. From ScoreSA-2 to ScoreSA-6, the spreads decrease as would be expected since these methods use progressively smaller initial  $\gamma_t$ . The six versions of ScoreSA show comparable amount of underestimation to IMSA-log, but all have larger spreads indicating inconsistency over repeated runs.

## 4.2 Salamander mating model

The second example we use is a model regarding the mating behavior among salamanders of two different species, originally investigated in McCullagh and Nelder (1989). Let  $y_{ij}, i, j = 1, \dots, 60$  be the indicator of mating between female  $i$  and male  $j$ , with  $y_{ij} = 1$  corresponding to a successful mating and  $y_{ij} = 0$  otherwise. Note that out of all possible female/male pairings, only 360 are observed. We label the two species by A and B. The response  $y_{ij}$  depends on both the species through fixed effects and sex through random effects. Let  $\beta = (\beta_1, \beta_2, \beta_3, \beta_4)^T$  be fixed effects for the female/male species combination in the order (A/A, A/B, B/A, B/B), e.g.,  $\beta_2$  corresponds to a female from species A and a male from species B, etc. Let  $x_{ij}$ , a vector of length 4, be the (0, 1) encoding of species combination of the  $(i, j)$ -th pair. Finally we denote  $u_i^{Female}$  and  $u_j^{Male}$  as random effects from the  $i$ -th female and  $j$ -th male respectively. Then the mixed effect model can be written as

$$\begin{aligned} y_{ij} | u_i^{Female}, u_j^{Male} &\sim \text{Bernoulli}(\pi_{ij}), \text{ independently,} \\ \pi_{ij} &= \text{expit}(x_{ij}^T \beta + u_i^{Female} + u_j^{Male}), \\ u_i^{Female} &\overset{i.i.d.}{\sim} N(0, \sigma_1^2), \quad u_j^{Male} \overset{i.i.d.}{\sim} N(0, \sigma_2^2). \end{aligned} \tag{7}$$

With  $\sigma^2 = (\sigma_1^2, \sigma_2^2)^T$ , the full parameter vector is  $\theta = (\beta^T, (\sigma^2)^T)^T$ . Booth and Hobert (1999) report the MLE of the original data to be  $\beta_1 = 1.03, \beta_2 = 0.32, \beta_3 = -1.95, \beta_4 = 0.99, \sigma_1^2 = 1.4$  and  $\sigma_2^2 = 1.25$ . We use these values as data generating parameters and create 100 synthetic data sets from (7). We then estimate  $\theta$  on each data set. Because this model is more complicated than Booth–Hobert example (now with 6 parameters and 120 latent variables), all methods are run for 4000 iterations. On average, an individual run takes 475 seconds for IMSA and IMSA-log, and 396 seconds for ScoreSA-1/2/3/4/5/6. Initial values are dispersed over the following intervals,  $\beta_1 \in (0, 2), \beta_2 \in (-1, 1), \beta_3 \in (-3, -1), \beta_4 \in (0, 2), \sigma_1^2 \in (1, 2.5)$  and  $\sigma_2^2 \in (1, 2.5)$ .

The results are plotted in Figure 2. ScoreSA-1/2/3 all encounter instability and produce extremely large values of  $\sigma_1^2, \sigma_2^2$ . In that sense we consider that these three methods fail on the salamander model and exclude them from the plots of variance component. All remaining methods are highly comparable in  $\beta$  with reasonably good fits. For the more challenging problem of estimating variance components, however, IMSA is distinctly superior over the others in both  $\sigma_1^2$  and  $\sigma_2^2$ . IMSA-log shows variation that is comparable to IMSA. It appears to underestimate  $\sigma_1^2$  and  $\sigma_2^2$ , but still covers the true values. For ScoreSA-4/5/6, their median estimates of  $\log \sigma_1$  and  $\log \sigma_2$  are slightly more accurate than IMSA-log, but they show wider spread and overall outperformed by IMSA.

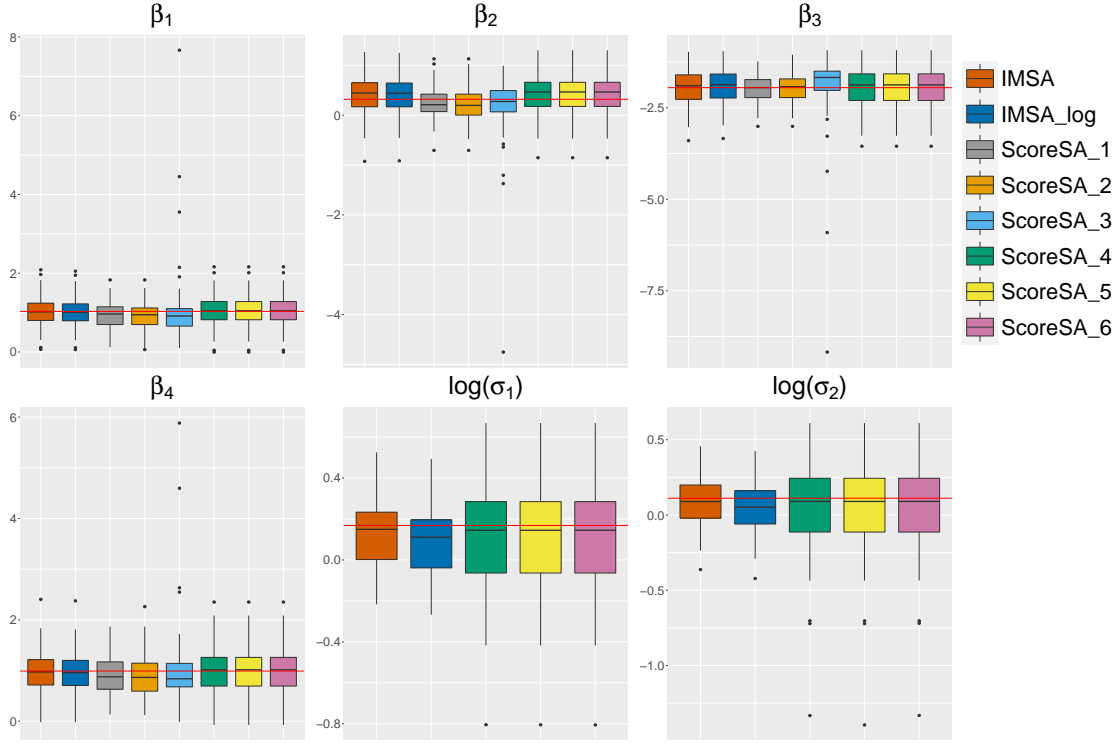

Figure 2: Boxplots of parameter estimates for the salamander mating model. Red lines mark true values. Variance estimates from ScoreSA-1/2/3 are omitted due to poor performance.

## 5 Conclusion

We develop imputation maximization stochastic approximation with application to generalized linear mixed models. The proposed IMSA method is prior-free, computationally fast, and easy to tune, even though the cost per iteration may be slightly higher than ScoreSA. The method also allows flexible parameter transformations and ensures that the corresponding estimates fall in the proper parameter ranges such as nonnegative variance components. In two sets of numerical experiments, IMSA consistently outperforms its main competitor ScoreSA. We also observe that IMSA yields better results when updating the variance components on the original scale than on the log scale. For future work, it is desired to investigate in detail the estimation of the variance of  $\tilde{\theta}_{IMSA}$ . Moreover, it is interesting to extend beyond GLMMs, and apply IMSA to other suitable latent variable models.

## Appendix A: Simulation details

Let  $X_{n \times p}$  and  $Z_{n \times q}$  be design matrices associated with covariates  $x_i$  and  $z_i$  respectively. The specific form of  $X, Z$  in Booth–Hobert example and salamander mating model are provided in our simulation codes which are available upon request. Define vectors of linear predictors as  $\eta^{(1)} = X\beta, \eta^{(2)} = Zu$  so that  $\eta^{(1)} + \eta^{(2)} = \eta$ . Transform the variance component as  $\tau_k = \log \sigma_k$  for  $k = 1, \dots, K$ . Then the gradient  $\frac{\partial}{\partial \theta} \log f(y, u; \theta)$  required for ScoreSA is given by

$$\frac{\partial}{\partial \beta} \log f(y, u; \theta) = X^T(y - \text{expit}(\eta)), \quad \frac{\partial}{\partial \tau_k} \log f(y, u; \theta) = \exp(-2\tau_k)[u^{(k)}]^T u^{(k)} - q_k.$$

In the above, the expit function is understood to be applied component-wise to the vector  $\eta$ .

For sampling latent variables  $u \sim f(u|y; \theta)$ , it is convenient to work with the negative log-likelihood, or potential energy function,  $Q$  such that  $\exp(-Q(u)) \propto f(u|y; \theta)$ . The expression of  $Q$  is given by

$$Q(u) = \frac{1}{2}u^T[\text{diag}(\sigma^2)]^{-1}u - \sum_{i=1}^n (y_i \eta_i^{(2)} - \log(1 + e^{\eta_i})).$$

In the argument of  $Q$ , we suppress the dependence on  $y$  and parameters  $\theta$  as they are fixed during each imputation step. The gradient  $\nabla Q$  and hessian  $\nabla^2 Q$  are also needed for the imputation:

$$\nabla Q(u) = [\text{diag}(\sigma^2)]^{-1}u - Z^T(y - \text{expit}(\eta)), \quad \nabla^2 Q(u) = [\text{diag}(\sigma^2)]^{-1} + Z^T \text{diag}[\text{expit}(\eta)(1 - \text{expit}(\eta))]Z.$$

The implementation of ScoreSA and IMSA in Section 4 are given by Algorithm 3 and 4, incorporating multiple imputation. For the imputation (described in Algorithm 5), in both examples we use 4 parallel MCMC samplers that run for 20 steps in between each parameter update. Preconditioning for MCMC is only applied after 500 iterations, that is  $T_0 = 500$ . During the first 500 iterations, the vanilla MALA is used. The sampling step size  $\epsilon$  is periodically adjusted to maintain MCMC acceptance rate at around 60%.

---

**Algorithm 5:** MALA/pMALA for sampling from  $f(u|y; \theta)$ 

---

Input current latent variables  $u$  and parameter  $\theta$

**if** *Using Preconditioning* **then**  
    Compute  $\Sigma = [\nabla^2 Q(0)]^{-1}$       #Evaluate inverse hessian at  $u = 0$

**else**  
    Set  $\Sigma = I$

Initialize  $u_{old} = u$  and  $\xi = u - \frac{\epsilon^2}{2} \Sigma \nabla Q(u)$  with  $\epsilon$  a step size

**for**  $i = 1, \dots, N$  **do**  
    Sample  $Z \sim N(0, \Sigma)$  and  $w \sim \text{Uniform}(0, 1)$   
    Compute  $u^* = \xi + \epsilon Z$   
    Compute  $\xi^* = u^* - \frac{\epsilon^2}{2} \Sigma \nabla Q(u^*)$   
    Compute  
         $\rho = \exp \left\{ Q(u_{old}) - Q(u^*) + \frac{1}{2\epsilon^2} (u^* - \xi)^T \Sigma^{-1} (u^* - \xi) - \frac{1}{2\epsilon^2} (u_{old} - \xi^*)^T \Sigma^{-1} (u_{old} - \xi^*) \right\}$  **if**  
         $w < \min(1, \rho)$  **then**  
            Set  $u_{old} = u^*, \xi = \xi^*$       #Accept  
Set  $u_{new} = u_{old}$

Output  $u_{new}$

---

The term  $(\tilde{\theta}_{t-1/2} - \tilde{\theta}_{t-1})$  in IMSA serves a similar role as the gradient  $\frac{\partial}{\partial \theta} \log f(y, u_t; \theta)$  in ScoreSA. As a way to monitor the converge, we record the norms  $\|\tilde{\theta}_{t-1/2} - \tilde{\theta}_{t-1}\|_\infty$  for IMSA and  $\|\frac{\partial}{\partial \theta} \log f(y, u_t; \theta)\|_\infty$  for ScoreSA at each iteration. We then compute rolling averages of the norms using a window length of 250. Histograms of the minimum of the rolling averages over repeated runs are plotted in Figure 3 and Figure 4 with red lines marking a threshold value of .05. A higher frequency below the threshold indicates better convergence by a certain number of iterations. According to the plots, in Booth–Hobert example all methods except for ScoreSA-1 show good convergence within 2000 iterations; in the salamander mating model, ScoreSA-1/2/3 do not converge as their  $\sigma^2$  estimates explode, while the remaining methods converge within 4000 iterations.

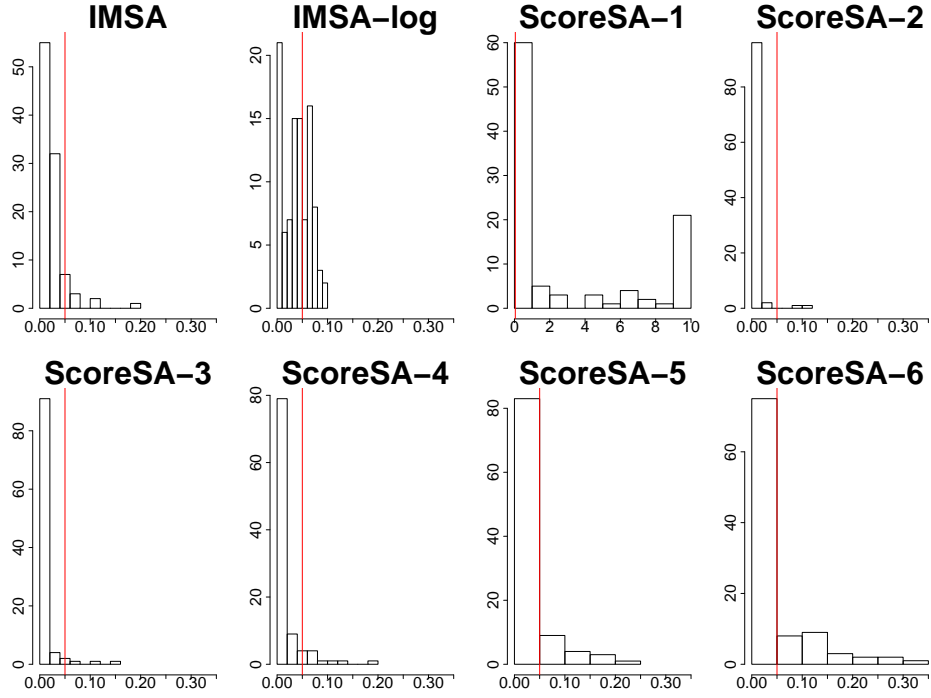

Figure 3: Histograms of rolling average of gradient norms in Booth–Hobert example

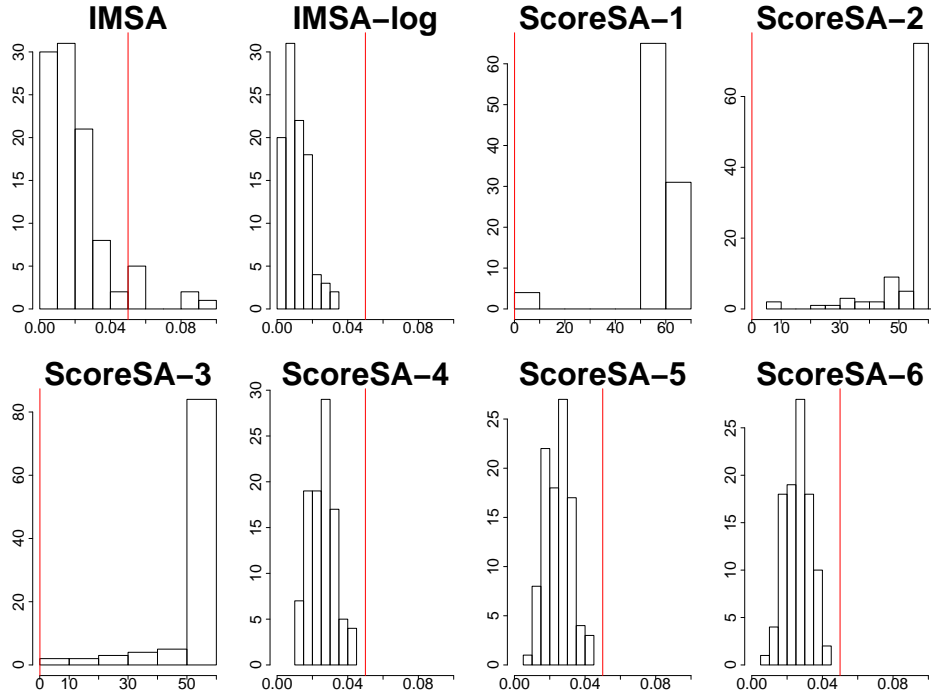

Figure 4: Histograms of rolling average of gradient norms in the salamander mating model

## Appendix B: IMSA with variance estimation

IMSA with variance estimation of  $\tilde{\theta}_{IMSA}$  is given in Algorithm 6.

---

### Algorithm 6: IMSA with variance estimation

---

Initialize  $\tilde{\theta}_0$ ,  $u_0$ , and  $(p + K)$ -dimensional vector  $\bar{r}_0$ ,  $(p + K) \times (p + K)$  matrices  $\bar{R}_0, \bar{H}_0$

**for**  $t = 1, 2, \dots, T$  **do**

    Sample  $u_t$  by MCMC given  $u_{t-1}$  leaving  $f(u|y; \tilde{\theta}_{t-1})$  invariant Compute

$\tilde{\theta}_{t-1/2} = \operatorname{argmax}_{\theta} \log f(y, u_t; \theta)$  Compute  $r = \tilde{\theta}_{t-1/2} - \tilde{\theta}_{t-1}$  Compute

$H = -\frac{\partial^2}{\partial \theta \partial \theta^T} \log f(y, u_t; \theta) |_{\theta=\tilde{\theta}_{t-1}}$  Update  $\bar{r}_t = \bar{r}_{t-1} + \rho_t(r - \bar{r}_{t-1})$  with  $\rho_t$  a step size

    Update  $\bar{R}_t = \bar{R}_{t-1} + \lambda_t((1 - \lambda_t)[r - \bar{r}_{t-1}][r - \bar{r}_{t-1}]^T - \bar{R}_{t-1})$  with  $\lambda_t$  a step size Update

$\bar{H}_t = \bar{H}_{t-1} + \nu_t(H - \bar{H}_{t-1})$  with  $\nu_t$  a step size Update  $\tilde{\theta}_t = \tilde{\theta}_{t-1} + \gamma_t r$  with  $\gamma_t$  a step size

Output  $\tilde{\theta}_t$  as point estimate and  $[\bar{H}_t(I - \bar{R}_t \bar{H}_t)]^{-1}$  as variance estimate

---
