Abstract

The $^{22}\text{Ne}(\alpha, n)^{25}\text{Mg}$ plays a major role on neutron flux in weak s-process nucleosynthesis path in AGB stars of mass ($M \geq 8M_{\odot}$). The recent evaluation by Philip *et al.* of $^{22}\text{Ne}(\alpha, n)^{25}\text{Mg}$ reaction rate using updated nuclear data of ^{26}Mg from number of sources shows sizable uncertainty and significant discrepancy with literature at low temperature. Also Philip *et al.* suggested that *R*-matrix modeling will be required to estimate ^{26}Mg resonance states parameters as well as study the interference patterns between distant levels. Here *R*-matrix analysis has been performed to study interference effects and constrain spin, parity of resonances by fitting the direct measurement data. The resonance states parameters of Philip *et al.* are not explained well due to strong interference between same spin, parity states. By changing spin parity of some states, experimental data are nicely explained by present *R*-matrix calculation for 0.8 to 1.45 MeV energy range.

R-matrix

Keywords: The resonance capture, *R*-matrix analysis

Almost half of the elements heavier than iron are synthesized via slow (over time scales of thousands of years) neutron capture reaction on stable isotopes in the s-process nucleosynthesis path [2]. The s-process is mainly activated in Asymptotic Giant Branch (AGB) stars, seeded by ^{56}Fe iron. The $^{13}\text{C}(\alpha, n)^{16}\text{O}$ and $^{22}\text{Ne}(\alpha, n)^{25}\text{Mg}$ reactions are the main sources of neutrons for the s-process. For low mass AGB stars with $1M_{\odot} \leq M \leq 3M_{\odot}$, both of these two reactions contribute as a neutron source and are responsible for the synthesis of elements with atomic masses $A \approx 90 - 209$. But for massive stars ($M \geq 8M_{\odot}$) only the $^{22}\text{Ne}(\alpha, n)^{25}\text{Mg}$ reaction is the main source of neutrons, which synthesizes isotopes of mass $A \approx 60 - 90$, so-called weak s-process nucleosynthesis. Also the $^{22}\text{Ne}(\alpha, \gamma)^{26}\text{Mg}$ reaction acts as a competing reaction that decides neutron release from the $^{22}\text{Ne}(\alpha, n)^{25}\text{Mg}$ reaction. So constraining the rate of these two reactions has high sensitivity for weak s-process nucleosynthesis.

So many direct [4] and [5–7] indirect experimental measurements have been performed to extract the spin, parity, partial widths ($\Gamma_{\alpha}, \Gamma_n, \Gamma_{\gamma}$) to constrain the rate of $^{22}\text{Ne}(\alpha, n)^{25}\text{Mg}$ and $^{22}\text{Ne}(\alpha, \gamma)^{26}\text{Mg}$ reactions. Recently the rate of these two reactions has been re-evaluated [3] based upon updated nuclear data from a number of sources, and they suggested that *R*-matrix modeling will be required due to the lack of uncertainty of spin, parity of so many relevant states of ^{26}Mg as well as interference effects of same partial waves between two states.

In this context, a multilevel *R*-matrix analysis has been performed on available cross-section data of $^{22}\text{Ne}(\alpha, n)^{25}\text{Mg}$ reaction, including interference effects in the energy range $E_{\alpha}^{c.m.} \approx 0.8$ to 1.45 MeV, and extrapolated up to 0.57 MeV energy. The main aim is to constrain spin-parity and study interference effects of states of ^{26}Mg in the excitation energy $E_x \approx 11.319$ to 11.828 MeV energy range.

1. *R*-matrix calculation

The behavior of the excitation function for the $^{22}\text{Ne}(\alpha, n)^{25}\text{Mg}$ reaction was mainly determined by the resonance capture process through several resonance states of the compound nucleus ^{26}Mg . In this work, an *R*-matrix calculation has been performed to describe the capture data and constrain the spin, parity, and width of the states of ^{26}Mg .

R-matrix modeling of the $^{22}\text{Ne}(\alpha, n)^{25}\text{Mg}$ reaction has been performed using the AZURE2 code [8]. This code was developed based on the theory developed by Lane [9] and Thomas [9] and by Vogt [10]. In the *R*-matrix formalism, the radial space is divided into two distinct regions—an internal region extended up to a

radius $R_c \approx r_0(A_p^{1/3} + A_t^{1/3})$ and an external region above R_c . A choice of radius for entrance and exit channels is needed for the model calculation. R_c of the two channels have been obtained through χ^2 minimization. However, as channel radius is not a free parameter in the model, we performed a grid search on the channel radius by changing the value in small steps and varying the parameters to get the fit. The chosen channel radii values are 5.37 fm for the $^{22}\text{Ne} + \alpha$ channel and 4.21 fm for the $^{25}\text{Mg} + n$ channel. During calculation in AZURE2, the energy resolution(3.38 KeV) of the system also accounted.

In this present work, initially R -matrix calculation has been performed $^{22}\text{Ne}(\alpha, n)^{25}\text{Mg}$ using the recently updated spin, parity and partial widths of resonance states reported in Ref. [3] for the observed resonances in $^{22}\text{Ne}(\alpha, n)^{25}\text{Mg}$ reaction. Parameters are listed in Table 1 and result of R -matrix calculation for S -factor of $^{22}\text{Ne}(\alpha, n)^{25}\text{Mg}$ reaction compare with experimental data of Ref [4] shown in Fig. 1. Now to better explain experimental data, we adjust resonance energy and widths of populated states. By adjusting this parameters we reproduced the data form 0.7 to 0.98 MeV energy region but fails to reproduced data 0.98 to 1.2 MeV energy region due to strong destructive interference between same J^π states. For batter explain of the experimental data, spin, parity of $E_x=11.63$ and 11.784 MeV resonances are changing form 1^- to 0^+ and Γ_α , Γ_n left as free parameters. The resultant R -matrix fit is nicely explain the experimental data in 0.8 to 1.45 MeV energy region. The fitted parameters are listed in Table 2. Also extrapolation has been done up to 0.57 MeV by fixed the resonance parameters in 0.57 to 0.8 energy that are evaluated via indirect measurement. Comparison shown in Fig. 2

A R -matrix modeling in $^{22}\text{Ne}(\alpha, n)^{25}\text{Mg}$ reaction was performed to the description of direct measurement data [4]. The present calculation with recently evaluated resonance parame-

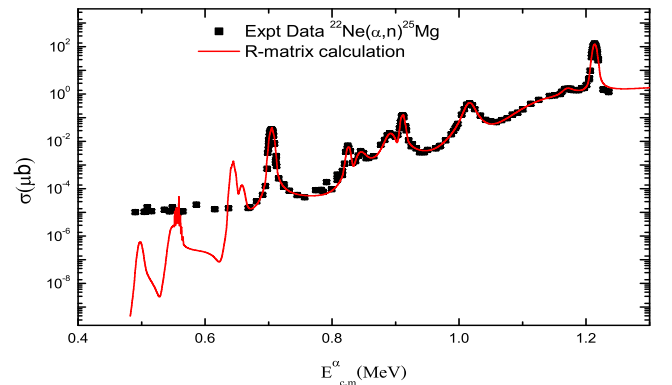

Figure 2: (Color Online) R -matrix fit with changing spin and parity shown in Table 2. Filled symbols represent the direct measurement data taken from Ref. [4]

ters [3] for ^{26}Mg are poorly describe the latested measurement data [4] due to strong destructive interference between consecutive same $J^\pi(1^-)$ states. With changing J^π form 1^- to 0^+ experimental data are well describe in 0.8 to 1.45 MeV energy region. The extrapolation with indirectly measured resonance parameters well off with respect to highly uncertain data of Jaeger et. al. [4] in 0.8 to 1.45 MeV energy region. So precise measurement of spin, parity and particle decay width (Γ_n, Γ_α) will be required for $E_\alpha \leq 0.8\text{MeV}$ to evaluate cross-section with less uncertainty including interference effects.
