Abstract. Choosing the placement of wildlife crossings (i.e., green bridges) to reconnect animal species' fragmented habitats is among the 17 goals towards sustainable development by the UN. We consider the following established model: Given a graph whose vertices represent the fragmented habitat areas and whose weighted edges represent possible green bridge locations, as well as the habitable vertex set for each species' habitat is connected. We study this problem from a theoretical (algorithms and complexity) and an experimental perspective, while focusing on the case where habitats induce cycles. We prove that the NP-hardness persists in this case even if the graph structure is restricted. If the habitats additionally induce faces in plane graphs however, the problem becomes efficiently solvable. In our empirical evaluation we compare this algorithm as well as ILP formulations for more general variants and an approximation algorithm with another. Our evaluation underlines that each specialization is beneficial in terms of running time, whereas the approximation provides highly competitive solutions in practice.

1 Introduction

Habitat fragmentation due to human-made infrastructures like roads or train tracks, leading to wildlife-vehicle collisions, a severe threat not only to animals, up to impacting biodiversity [3, 20], but also to humans. Installing wildlife crossings like bridges, tunnels [23], ropes [10], et cetera (we refer to those as *green bridges* from here on) in combination with road fencing (so as to ensure that the green bridges are being used) allows a cost-efficient [14] reduction of wildlife-vehicle collisions by up to 85% [13]. In this paper, we study the problem of finding the right positions for green bridges that keeps the building cost at a minimum and ensures that every habitat is fully interconnected. We focus on those cases in which the structure of the habitats is very simple and study the problem from both a theoretical (algorithmics and computational complexity) as well as an experimental perspective.

We follow a model recently introduced by Fluschnik and Kellerhals [6]. Herein, the modeled graph can be understood as path-based graph [22, 8]: a vertex corresponds to a part fragmented by human-made infrastructures subsuming habitat patches of diverse animal habitats, and any two vertices are connected by an edge if the corresponding patches can be connected by a green bridge.

The edges are equipped with the costs of building the respective green bridge (possibly including fencing) in the respective area. The goal is to construct green bridges in a minimum-cost way such that in the graph spanned by the green bridges, the patches of each habitat form a connected component. Formally, we are concerned with the following.

Problem 1. 1-REACH GREEN BRIDGES PLACEMENT WITH COSTS (1-REACH GBP-C)

Input: An undirected graph $G = (V, E)$ with edge costs $c: E \rightarrow \mathbb{N}$, a set $\mathcal{H} = \{H_1, \dots, H_r\}$ of habitats with $H_i \subseteq V$ and $|H_i| \geq 2$ for all $i \in \{1, \dots, r\}$, an integer $k \in \mathbb{N}_0$.

Question: Is there a subset $F \subseteq E$ with $c(F) := \sum_{e \in F} c(e) \leq k$ such that for every $i \in \{1, \dots, r\}$ it holds that $H_i \subseteq V(G[F])$ and $G[F][H_i]$ is a connected graph?

In accordance with Fluschnik and Kellerhals [6], we denote by 1-REACH GREEN BRIDGES PLACEMENT (1-REACH GBP) the unit-cost version of 1-REACH GBP-C.

Our contributions. Our study focuses on habitats which induce small cycles. This is well motivated from practical as well as theoretical standpoints. Small habitats, in terms of size and limited structures (as to trees and cycles), appear more often for small mammals, amphibians, and reptiles, among which several species are at critical state [11, 12]. From a theoretical point of view, since the problem is already NP-hard in quite restricted setups [6], it is canonical to study special cases such as restrictions on habitat and graph structure. As the problem is polynomial-time solvable if each habitat induces a tree (**Observation 1**), studying habitats inducing cycles are an obvious next step.

Our theoretical results are summarized in **Table 1**. We prove that 1-REACH GBP remains NP-hard even if each habitat induces a cycle, even of fixed length at least three. Most of our NP-hardness results hold even on restricted input graphs, i.e., planar graphs of small maximum degree. On the positive side, we prove that for cycle-inducing habitats we can reduce the problem to maximum-weight matching in an (auxiliary) multi-hypergraph. From this we derive a polynomial-time special case: If every edge is shared by at most two habitats, we can reduce the problem to maximum-weight matching, a well-known polynomial-time solvable problem.

We perform an experimental evaluation of several algorithms, including the two mentioned above, the approx-

Table 1: Our NP-hardness (refer to [Theorem 1](#)) and upper bound results regarding our habitat families. $\mathcal{C} = \bigcup_{\ell \in \mathbb{N}_{\geq 3}} \{C_\ell\}$ denotes the class of all cycles C_ℓ of length ℓ . “P” is short for “polynomial-time solvable”, Δ for $\Delta(G)$. * ($\ell \neq 5$) \dagger (if every edge is in at most two habitats ([Thm. 2](#))) \ddagger (if $\Delta \leq 2$ ([Obs. 2](#))) \S (if $\Delta \leq 3$ ([Cor. 1](#)))

| Habitat family | NP-hard, even if | Upper |
|---|---------------------------------------|--------------------------|
| $\{P_2, C_3\}$ | G is a clique | $P^{\dagger\nu\ddagger}$ |
| $\{C_3\}$ | (no further restrictions) | $P^{\dagger\nu\S}$ |
| $\{P_2, C_\ell\}, \ell \in \mathbb{N}_{\geq 4}$ | $\Delta \geq 4$ or if G is planar* | $P^{\dagger\nu\ddagger}$ |
| $\{C_\ell\}, \ell \in \mathbb{N}_{\geq 4}$ | $\Delta \geq 10$ or if G is planar* | $P^{\dagger\nu\ddagger}$ |
| $\{P_2\} \cup \mathcal{C}$ | $\Delta \geq 3$ and G is planar | $P^{\dagger\nu\ddagger}$ |
| \mathcal{C} | $\Delta \geq 9$ and G is planar | $P^{\dagger\nu\ddagger}$ |

imation algorithm given by Fluschnik and Kellerhals [6], as well as an ILP formulation for the case of general (i.e., not necessarily inducing cycles) habitat structures. Our evaluation shows that each more specialized algorithm for the cycle-inducing habitats perform much better than the next more general one. Moreover, we show that the approximation algorithm is fast with very small loss in solution quality. Finally, we underline the connection between solution quality and running time on the one side, as well as the way of how habitats intersect on the other side.

Further related work. Ament et al. [1] gives an informative overview on the topic. The placement of wildlife crossings is also studied with different approaches [4, 5, 19, 2]. A related problem is STEINER FOREST (where we only need to connect habitats, without requesting connected induced graphs), which (and an extension of it) is studied from an algorithmic perspective [18, 15].

2 Preliminaries

Let \mathbb{N} (\mathbb{N}_0) be the natural numbers without (with) zero. For a set $X \subseteq \mathbb{N}_0$ and $y \in \mathbb{N}_0$, let $X_{\geq y} := \{x \in X \mid x \geq y\}$.

Graph Theory. For a graph $G = (V, E)$, we also denote by $V(G)$ and $E(G)$ the vertex set V and edge set E of G , respectively. For an edge set $E' \subseteq E$ and vertex set $V' \subseteq V$, we denote by $G[E'] = (\bigcup_{e \in E'} e, E')$ and by $G[V'] := (V', \{e \in E \mid e \subseteq V'\})$ the graph induced by E' and by V' , respectively. The graph $G[E'][V']$ is the graph $G'[V']$ with $G' = G[E']$. By $\Delta(G)$ ($\delta(G)$) we denote the maximum (minimum) vertex degree of G . Denote by $N_G(v) := \{w \in V(G) \mid \{v, w\} \in E(G)\}$ and $N_G[v] := N_G(v) \cup \{v\}$ the open and closed neighborhood of v in G .

Basic Observations. We can assume that every vertex in our graph is contained in a habitat. We say that an edge e is *shared* by two habitats H, H' if $e \subseteq H \cap H'$. We say that a set $F' \subseteq E$ *satisfies* a habitat $H \in \mathcal{H}$ if $H \subseteq V(G[F'])$ and $G[F'][H]$ is connected. We have the following.

Observation 1. 1-REACH GBP-C where each habitat induces a tree is solvable in $O(|\mathcal{H}| \cdot |G|)$ time.

Proof. Since each habitat $H \in \mathcal{H}$ induces a tree, we need to take all edges of $G[H]$ into the solution. Hence $F = \bigcup_{H \in \mathcal{H}} E(G[H])$ is a minimum-cost solution computable in $O(|\mathcal{H}| \cdot |G|)$ time. \square

Observation 2. 1-REACH GBP-C on graphs of maximum degree two is solvable in $O(|\mathcal{H}| \cdot |G|)$ time.

Proof. Every connected component is a cycle or a path. Hence, every habitat is either a cycle or a path. In a connected component which is a cycle, all edges induced by habitats inducing paths must be taken. If not all edges are taken, then we can leave out exactly one remaining edge of largest cost from the solution. \square

3 Lower Bounds

In this section we show that the NP-hardness of 1-REACH GBP persists even if the habitats induce simple structures and the graphs are restricted. We prove the following.

Theorem 1. 1-REACH GBP is NP-hard even if:

- (i) each habitat induces a P_2 or a C_3 and G is a clique, or each habitat induces a C_ℓ for any fixed $\ell \geq 3$.
- (ii) each habitat induces (a P_2 or) a C_ℓ for any fixed $\ell \in \mathbb{N}_{\geq 4} \setminus \{5\}$ and G is planar.
- (iii) each habitat induces a P_2 or a C_ℓ for any fixed $\ell \geq 4$ and $\Delta(G) \geq 4$, or each habitat induces a C_ℓ for any fixed $\ell \geq 4$ and $\Delta(G) \geq 10$.
- (iv) each habitat induces a P_2 or a cycle, G is planar, and $\Delta(G) \geq 3$, or each habitat induces a cycle, G is planar, and $\Delta(G) \geq 9$.

For each case we provide a polynomial-time reduction from the following NP-hard [9] problem.

Problem 2. CUBIC VERTEX COVER (CVC)

Input: An undirected, cubic graph $G = (V, E)$ and an integer $p \in \mathbb{N}_0$.

Question: Is there a set $V' \subseteq V$ with $|V'| \leq p$ such that $G[V \setminus V']$ contains no edge?

We first provide constructions for the four cases before presenting the correctness proofs.

Constructions. We next provide the constructions for the base cases (i.e., small cycle lengths and habitats inducing P_2 s) of [Theorem 1](#)(i)–(iv). The results can be extended by employing a central gadget which we call *crown*. The crown allows us to exclude P_2 s from the habitat family and to extend cycle lengths all while preserving the planarity of the reductions. See [Figure 1](#)(a) for a crown.

Definition 1. Let G be a graph with two distinct vertices $a, b \in V(G)$ and habitats \mathcal{H} . When we say we (p, q) -crown a and b , then we connect a and b by a so-called base path P^0 of length $p + 1$ and two crown-paths P^1, P^2 , each of length $q + 1$, and add two crown-habitats $H_i = V(P^0) \cup V(P^i)$ for $i \in \{1, 2\}$.

Observation 3. The minimum number of edges to satisfy both crown habitats of a (p, q) -crowning is $p + 2q + 1$ (every edge from the base path and in each crown-path, all but one edge).

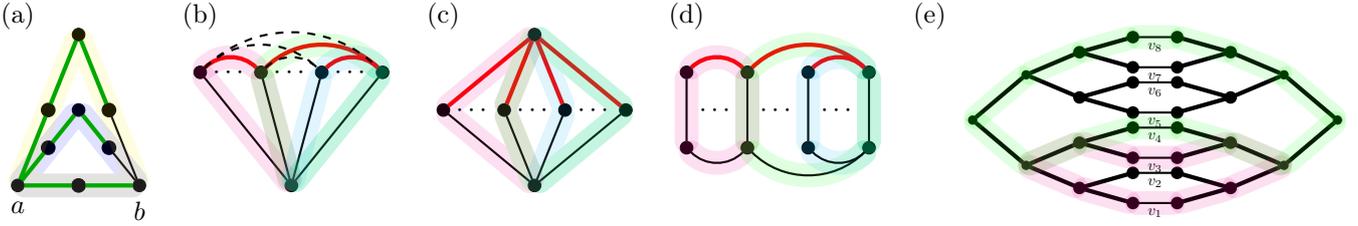

Figure 1: (a) A crowning and (b)–(e) four construction types. (a) The graph introduced by a (1,3)-crowning with its two crown-habitats (blue and yellow). Thick (green) edges form a minimum cardinality solution for the crown-habitats with 8 edges. (b)–(d) The construction are exemplified for a graph containing the edges $\{v_1, v_1\}$, $\{v_1, v_2\}$, and $\{v_2, v_2\}$, but not the edges $\{v_1, v_2\}$, $\{v_1, v_3\}$, and $\{v_2, v_3\}$, (b)+(c) Three habitats corresponding to the edges $\{v_1, v_1\}$ (magenta), $\{v_1, v_2\}$ (green), and $\{v_2, v_2\}$ (blue) are depicted. Endpoints of thick (red) edges are candidates for (p, q) -crowning. In (b), dashed edge can be added without changing the correctness. (d) Thick (red) edges are candidates for subdivisions. (e) Habitats for the edges $\{v_1, v_3\}$ and $\{v_4, v_8\}$ are depicted. Each of the thick edges forms a habitat.

Construction 1. Let $I = (G, p)$ be an instance of CVC with $G = (V, E)$, $V = \{v_1, \dots, v_n\}$, and $E = \{e_1, \dots, e_m\}$. Construct an instance $I' = (G', \mathcal{H}, k)$ as follows (see Figure 1(b)). Let $G' = (V', E')$ with $V' := V \cup \{x\}$ and $E' := E \cup \bigcup_{i=1}^n \{\{x, v_i\}\}$. Let $\mathcal{H} = \{H_1, \dots, H_m\} \cup \{H'_1, \dots, H'_m\}$, where $H_i := e_i$ and $H'_i := e_i \cup \{x\}$ for all $i \in \{1, \dots, m\}$. Let $k := m + p$. \diamond

Construction 2. Let $I = (G, p)$ be an instance of CVC with $G = (V, E)$, $V = \{v_1, \dots, v_n\}$, and $E = \{e_1, \dots, e_m\}$. Construct an instance $I' = (G', \mathcal{H}, k)$ as follows (see Figure 1(c)). Let $G' = (V', E')$ with $V' := V \cup \{x, y\}$ and $E' := \bigcup_{i=1}^n \{\{x, v_i\}, \{y, v_i\}\}$. Let $\mathcal{H} = \{H_1, \dots, H_n\} \cup \{H'_1, \dots, H'_m\}$, where $H_i := \{v_i, x\}$ for all $i \in \{1, \dots, n\}$ and $H'_i := e_i \cup \{x, y\}$ for all $i \in \{1, \dots, m\}$. Let $k := n + p$. \diamond

Construction 3. Let $I = (G, p)$ be an instance of CVC with $G = (V, E)$, $V = \{v_1, \dots, v_n\}$, and $E = \{e_1, \dots, e_m\}$. Construct an instance $I' = (G', \mathcal{H}, k)$ as follows (see Figure 1(d)). Let $G' = (V', E')$ with $V' := V \cup V^*$ where $V^* = \{v_1^*, \dots, v_n^*\}$ and $E' := E \cup E^* \cup \bigcup_{i=1}^n \{\{v_i, v_i^*\}\}$, where $E^* = \{e_\ell^* = \{v_i^*, v_j^*\} \mid e_\ell = \{v_i, v_j\} \in E\}$. Let $\mathcal{H} = \{H_1, \dots, H_m\} \cup \{H_1^*, \dots, H_m^*\} \cup \{H'_1, \dots, H'_m\}$, where $H_i := e_i$, $H_i^* := e_i^*$, and $H'_i := e_i \cup e_i^*$ for all $i \in \{1, \dots, m\}$. Let $k := 2m + p$. \diamond

Construction 4. Let $I = (G, p)$ an instance of CVC with $G = (V, E)$, $V = \{v_1, \dots, v_n\}$, and $E = \{e_1, \dots, e_m\}$. W.l.o.g. we assume n to be a power of two as we can add isolated vertices. Construct an instance $I' = (G', \mathcal{H}, k)$ as follows (see Figure 1(e)). Let T be a full binary tree of height $\log_2(n)$ with root w .¹ Denote by w_1, \dots, w_n the leaves in the order provided by a depth-first search starting at w . Let T' be a copy of T , and denote by w'_i the copy of leaf w_i . Add T and T' to G' and for each $i \in \{1, \dots, n\}$, add the edge $\{w_i, w'_i\}$. For the construction of the habitats, denote the non-leaf vertices of T by w_C where $C \subseteq \{1, \dots, n\}$ is the maximal subset of leaf indices in the subtree of T rooted at w_C (analogously for T'). For each edge $e \in E(T) \cup E(T')$, \mathcal{H} contains the habitat $H_e = e$. Now, for each edge $e_\ell = \{v_i, v_j\} \in E$, \mathcal{H} contains the habitat $H'_\ell := V(T_\ell) \cup V(T'_\ell)$, where T_ℓ is the subtree of T

¹A full binary tree T with root w of height t is a tree with exactly 2^t leaves each of distance exactly t to w and every inner node has exactly two children.

rooted at w_C with C being the smallest set with $\{i, j\} \subseteq C$ (analogously for T'_ℓ). Finally, let $k := |E(T)| + |E(T')| + p$. \diamond

Correctness. We next prove Theorem 1(i)–(iv), by using Constructions 1 to 4 and extending it with the crown (see Definition 1).

Proof of Theorem 1(i). Let $I = (G, p)$ be an instance of CVC, and let $I' = (G', \mathcal{H}, k)$ be an instance of 1-REACH GBP obtained from I using Construction 1. We claim that I is a yes-instance if and only if I' is a yes-instance.

(\Rightarrow) Let $V' \subseteq V$ be a vertex cover of size at most p . We claim that $F = E \cup \bigcup_{v_i \in V'} \{\{x, v_i\}\}$ is a solution to I' . Note that $|F| \leq m + p$ and $H_i \in F$ for all $i \in \{1, \dots, m\}$. Suppose the claim is false, that is, there is a habitat $H'_\ell \in \mathcal{H}$ that is not connected. Since $e_\ell = \{v_i, v_j\} \subseteq F$, neither $\{x, v_i\}$ nor $\{x, v_j\}$ is in F . Hence, $V' \cap e_\ell = \emptyset$, a contradiction.

(\Leftarrow) Let F be a solution to I . We know that $H_i \in F$ for all $i \in \{1, \dots, m\}$. We claim that $V' = \{v_i \mid \{x, v_i\} \in F\}$ is a vertex cover of G . Note that $|V'| \leq p$ since $|F \setminus E| \leq p$. Suppose the claim is false, that is, there is an edge $e_\ell = \{v_i, v_j\} \in E$ with $e_\ell \cap V' = \emptyset$. By construction of V' , we have that each of $\{x, v_i\}$ and $\{x, v_j\}$ are not in F . Hence the habitat H'_ℓ is not connected, a contradiction.

Note that adding any edge to G' does not change the correctness. For the NP-hardness for only C_ℓ -habitats, $\ell \geq 3$, replace every edge $e = \{v, w\}$ in E by a $(\ell - 3, 1)$ -crowning and adjust \mathcal{H} and k accordingly. \square

Proof of Theorem 1(ii). Let $I = (G, p)$ be an instance of CVC, and let $I' = (G', \mathcal{H}, k)$ be an instance of 1-REACH GBP obtained from I using Construction 2. We claim that I is a yes-instance if and only if I' is a yes-instance.

(\Rightarrow) Let $V' \subseteq V$ be a vertex cover of size at most p . We claim that $F = \bigcup_{v_i \in V'} \{\{x, v_i\}\} \cup \bigcup_{v_i \in V'} \{\{y, v_i\}\}$ is a solution to I' . Note that $|F| \leq n + p$ and $H_i \in F$ for all $i \in \{1, \dots, n\}$. Suppose the claim is false, that is, there is a habitat $H'_\ell \in \mathcal{H}$ that is not connected. Since $\{\{v_i, x\}, \{x, v_j\}\} \subseteq F$, neither $\{y, v_i\}$ nor $\{y, v_j\}$ is in F . Hence, $V' \cap e_\ell = \emptyset$, a contradiction.

(\Leftarrow) Let F be a solution to I . We know that $H_i \in F$ for all $i \in \{1, \dots, n\}$. We claim that $V' = \{v_i \mid \{y, v_i\} \in F\}$ is a vertex cover of G . Note that $|V'| \leq p$ since $|F \setminus E| \leq p$.

$\bigcup_{v_i \in V} \{\{x, v_i\}\} \leq p$. Suppose the claim is false, that is, there is an edge $e_\ell = \{v_i, v_j\} \in E$ with $e_\ell \cap V' = \emptyset$. By construction of V' , we have that each of $\{y, v_i\}$ and $\{y, v_j\}$ are not in F . Hence the habitat H'_ℓ is not connected, a contradiction.

For the NP-hardness for only C_ℓ -habitats with even $\ell \geq 6$ or $\ell = 4$, replace every edge $e = \{v_i, x\}$ by an $(\ell/2 - 2, \ell/2)$ -crowning. For the NP-hardness for C_ℓ -habitats with odd $\ell \geq 7$, replace every edge $e = \{v_i, x\}$ by two crownings, an $((\ell - 1)/2 - 2, (\ell + 1)/2)$ -crowning and an $((\ell + 1)/2 - 2, (\ell - 1)/2)$ -crowning. Adjust \mathcal{H} and k accordingly. \square

Proof of Theorem 1(iii). Let $I = (G, p)$ be an instance of CVC, and let $I' = (G', \mathcal{H}, k)$ be an instance of 1-REACH GBP obtained from I using Construction 3. We claim that I is a yes-instance if and only if I' is a yes-instance.

(\Rightarrow) Let $V' \subseteq V$ be a vertex cover of size at most p . We claim that $F = E \cup E^* \cup \bigcup_{v_i \in V'} \{\{v_i^*, v_i\}\}$ is a solution to I' . Note that $|F| \leq 2m + p$ and $H_i, H_i^* \in F$ for all $i \in \{1, \dots, m\}$. Suppose the claim is false, that is, there is a habitat $H'_\ell \in \mathcal{H}$ that is not connected. Since $\{\{v_i, v_j\}, \{v_i^*, v_j^*\}\} \subseteq F$, neither the edges $\{v_i^*, v_i\}$ nor $\{v_j^*, v_j\}$ are in F . Hence, $V' \cap e_\ell = \emptyset$, a contradiction.

(\Leftarrow) Let F be a solution to I . We know that $H_i, H_i^* \in F$ for all $i \in \{1, \dots, m\}$. We claim that $V' = \{v_i \mid \{v_i, v_i^*\} \in F\}$ is a vertex cover of G . Note that $|V'| \leq p$ since $|F \setminus (E \cup E^*)| \leq p$. Suppose the claim is false, that is, there is an edge $e_\ell = \{v_i, v_j\} \in E$ with $e_\ell \cap V' = \emptyset$. By construction of V' , we have that each of $\{v_i^*, v_i\}$ and $\{v_j^*, v_j\}$ are not in F . Hence the habitat H'_ℓ is not connected, a contradiction.

For the NP-hardness for $\{P_2, C_\ell\}$ -habitats with $\ell \geq 4$, subdivide each edge $\ell - 4$ times. For the NP-hardness for only C_ℓ -habitats with $\ell \geq 4$, replace every edge $e \in E$ by an $(\ell - 4, 2)$ -crowning and every edge $e^* \in E^*$ by an $(0, \ell - 2)$ -crowning. Note that this increases the maximum degree by six to at most ten. Adjust \mathcal{H} and k accordingly. \square

Proof of Theorem 1(iv). Let $I = (G, p)$ be an instance of VC, and let $I' = (G', \mathcal{H}, k)$ be an instance of 1-REACH GBP obtained from I using Construction 4. It is not difficult to see that $\Delta(G) \leq 3$ and that each habitat induces either a P_2 or a cycle. We claim that I is a yes-instance if and only if I' is a yes-instance. For notation, let $E_T := E(T) \cup E(T')$.

(\Rightarrow) Let $V' \subseteq V$ be a vertex cover of size at most p . We claim that $F = \bigcup_{e \in E_T} \{e\} \cup \bigcup_{v_i \in V'} \{\{w_i, w'_i\}\}$ is a solution to I' . Note that $|F| \leq |E_T| + p$ and $H_e \in F$ for all $e \in E_T$. Suppose the claim is false, that is, there is a habitat $H'_\ell \in \mathcal{H}$ corresponding to $e_\ell = \{v_i, v_j\}$ that is not connected. Thus, each of the edges $\{w_i, w'_i\}$ and $\{w_j, w'_j\}$ is not in F . Hence, $V' \cap e_\ell = \emptyset$, a contradiction.

(\Leftarrow) Let F be a solution to I . We know that $H_e \in F$ for all $e \in E_T$. We claim that $V' = \{v_i \mid \{w_i, w'_i\} \in F\}$ is a vertex cover of G . Note that $|V'| \leq p$ since $|F \setminus E_T| \leq p$. Suppose the claim is false, that is, there is an edge $e_\ell = \{v_i, v_j\} \in E$ with $e_\ell \cap V' = \emptyset$. By construction of V' , we have that each of $\{w_i, w'_i\}$ and $\{w_j, w'_j\}$ are not in F . Hence the habitat H'_ℓ is not connected, a contradiction.

For the NP-hardness for only cycle-habitats, replace every edge $e \in E_T$ by a $(0, 1)$ -crowning on e 's endpoints. Note that this increases the maximum degree by six to at most nine. Adjust \mathcal{H} and k accordingly. \square

4 Upper Bounds

This section is devoted to instances of 1-REACH GBP-C in which every habitat induces a cycle. We will first show that this case can be reduced to the following problem.

Problem 3. MAXIMUM-WEIGHT HYPERGRAPH MATCHING (MWHM)

Input: A hypergraph $G = (V, E)$ with edge weights $w: E \rightarrow \mathbb{N}$.

Task: Find a set $M \subseteq E$ of maximum weight such that for all $e, e' \in M$ holds that $e \cap e' = \emptyset$.

MWHM is NP-hard [9], but if every hyperedge is of cardinality at most two, it is equivalent to the well-known MAXIMUM-WEIGHT MATCHING (MWM) problem which is solvable in $O(|V|(|E| + \log |V|))$ time [7]. We make use of this to prove that some special cases of 1-REACH GBP-C are polynomial-time solvable.

4.1 The general case for cycles

In this subsection we show the following.

Proposition 1. 1-REACH GBP-C where every habitat induces a cycle can be decided by solving MWHM where the largest hyperedge is of size of the largest number of habitats intersecting in one edge.

Remark. MWHM admits an ILP formulation with linearly many variables and constraints (used for our experiments):

$$\begin{aligned} \max \quad & \sum_{e \in E(H)} c(e) \cdot x_e \\ \text{s.t.} \quad & x_e \in \{0, 1\} \quad \forall e \in E(H) \\ & \sum_{e \in E(H): v \in e} x_e \leq 1 \quad \forall v \in V(H) \end{aligned} \quad (1)$$

Central for the translation to MWHM is the following graph.

Definition 2 (Habitat graph). Let $G = (V, E)$ be a graph with edge cost $c: E \rightarrow \mathbb{N}$ and \mathcal{H} be a set of habitats each inducing a cycle. The multi-hypergraph $B = (V_B, E_B)$ with edge weights $w_B: E_B \rightarrow \mathbb{N}$ and bijection $f: E \rightarrow E(B)$ are obtained as follows. B contains a vertex b_i for each habitat H_i . For every edge $e \in E$ shared by at least two habitats H_{i_1}, \dots, H_{i_j} , add a hyperedge $e' = \{b_{i_1}, \dots, b_{i_j}\}$ and set $f(e) := e'$ and $w_B(e') := c(e)$. Finally, for every edge $e \in E$ induced by only one habitat H_i , add a vertex b_e and the edge $e' := \{b_e, b_i\}$, and set $f(e) := e'$ and $w_B(e') := c(e)$.

The following connection between 1-REACH GBP-C and MWM proves Proposition 1.

Lemma 1. Let $G = (V, E)$ be a graph with edge cost $c: E \rightarrow \mathbb{N}$, let \mathcal{H} be a set of habitats each inducing a

cycle, and let B denote the habitat graph with edge weights $w_B: E_B \rightarrow \mathbb{N}$ and function f . (i) If M is a matching in B , then $G[E \setminus f^{-1}(M)][H]$ is connected for every $H \in \mathcal{H}$; (ii) If $G[F][H]$ is connected for every $H \in \mathcal{H}$, then $E(B) \setminus f(F)$ is a matching in B .

Proof. (i) Let M be a matching in B and let $F := E \setminus f^{-1}(M)$. Then for every $b_i \in V(B)$ there is at most one edge in M that is incident with b_i . Thus, for every $H \in \mathcal{H}$, $|E(G[H]) \cap F| \geq |H| - 1$, and hence $G[F][H]$ is connected.

(ii) Let $G[F][H]$ be connected for every $H \in \mathcal{H}$ and let $M := E(B) \setminus f(F)$. Suppose there are two edges in M that are both incident to some $b_i \in V(B)$. Then there are two edges in $E(G[H_i])$ not contained in F , and hence $G[H_i][F]$ is not connected—a contradiction. Thus, M is a matching. \square

Proof of Proposition 1. Due to Lemma 1(i), we know that every matching forms a solution. With the addition of Lemma 1(ii), we know that every maximum-weight matching forms a minimum-cost solution. \square

Remark. We can simplify the habitat graph to a simple hypergraph: If there are multiple edges with the same vertex set, then it is enough to keep exactly one of maximum weight. We will make use of this in our experiments.

4.2 Polynomial-time solvable subcases

If every habitat induces a cycle and every edge is in at most two habitats, then the habitat graph is a hypergraph with edges of cardinality at most two. We have the following.

Theorem 2. 1-REACH GBP-C where every habitat induces a cycle is solvable in $O(|V| \cdot |E| \cdot |\mathcal{H}|)$ time when every edge is in at most two habitats.

We next present two special cases of 1-REACH GBP-C that become polynomial-time solvable due to the above.

Habitats inducing faces. Suppose our input graph is a plane graph (that is, a planar graph together with an crossing-free embedding into the plane). If every habitat induces a cycle which is the boundary of a face, then clearly every edge is shared by at most two habitats since every edge is incident with exactly two faces. Thus, we get the following.

Corollary 1. 1-REACH GBP-C where every habitat induces a cycle is solvable in $O(|V| \cdot |E| \cdot |\mathcal{H}|)$ time on plane graphs when every habitat additionally induces a face.

Habitats inducing triangles in graphs of maximum degree three. Suppose our input graph has maximum degree three and each habitat induces a triangle. Observe that every vertex of degree at most one cannot be contained in a habitat. Moreover, every degree-two vertex is contained in at most one habitat. For degree-three vertices we have the following.

Lemma 2. If a vertex v is contained in three habitats, then $N_G[v]$ is a connected component isomorphic to a K_4 .

Proof. Firstly, observe that 6 slots are distributed among 3 vertices, and hence, for every $w \in N(v)$ there are two distinct habitats H, H' with $\{v, w\} \subseteq H \cap H'$. This means that $|N(w) \cap N(v)| = 2$. Hence, each vertex $G[N[v]]$ has degree three, and thus $N_G[v]$ is a connected component. \square

We immediately derive the following data reduction rule.

Reduction Rule 1. If a vertex v is contained in three habitats, then delete $N_G[v]$ and reduce k by the minimum cost of a solution for $G[N_G[v]]$.

If the reduction rule is inapplicable, then every vertex is contained in at most two habitats. Consequently, every edge is shared by at most two habitats. We obtain the following.

Corollary 2. 1-REACH GBP on graphs of maximum degree three is solvable in $O(|V| \cdot |E| \cdot |\mathcal{H}|)$ time when every habitat induces a triangle.

5 Experiments

In this section, we present and discuss our experimental and empirical evaluation. We explain our data in Section 5.1, our algorithms in Section 5.2, and our results in Section 5.3.

5.1 Data

Graphs. Our experiments are conducted on planar graphs only. We used data freely available by Open Street Maps (OSM). For each state of Germany (except for the city states Berlin, Bremen and Hamburg; abbreviated by ISO 3166 code), we set a bounding box and extracted the highways within. For each area encapsulated by highways, we created a vertex. Two vertices are connected by an edge whenever they are adjacent by means of a highway. Additionally, we generated five artificial graphs which are relative neighborhood graphs [21] of sets of $500 + i \cdot 1125$ points in the plane, placed uniformly at random, with $i \in \{0, \dots, 4\}$. To all graphs we randomly assigned edge costs from $\{1, \dots, 8\}$. Table 2 provides an overview over some instances' properties.

Habitats. We created multiple instances from every graph above by equipping them with different types and numbers of habitats. We created three types of instances: *face* instances, *cycle* instances, and *walk* instances. Given a plane graph G , a number r of habitats and, in the case of cycle and walk instances, a habitat size q , the instances were created as follows.

Face instances: Out of those faces of G that induce cycles, randomly choose r faces as habitats.

Cycle instances: List all induced cycles of length $q \pm 1$. For each such q , randomly choose r of the cycles as habitats.

Walk instances: Compute r self-avoiding random walks on $q' = q \pm 1$ vertices, where q' is chosen uniformly at random. Add the vertices of each walk to a habitat.

For each instance type, for each graph above, for each $r \in \{50, 100, 150, 200\}$, for each $q \in \{5, 7, \dots, 13\}$ in the case of cycle and walk instances, we generated 5 instances.

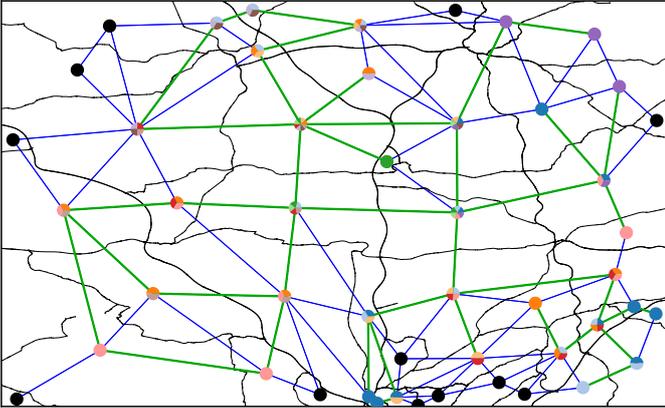

Figure 2: Drawing of the graph SL (blue and green edges), based on the street network of Saarland (black). The graph is equipped with 21 cycle habitats, each of which is represented by a unique color. The green edges represent an optimum solution for the instance.

We remark that the real-world graphs MV, SH, and SL did not have sufficiently many cycles of length $q \pm 1$ for $q \in \{5, 7\}$, $q \in \{5, 7, 9\}$, and $q = 5$, respectively. In this case, every cycle was chosen to be a habitat.

Figure 2 is a drawing of the graph SL, based on the street network of Saarland, together with a set of cycle habitats.

5.2 Algorithms

We implemented three exact solvers and one approximate solver. Two of the three exact solvers can be run only on some types of habitats (see Table 4).

For the face instances we implemented the MWM-based algorithm (Corollary 1) which we will denote by \mathcal{A}_{mwm} . The habitat graph generation is implemented in Python 3. The matching is computed using Kolmogorov’s [17] C++ implementation of the Blossom V algorithm.

For the cycle instances generated the habitat graph in

Python 3 and used Gurobi 9.5.0 to solve ILP formulation (1). We call the respective solver $\mathcal{A}_{\text{mwhm}}$.

The generic solver \mathcal{A}_{gen} can solve all instances of 1-REACH GBP-C and uses Gurobi 9.5.0 to solve the following ILP formulation with an exponential number of constraints.

$$\begin{aligned} \min \quad & \sum_{e \in E(G)} c(e) \cdot x_e \\ \text{s.t.} \quad & x_e \in \{0, 1\} \quad \forall e \in E(G) \\ & \sum_{e \in \delta_H(S)} x_e \geq 1 \quad \forall \emptyset \neq S \subsetneq H, \forall H \in \mathcal{H} \end{aligned}$$

By $\delta_H(S) := \{e \in E \mid e \cap S \neq \emptyset \wedge e \cap (H \setminus S) \neq \emptyset\}$, we denote for a graph $G = (V, E)$, vertex set $H \subseteq V$, and subset $\emptyset \neq S \subsetneq H$, the set of edges between S and $H \setminus S$.

The approximate solver \mathcal{A}_{apx} , implemented in Python 3, is a weighted adaption of the $O(r)$ -approximation algorithm for 1-REACH GBP given by Fluschnik and Kellerhals [6]. Their algorithm computes for every habitat a spanning tree, and then combines the solutions. The weighted adaption has the same approximation guarantee. Further, for induced cycles it has an additive approximation guarantee that depends on the number of habitats and the maximum cost of any edge.

Observation 4. \mathcal{A}_{apx} is an additive $(r \cdot c_{\max})$ -approximation for 1-REACH GBP-C with each habitat inducing a cycle, where $c_{\max} = \max_{e \in E} c(e)$.

Proof. Let F_1, \dots, F_r and $F := \bigcup_{i=1}^r F_i$ denote the solution of the approximation algorithm, and let $F^* = \bigcup_{i=1}^r F_i^*$ denote any optimal solution. For each $i \in \{1, \dots, r\}$, let $\{e'_i\} = F_i \setminus F_i^*$. Then:

$$\begin{aligned} c(F) &= c(F_1 \cup \dots \cup F_r) \\ &\leq c(F_1^* \cup \{e'_1\} \cup \dots \cup F_r^* \cup \{e'_r\}) \\ &\leq c(F_1^* \cup \dots \cup F_r^*) + \sum_{i=1}^r c(e'_i) \\ &\leq c(F^*) + r \cdot c_{\max}. \quad \square \end{aligned}$$

5.3 Results

We compared the implementations on machines equipped with an Intel Xeon W-2125 CPU and 256GB of RAM running Ubuntu 18.04. For the ILP-based solvers, we set a time limit of 30s for the solving time (not the build time). For 43 of the 100 artificial faces instances \mathcal{A}_{gen} was not able to compute any feasible solution. For all remaining instances, \mathcal{A}_{gen} provided an optimal solution in the given time limit.

All material to reproduce the results is provided in the supplementary material.

Comparison of the optimal solvers. Our experiments underline that each specialized solver outperforms the next less specialized solver (see Figure 3(a)). For instance, on real-world instances with face habitats, \mathcal{A}_{mwm} is on average 1.7 times faster than $\mathcal{A}_{\text{mwhm}}$, and on artificial instances with cycle habitats, \mathcal{A}_{mwm} is on average 82 times faster than \mathcal{A}_{gen} (see Table 5). Moreover, \mathcal{A}_{mwm} is 1.5 times faster than $\mathcal{A}_{\text{mwhm}}$ on 80% of the face instances,

Table 3: Summary of our results regarding \mathcal{A}_{apx} . The quality ratio is $\text{cost}(\mathcal{A}_{\text{apx}})/\text{OPT}$. The additive ratio is $(\text{cost}(\mathcal{A}_{\text{apx}}) - \text{OPT}) / (d \cdot |\mathcal{H}|)$, where d is the average weight of an edge in an optimal solution. The running time ratio is $\text{time}(\text{BEST})/\text{time}(\mathcal{A}_{\text{apx}})$, where BEST is the exact solver with the best overall running time on the instance.

| Cycles _{Real} | 0.834 | 2266.312 | 315.597 | 483.523 |

and $\mathcal{A}_{\text{mwhm}}$ is 10 times faster than \mathcal{A}_{gen} on 76% of the cycle instances.

Approximate solver. On real-world instances, \mathcal{A}_{apx} is 2 times faster than \mathcal{A}_{mwm} on face instances and 4 times faster than $\mathcal{A}_{\text{mwhm}}$ on cycle instances, whereas the approximation factor never exceeds 1.348. The additive error is

significantly better than the theoretical bound in **Observation 4**. See **Table 3** and **Figure 3(b)**. On the artificial instances, the approximation ratios are even better on average. This may be due to the fact that these instances are rather sparse (see **Table 2**).

Intersection. We also considered the intersection rate $\lambda := |\sum_{H \in \mathcal{H}} |E(G[H])| / |\cup_{H \in \mathcal{H}} |E(G[H])||$, which measures the average number of habitats in each edge (see **Figures A.4 & A.5** in the appendix for a comparison of the solution quality and the speedup factor of \mathcal{A}_{apx}). For $\lambda \geq 10$ the approximation quality improves slightly in the real-world cycle and walk instances. As the habitats lie more dense, it is more likely for an edge to be in the solution. It thus seems plausible that \mathcal{A}_{apx} chooses fewer unnecessary edges.

As for the running time, the intersection rate seems only to have an effect on $\mathcal{A}_{\text{mwhm}}$. Especially on real-world cycle instances one can see that the running time quotient of $\mathcal{A}_{\text{mwhm}}$ and \mathcal{A}_{apx} decreases with growing λ . This is likely due to the habitat graph B : If there are less edges that are in a unique habitat, then there are less vertices in B that are incident to a single cardinality-two edge, and hence less variables and constraints in (1). Note that one can deal with such vertices in a preprocessing routine as proposed i.e. by Koana et al. [16]. This may significantly improve the running times of \mathcal{A}_{mwm} and $\mathcal{A}_{\text{mwhm}}$ for instances with

low intersection rate.

6 Conclusion

While we prove that when every habitat induces a cycle, 1-REACH GBP-C remains NP-hard, even on planar graphs and graphs of small maximum degree, we provide an ILP-based solver that performs exceptionally well in our experiments. Moreover, when each habitat additionally induces a face in a given plane graph, the problem becomes solvable in polynomial time, with even faster practical running times. Lastly we observe that the approximation algorithm by Fluschnik and Kellerhals [6] performs well in our experiments.

In a long version of this paper, we wish to address several theoretical and experimental tasks. On the experimental side, we plan to test our code on larger input instances. As mentioned in Section 5.3, we believe that the implementation of preprocessing routines may improve the running times of \mathcal{A}_{mwm} and \mathcal{A}_{mwhm} significantly. On the theoretical side, we plan to settle the computational complexity of 1-REACH GBP-C for the following cases: for habitats in $\{P_2, C_3\}$ in planar graphs or with constant maximum degree at least 4; for habitats in $\{P_2, C_\ell\}$ in graphs of maximum degree at most 3. Future work may include restrictions on the habitats other than induced cycles.

Appendix

A Additional figures and tables

We provide additional figures and tables for a more in-depth overview over our results. In [Figure A.6](#), we show how \mathcal{A}_{mwm} and $\mathcal{A}_{\text{mwhm}}$ perform (in terms of time) against \mathcal{A}_{gen} . Interestingly, in some few cases for real-world instances with 200 cycle habitats, \mathcal{A}_{gen} runs faster than $\mathcal{A}_{\text{mwhm}}$. In [Figure A.7](#), we show how \mathcal{A}_{apx} performs (in terms of solution quality) against OPT. One can see that there are no big fluctuation from the diagonal (approximation ratio 1). Moreover, larger solution costs and large set of habitats increases the approximation ratio.

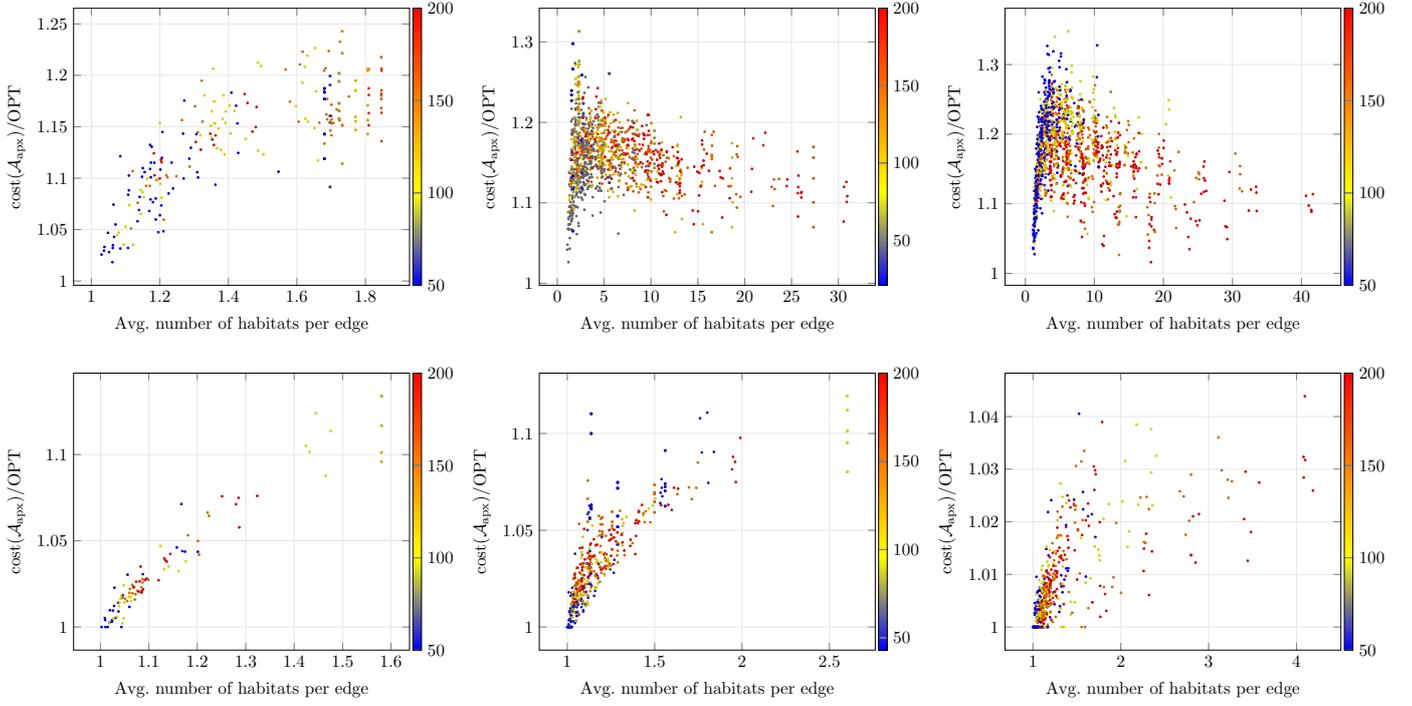

Figure A.4: Approximation algorithm ratio against our intersection measure. (Top) Real-world. (Bottom) Artificial. (Left) Faces. (Middle) Cycles. (Right) Random Walks.

Table A.6: Summary of our results regarding Faces on NW. “btime” is short for “building time”.
